ii) Development of electronic database: There is need to develop an electronic database for agricultural production survey. All data should be centrally stored and managed. By having micro-data, the Ministry will be able to derive estimates with coefficient of variations to determine precision of estimates for each crop at all levels. The database should be programmed so that estimates are calculated automatically as data is being transmitted to the database. The data collection program should be designed in such a way that errors are detected automatically as data is being transmitted hence reducing period for data cleaning.

iii) Introduction of moisture content measurement for crops: The current methodology does not measure moisture content for crops. It is recommended that weighing of crops should be done when the crop is completely dry. However, it is not certain whether this protocol is strictly followed by the extension officers. If it is not followed, this gives a chance for overestimation. Even if it is followed, this means that the extension officers have to wait for the crop to dry in cases of early harvesting, hence, delay in submission of the data. It is strongly recommended that moisture content measurement as learnt from the area frame methodology be introduced to improve data quality and facilitate early submission of the data.

5.2 Long-Term Recommendations

i) Use of point frame approach for hectarage estimation: The point frame methodology should be adopted for hectarage estimation. However, to achieve good estimates at all levels, there is need to increase the sample size for points. The point frame hectarage estimation has proven to be more accurate, quick, easy, less time consuming and requires less human resource.

ii) aintain yield estimation method from the list frame: Crop cutting method from list frame methodology has proven to produce credible results. The method is applicable to all crops. Yield estimation methods from the pilot methodologies either require some adjustments (point frame methodology) or separate methods for non-cereal crops (area frame methodology).

iii) Revision of sampling frame for the list frame: The current methodology samples 15 households in each block. This means that all blocks are treated as homogeneous entities. This may result in oversampling in areas where there are less agricultural households and under sampling in areas with more households. The sampling plan should be revised. The sampling plan should be based on agricultural land use, meaning, a sample of households should be allocated according to the agricultural land in that particular area. Stratification taking advantage of differences in agricultural land use intensity will provide a significant increase in precision. Therefore, from the area frame methodology, revising the sampling methodology under list frame based on actual agricultural land use density rather than population estimates is recommended.

iv) Development of strong capacity building programme: If the recommendations are approved, there will be need for strong capacity building in the Ministry mainly through short and medium-term training. Arrangements should be made with the Development Partners such as Food and Agricultural organization (FAO) of the United Nations for local technical support in sampling, GIS and image analysis.

6.0 CONCLUSION

Great lessons have been learnt from the pilot studies which can improve crop area and production statistics. Application of remote sensing and satellite imagery technologies in crop production estimation has proven to provide quick, reliable and timely statistics. It has also uncovered an opportunity for early objective yield estimation for crops, more precise hactarege estimation, provision of tangible land use distribution criteria to use for the rural road rehabilitation programmimg and generation of crop production maps which can be used for strategic establishment of grain storage facilities in the country. However, to ensure successful implementation of the lessons leant, there is great need for strong capacity building programme in the area of GIS and remote sensing.

The use of satellite pictures and data provided by drones for the purposes of identification of crops and assessment of plant production

DOI: 10.1481/icasVII.2016.f30b

ABSTRACT

The first part of the speech will present the results of cooperation between the Department of Agriculture in the Central Statistical Office and the Space Research Centre of the Polish Academy of Sciences in Warsaw. It will be concerned with the possibility of distinguishing particular groups of crops and classes of land cover, including identification of selected crops on the basis of satellite images (taken by Sentinel 1 type satellite) to the lowest possible level of aggregation, i.e. voivodship (NTS2) or district (NTS3). Such research was conducted on a selected Polish voivodeship in 2015. The speech will present the applied method of sample selection (ca. 550 measurement plots) based on administrative sources of the IACS, the field survey of crops in that area, the adopted methodology of identification of crop groups, as well as the possibilities to use data from Sentinel 2 type satellite for such kind of work.

The second part of the speech will present a study of the data acquired from a drone approach for the purposes of assessment of production from grasslands. The work was developed in cooperation with the Department of Agriculture in the Central Statistical Office and the Institute of Geodesy and Cartography in Warsaw in 2015. The analysis was conducted on 21 plots with total area of approximately 460 ha of permanent grasslands in the selected voivodships. It is planned to describe the methodology of the research consisting in using non-piloted measuring platform (a drone) equipped with a hyperspectral camera capable of imaging within the scope of 480-890 nanometres. Imaging with the use of a drone took place in the course of two field campaigns conducted at the turn of May and June of 2015, and was supplemented with data from LANDSAT 8 satellite in the case of fragments of plots, for which obtaining data with a drone was impossible due to adverse weather conditions. Additionally, simultaneously with the conducted drone approaches, ground measurements were conducted (74 points within the area of the analysed plots), using specialist apparatus owned by the Institute of Geodesy and Cartography, providing information about LAI (Leaf Area Index), soil humidity and temperature of plant surface. The collected data described above enabled analysing and assessing production on grasslands by assigning to each indicated plot the estimated value of fresh biomass and biomass per hectare. A starting point for such an analysis was a comprehensive set of data, collected within a few decades by the Institute of Geodesy and Cartography, enabling the use of already created, and used by the Institute for many years, models describing the correlation between biomass and the LAI. The collected information about the crop yield from grasslands were compared with the local estimates of experts. During the

speech, it is planned to present chapters describing one by one the specification of data and sensors used to obtain them, the applied methodology of assessment of production size from the designated grasslands, the results of the conducted analysis with breakdown into particular plot groups. A SWAT analysis will be also presented, summing-up the conducted research and assessing the potential of the used method.

Keywords: Drone, IACS, Sentinel, Grasslands

1. Introduction

1.1 Preface

The Agriculture Department at the Central Statistical Office OF Poland (CSO) is responsible for maintaining official national statistics connected with agriculture in Poland. Its standard work based on annual periodic surveys, information obtained from field experts, voivodship experts, and administrative data, includes the processing of information on issues such as area assessment, yields, and crops at the voivodship level (NTS2). There is a demand for data pertaining to aggregation at the district (NTS4) or commune (NTS5) levels. Unfortunately, the information that has been collected to date during questionnaire surveys is based on farmers' declarations as regards the land used, but without details on the locations of such land. This makes it impossible to aggregate results at a level which in terms of area is classified lower than voivodship. Therefore, new methods, possibilities and solutions are sought for in order to increase the accuracy of estimates. The Agriculture Department is closely following the latest technological developments and possibilities of applying them for its own needs, in particular the Copernicus programme and missions by the Sentinel satellites. The satellites of this type are developed under the Copernicus programme, funded by the European Commission and the European Space Agency (ESA). It should be noted that while being free of charge, the efficient use of data transmitted by these satellites requires substantial experience and knowledge on remote sensing. For this reason, close cooperation with a number of institutions is being conducted, allowing these data to be used directly.
The report consists of two thematic blocks presenting the results of cooperation between the CSO and scientific institutions in order to improve the quality of published data and enhance their usefulness by increasing the resolution of presented data.

1.2 Part I

The first part of the report presents the results of cooperation between the CSO, the Regional Statistical Office in Olsztyn (RSO), and the Space Research Centre of the Polish Academy of Sciences (SRC) within a pilot study in one of the voivodships, aimed at assessing whether it would be possible to single out and identify individual crop groups on the basis of radar data from the Sentinel 1 satellite and field calibration based on data from the Agency for Restructuring and Modernisation of Agriculture (ARMA) – the database of the Land Parcel Identification System (LPIS).

1.3 Part II

The second part of the report discusses the results and experience gained in the implementation of a contract between the CSO and the Institute of Geodesy and Cartography in Warsaw (IGiK). The contract regarded the preparation of a study on the possibility of assessing grassland production on the basis of image information transmitted with the use of an unmanned measurement platform (a drone) and a hyperspectral camera.

2. Part I

2.1 The objective of the study

As part of the study, crops in the Warmia and Mazury voivodship were identified with the use of Sentinel-1 satellite radar images. The images served the creation of a data time series presenting how the crops evolved throughout 2015, and then were processed and classified. As reference data, the administrative databases on crops, including data from the LPIS database were utilised. The results were aggregated at the district and voivodship levels.

2.2 The methodology for selecting samples and conducting in situ survey.

The Warmia and Mazury voivodship is located in the north-eastern corner of Poland. To select a random sample, the coordinates of points from the European LUCAS 2012 survey were used. First, an analysis was carried out to designate points potentially located on agricultural areas. With the use of ArcGIS software (the Intersect function), the LUCAS 2012 points were analysed in relation to the vector layer of managed land (ML) from ARMA. As a result of the analysis, 885 points were selected on record parcels with the area of nearly 213 km^2.

Figure 1: *A sample point selected for the analysis*

In order to increase the likelihood of selecting points that were located within large-area crops, 885 points were additionally analysed in relation to the record parcel layer. As a result of this analysis, the designated points were grouped in line with the adopted field size buffers. Each interviewer had to visit all points assigned to him/her and collect the necessary data, as specified in the form for the in situ survey. The interviewers were provided with GPS receivers with navigation capabilities in order to arrive in a given point and record its actual location, as well as GPS-capable tablets to take geotagged photographs. For each analysed point, a description had to be prepared in accordance with a questionnaire drawn up earlier. The collected data regarded issues such as the type of crop – a dropdown list of plants, with the possibility of providing more details on a given species, the homogeneity of a crop, the plant development stage, land topography, the type and humidity of soil, the amount of weeds, and the angle in which a photograph was taken in relation to the cardinal directions. In total, the interviewers provided descriptions for 596 points and took 1847 photographs. The field studies were held between 15 June 2015 and 22 July 2015.

2.3 Reference data

Satellite data were classified on the basis of information from the database on crops in the Warmia and Mazury voivodship in 2015. The database contained geospatial information on control areas, crops cultivated on them, the interviewer's location, a survey on the state of a crop and a field, and photo documentation. The report was made on the basis of type-2 data registered in the VH and VV polarisations. Since the beginning of 2015, more than 300 Sentinel-1 capturing the area of this voivodship. The data were collected automatically and for further analyses, 13 scenes were selected.

2.4 Data processing

The multitemporal coherence matrices for satellite radar images were calculated with the MT_SAR software developed specifically for this purpose by the SRC. With the software, multitemporal polarimetric processing can be performed, including correlation and coherence matrices serving as a basis for applying polarimetric decompositions that model the mechanisms of reflection of radar beams from structures on the surface of the Earth. The software can also automatically process large image sets. In order to speed up the calculations and for safety reasons (minimising the risk of interruption of prolonged calculations), the images were divided into smaller pieces.

Figure 2: *Contour of the voivodship (in green) with a mosaic of cut-up pieces*

For each of pieces, calculations were carried out with regard to the coherence matrix, entropy, and the polametric Alpha parameter. Upon completion of the calculations, the pieces were merged together. By means of the functions offered by the Sentinel-1 Toolbox, each of the 13 images selected with the Wishard's classifier was subjected to polametric unsupervised classification. The methods of supervised classification were deployed on the basis of training fields defined by means of the information on crops obtained by CSO interviewers for statistically selected plots within the analysed voivodship. Segments were created with the use of optical data from the Landsat 8 satellite and LPIS vector data provided by the ordering party. With LIPS taken as reference, the first level of segmentation was developed, overlapping borders of the LPIS plots. The segments thus obtained were used in the next step of the segmentation process, where the plot-designation plots were divided depending on the value of Landsat spectral images, in such a manner as to ensure that the newly created segments reflected the structure of sown areas.

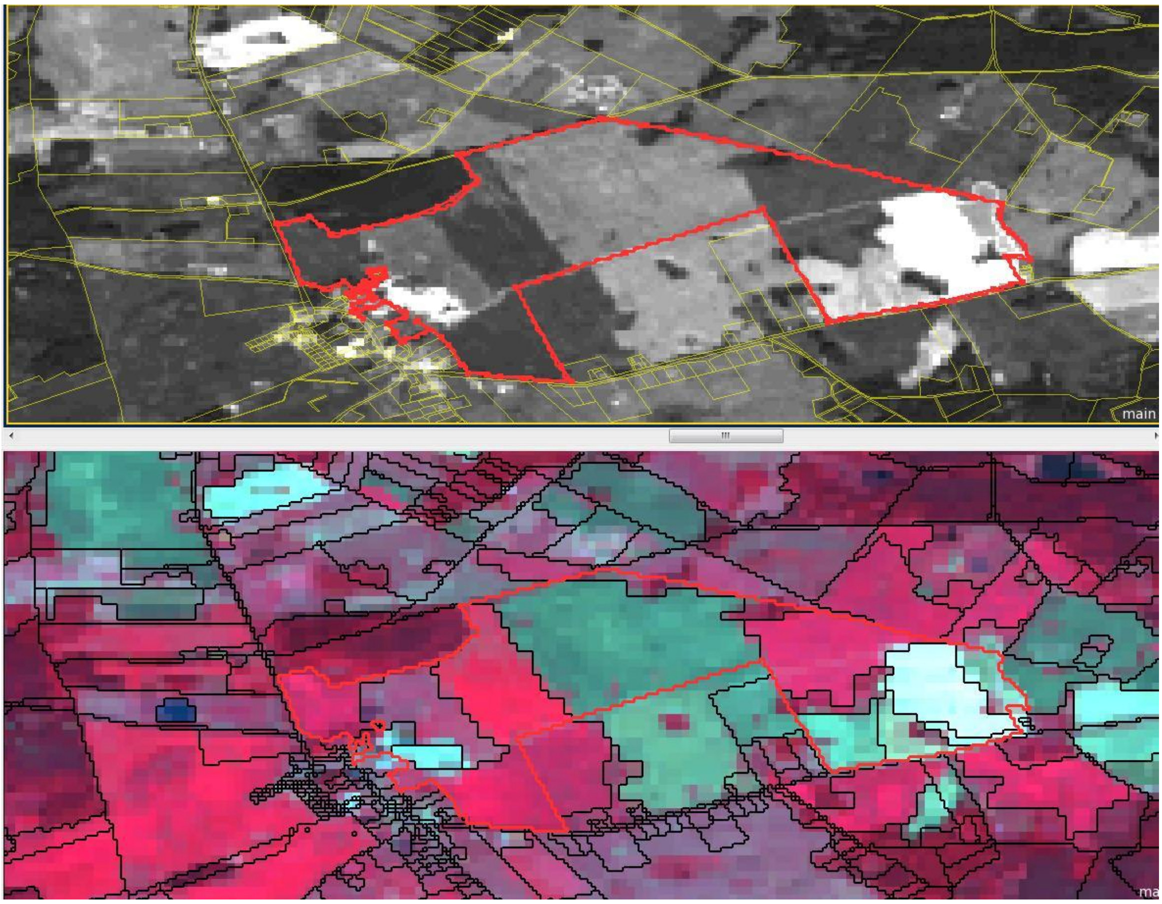

Figure 3: *Updating the borders of arable fields. Top – plot borders determined on the basis of the LPIS database; bottom – new crop borders obtained on the basis of segmentation of a multispectral Landsat image.*

2.5 Results of the classification

Three different classification algorithms were followed: Decision Trees, K-Nearest Neighbours and Support Vector Machine. The accuracy of the obtained results of classification was assessed on the basis of training fields and also with the use of an independent set of data from farmers' questionnaires collected in the ARMA system. The most reliable results were obtained for the classification carried out on the basis of Wishard's distance parameters, with the K-Nearest Neighbours method (KNN) and with the use of the temporal series of the σ0 back-reflection coefficient with the Support Vector Machine (SVM) method. To continue the assessment of the classification results, the areas of crops obtained through the classification of Sentinel-1 radar images and the estimated sown areas recorded in the CSO system were compared. Next, the results of crops were aggregated at the district level.

2.6 Summary and conclusions

Each classification of satellite images should conclude with an assessment of the results, to provide a basis for establishing the usability of image processing methods. In this case, the classification was assessed by being compared with the official CSO data on the status of crops in the Warmia and Mazury voivodship in 2015. At the same time it should be noted that, given the limited number of validation points, the results of the validation are indicative only.
The conclusions:

- The random selection of training fields should be replaced with the supervised method which allows selecting the sufficient number of large, adequately shaped fields that are well representative of each crop.
- The training fields should be identified at the level of the LPIS database, not on the basis of GPS indications during field measurements.
- Each point should be verified on the basis of photographs taken during a visit on the field.
- The validation on independent data were subjected suggests that the method has considerable potential, it also indicates the need for seeking other solutions, e.g. supplementing the data with optical photographs.
- The results of object classification depend on the quality of segmentation.
- The analyses of multitemporal radar data are connected with the necessity of processing very large image sets. All stages of classification work must be optimised in terms of the duration of operation and calculation capabilities.

3. Part II

3.1 The objective of the study

As part of the work we attempt to use drone with a hyperspectral camera for the purpose of estimating the production of permanent grassland.

3.2 Characteristics of the study area and used equipment.

The analysis covered the area of 21 plots indicated by the CSO, with total area of 460.2 hectare, located in the area of the Biebrza National Park (the BPN). During implementation of the project, to obtain hyperspectral imaging from low altitude an unmanned measurement platform (drone) was used in the form of multicopter with six rotor. Multicopter VersaX6 with take-off mass of 4 kg is able to carry measurement apparatus with weight up to 1.5 kg. The system of autonomous flight handling integrated in the platform allows conducting ortophotogrammetric flights in semi-automatic mode, when the platform follows the route of flight scheduled before along with possibility to set points of hovering optimising acquisition of data from hyperspectral camera. Total of 19 flights was performed along the routes programmed on the basis of cartographic materials prepared before and land survey. The distance of single flight was within the range of 1,000 – 2,000 meters and was performed at the altitude of 150 or 200 meters. To obtain hyperspectral imaging the Rikola full frame camera was used, imaging within the range of 480-890 nanometers. During flight imaging was performed in 16 spectral channels.

3.3 The survey methodology

Imaging from drone took place in the course of two field campaigns conducted on May and June 2015. For the needs of the project, fragments of two scenes coming from Landsat 8 satellite were used. In addition, simultaneously with conducted flights the ground measurements were performed (74 points on the area of the analysed plots) using specialist apparatus being in the possession of the Institute of Geodesy and Cartography, offering information about LAI (Leaf Area Index, ratio of projection area of leaves), humidity of soil and temperature of plants' surface. The collected data described above allowed for analysis and calculation of the production from the grasslands by assigning to each indicated plot an estimated value of fresh biomass and biomass with regard to one hectare. The main and the most time-consuming stage of the analysis was to prepare adequately the imagery acquired from the drone. Those images were then calibrated and combined to create a single mosaic for each of flights. The next step was establishment of colour composition (in false colours) and calculation of normalised difference vegetation index - NDVI, used in further parts of analyses.

Together with values from range (-1, 1) we obtained information on the development state and condition of vegetation, and high values of index correspond to the areas overgrown with thick vegetation of good condition. Based on the dedicated models, calculated values of fresh biomass from hectare were assigned to homogenous areas of the analysed fields and after calculation of surface of those areas a total estimated weights were obtained of fresh biomass (in tons) and of biomass from hectare (in tons/hectare), separately for each of the analysed plots.

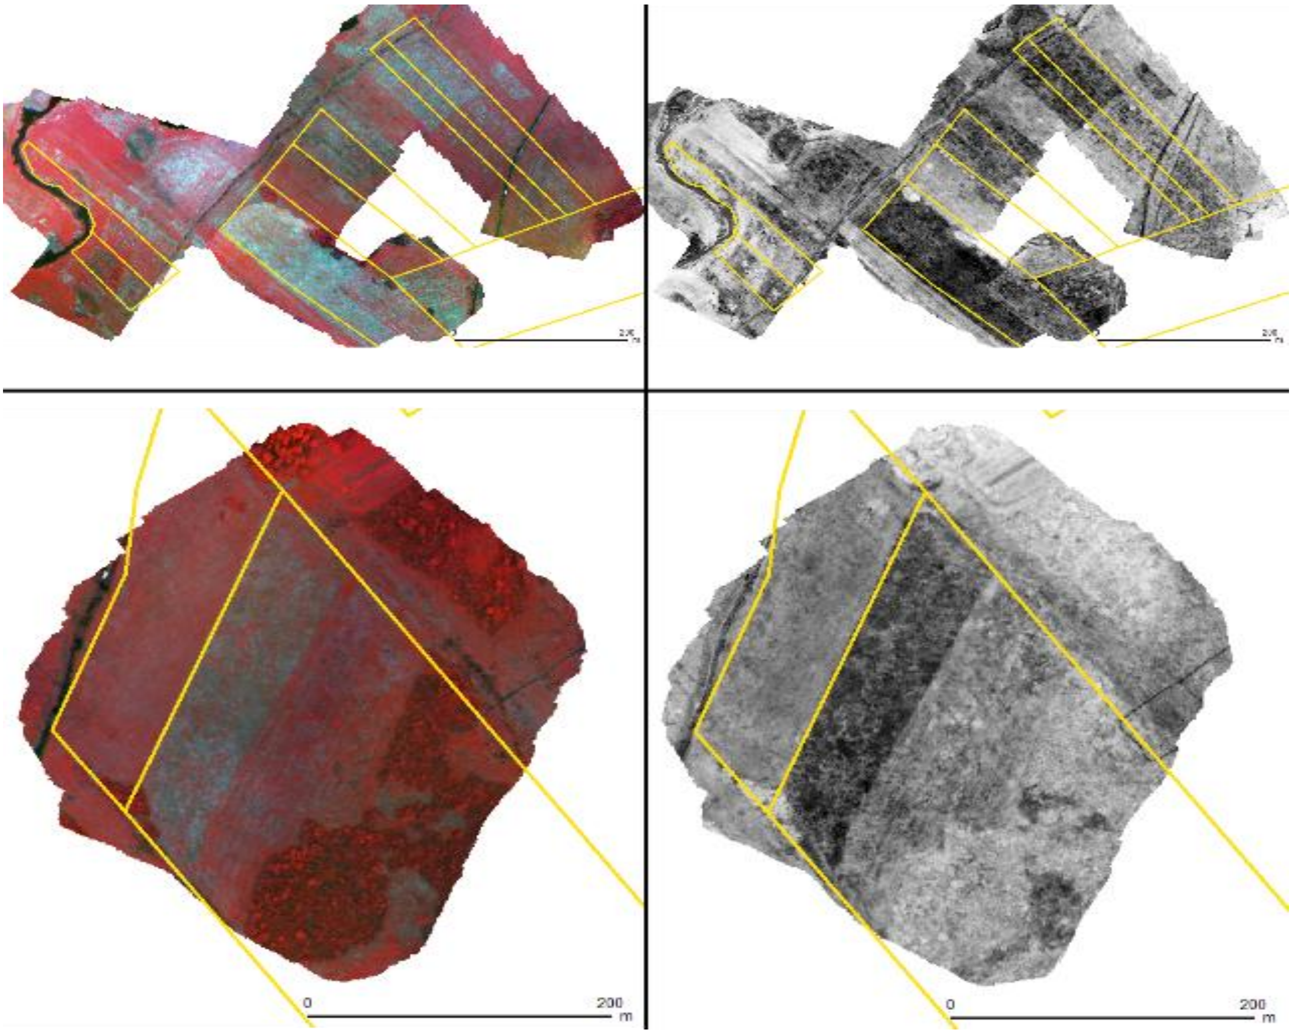

Figure 5: *Two examples of data obtained from drone; on the left, the composition of channels 16-6-4 (bluish areas correspond to sections of meadows with larger share of dry vegetation) on the right established NDVIs.*

3.4 Evaluation of accuracy and summary

To summarise this project, it is worth paying attention to pros and cons of the decision on using this technology to obtain teledetection data, so that it could be used intentionally and reasonably for subsequent analyses. An unquestionable advantage of imaging with the use of a drone is the possibility of taking pictures at low heights, as low as a few dozen meters, as well as smooth selection of height in vertical profile (which is impossible in the case of an aircraft or a satellite). Thus, such pictures are characterised by high spatial resolution, impossible to obtain by satellite images. Spatial resolution at the flight ceiling of 200 m. is approx. 12 cm. Such level of detail is necessary for precise determination of models, as well as for modification (detailing) of mathematical models used for image analyses, e.g. satellite images with greater data generalization, covering significantly larger areas. Obtaining such detailed images for large surfaces, e.g. community area, would be excessive. Therefore, for such areas, imaging is made at higher ceilings (at the same time, the image covers a significantly larger area). Important factors include also mobility, flexibility and relatively small cost of conduct of a single flight that can be carried out with a possibly short preparation time. Additionally, the need to maintain eye contact with the device by the drone operator provides a chance for good recognition of the imaged areas from the ground level and execution of additional measurements, which positively affects the accuracy of analyses.

On the other hand, the use of a drone has clear limitations that were impossible to avoid also in the case of the concerned project. The time of a single flight amounting to ca. fifteen minutes, high dependence on weather conditions, fairly low threshold conditions for wind power, during which flights cannot be performed for safety reasons (but also due to image quality), as well as the need to maintain eye contact with the drone limiting the scope of the survey - those factors result in the fact that the use of a drone in the case of analyses of large surfaces becomes difficult and ineffective.

But stronger winds means that even when using advanced stabilization, the individual channels can be spatially offset in relation to each other, which raises the need to use the compilation of time-consuming algorithms automatically adjust to each channel, or very time-consuming - even manual geometry corrections. This need not occur when we could use the muli-lens camera recording the appropriate channels at the same time (which of course increases the weight of the camera).

Trying to simulate the performance of imagery from drone on a scale of Podlaskie province with an area of 20180 km^2, where being a potential interest to agricultural land is 10741 km^2 (CSO, 2013) and based on framework price list of one of the companies carrying out flights by drones, total, multimillion cost and the huge amount of time needed for the execution of such a large area of the project make use of established technology, it is impossible to predict.

3.4 Recommendations

With the analysis of agricultural production with the use of remote sensing techniques, the first step should be to align the source of the obtained data for the planned scale of the study and the needs related to spatial resolution. While in the case of single plots, imaging from the level of a drone can provide valuable material for the purpose of conducting detailed analysis of production from grasslands, as well as provide possible additional significant data for verification of models used for analysis of image content. In the case of municipality or district levels, it may be more reasonable to use data from small airplane flights, with the use of the same equipment as the one used in drone studies, or even data from satellite (e.g. data from satellites Landsat 8 or Sentinel-2), which may enable analysis in the scale of a voivodeship, districts or the whole country.

Nationwide demonstration cases of Sentinel-2 satellite exploitation towards early crop area indicator

ABSTRACT

Satellite Earth Observation (EO) is a relevant source of transparent, timely and consistent information to monitor crop growth, to provide early area indicator and to stratify the agricultural regions. Thanks to the Copernicus program of the European Union, the satellite EO has recently entered in an operational mode where the data quality, the free and open access and the long-term continuity are major breakthroughs opening the avenue for more ambitious contribution to crop area and production estimate. This is the reason why developing operational agriculture applications from Landsat-8 and Sentinel missions became a strategic target for the remote sensing community, e.g. GEO-Global Agricultural Monitoring Initiative (GEOGLAM) building on GEO's Agricultural Community of Practice (AG COP) and the Joint Experiment of Crop Assessment and Monitoring (JECAM) supported by the space agencies' committee (CEOS). In particular, the Sentinel-2 mission was designed to optimize the observation capacity for regional to global agriculture monitoring at field scale in terms of spatial and spectral resolution (10 or 20 meters for targeted spectral bands), revisit frequency (5 days when two satellites in orbit), and coverage (systematic global acquisition). The combination of these features makes them most relevant to deal with a large diversity of agricultural landscapes.

In this context, the European Space Agency launched in 2014 the "Sentinel-2 for Agriculture" (Sen2-Agri) project, which aims at preparing the exploitation of Sentinel-2 data for agriculture monitoring through the development of an open source processing system. Based on key end-users requirements, this is designed to generate four relevant products, i.e. (i) cloud-free surface reflectance composite, (ii) dynamic cropland mask, (iii) cultivated crop type map and area indicator for main crop groups and (iv) vegetation indicators describing the vegetative development of crops. Crop type area indicators will be available after the first half of the season and thus, can serve as early estimate while waiting for the official agricultural statistics. Even if the area estimates accuracy is not yet matching the statistical standards, this product could be highly valuable as complementary geospatial information in a more and more georeferenced world

Thanks to fruitful interactions with key end-users and the network of JECAM sites globally distributed, the first phases of the project completed the product specifications, the algorithms selection, the system design, development and implementation. The third phase is currently dedicated to the demonstration of the Sen2-Agri system in operational conditions at full scale using Sentinel-2 and Landsat-8 data. Nationwide applications are on-going in close interactions with national and international partners, with the additional objective to transfer the system to the end-user's entity. A group of more than 15 champion users are closely engaged in the Sen2-Agri project including international organizations such as FAO, WFP, CGIAR or JRC of the European Commission as well as national mandated institutions in e.g. Mali, South Africa and Sudan. While the system already delivered successful SPOT4 Take 5 and SPOT5 Take 5 results for a dozen of JECAM sites, nationwide demonstration started in 2016 in Mali, Ukraine and South Africa. Five additional local sites were selected in Morocco, Sudan, France, China, and Madagascar covering up to 300 x 300 km in order to further increase the global representativeness of the demonstration findings.

Early results of these on-going demonstration cases are presented, as well as the preliminary lessons learned in the real-life context of the engaged user entities. In particular, the field data campaign, the cultivated area mask and the crop type map are discussed for Ukraine while the other demonstration cases are still going on.

Keywords: crop mapping, Sentinel-2 satellite, early estimate of cultivated areas

1. Introduction

Since years, satellite Earth Observation (EO) was proved to be a relevant source of comprehensive, timely and spatially consistent reflectance measurement to derive land cover map or even land use map in order to stratify national or regional territory for agricultural sampling. For crop area estimate, stratification allows either to optimize the sampling rate for area estimate and/or to improve the area estimate quality. Mapping crop to derive area estimate was found very challenging for various reasons: (i) classification accuracy hardly reaches the required level to capture the often marginal inter-annual change of the respective crop type areas, (ii) classification precision and accuracy are very dependent to the number and the dates of cloud free image acquisition, (iii) classification results are sometimes biased towards specific crop according to field patterns and pairwise crop spectral signature separability, (iv) statistical system cannot afford to rely on exploratory satellite mission which cannot ensure long-term continuity of observations.

More recently, satellite remote sensing is also used to empirically estimate the yield wherever the field size is compatible with the spatial resolution of existing satellite time series.

With the Sentinel-1a satellite in orbit since April 2014, the Copernicus program of the European Commission started to launch a fleet of EO satellites, which change completely the game for agriculture remote sensing. Unlike many other EO satellites, the Copernicus space segment is designed as an operational service providing consistent data quality, open and free access and long-term continuity (more than 20 years). For instance, Sentinel-1a and -1b, already both in orbit, carry exactly the same instruments providing complementarity but more importantly redundancy. Recurrent satellites for each of the Sentinels are in preparation and will be ensuring long-term continuity. While Sentinel-1 SAR instruments operate in the microwave domain to observe through the clouds, Sentinel-2 satellites capitalize on the heritage of Landsat and SPOT experiences to provide the first non-commercial EO system really designed for agriculture remote sensing. Combining visible and near-infrared bands with red-edge bands allows capturing most of the key vegetation properties while three other specific spectral bands support a better atmospheric correction (figure 1). The 10-day revisit cycle with a 10 – 20 m resolution and a wide swath of 290 km make it capable to acquire observation time series over large areas while capturing the field level. These features allow addressing a lot of the diversity of the agricultural landscapes. Launched in June 2016, Sentinel-2a will be complemented by Sentinel-2b scheduled for early 2017 to enhance the revisit cycle to 5 days. This is expected to provide dense time series adapted to temporal crop dynamics in most cropland regions. Some areas cloudy during the growing season would require even a more frequent observation capacities or the complementarity of SAR system not affected by cloud coverage like Sentinel-1. The Copernicus fleet also includes several additional satellites such as Sentinel-3 providing 300 m daily observation once both will be operating. Last but not least, the global systematic acquisition of Sentinel-2 and the open and free access license policy clearly open the door for more ambitious contribution of satellite remote sensing to agriculture assessment.

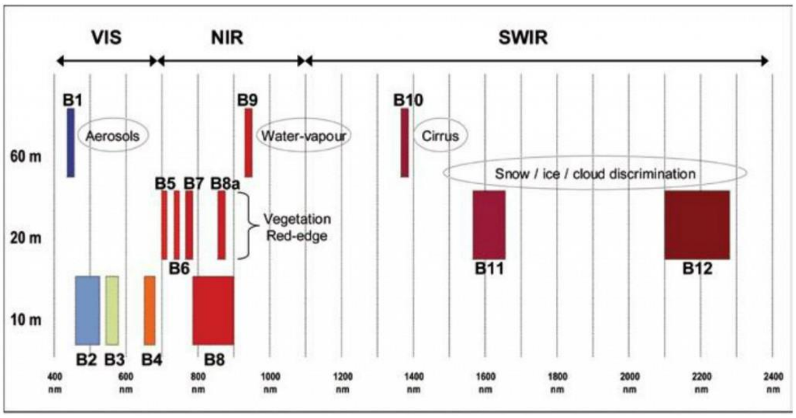

Figure 1: *Sentinel-2 spectral bands distribution (source: ESA).*

In this evolving environment, developing operational agriculture applications from Landsat-8 and Sentinel missions became a strategic target for the remote sensing community. Building on GEO's Agricultural Community of Practice (AG COP), the Joint Experiment of Crop Assessment and Monitoring (JECAM) and the Geo-Global Agricultural Monitoring Initiative (GEOGLAM) both supported by the space agencies' committee (CEOS) are instrumental to develop best practices and speed up the operational adoption of state-of-the-art remote sensing methods.

In this context, the European Space Agency launched in 2014 the "Sentinel-2 for Agriculture" (Sen2-Agri) project, which aims at preparing the exploitation of Sentinel-2 data for agriculture monitoring through the development of an open source processing system. Based on key end-users requirements, this is designed to generate four relevant products, i.e. (i) cloud-free surface reflectance composite, (ii) dynamic cropland mask, (iii) cultivated crop type map and area indicator for main crop groups and (iv) vegetation indicators describing the vegetative development of crops. Crop type area indicators will be available after the first half of the season and thus, can serve as early estimate while waiting for the official agricultural statistics. Even if the area estimates accuracy is not yet matching the statistical standards, this product could be highly valuable as complementary geospatial information in a more and more georeferenced world.

Thanks to fruitful interactions with key end-users and the network of JECAM sites globally distributed, the first phases of the project completed the product specifications, the algorithms selection, the system design, development and implementation. The third phase is currently dedicated to the demonstration of the Sen2-Agri system in operational conditions at full scale using Sentinel-2 and Landsat-8 data. Nationwide applications are on-going in close interactions with national and international partners, with the additional objective to transfer the system to the end-user's entity. A group of more than 15 champion users are closely engaged in the Sen2-Agri project including international organizations such as FAO, WFP, CGIAR or JRC of the European Commission as well as national mandated institutions in e.g. Mali, South Africa and Sudan. The system already delivered successful SPOT4 Take 5 and SPOT5 Take 5 results for a dozen of JECAM sites.

2. Objectives

This demonstration study aims to assess the performances of the Sen2-Agri system to deliver in a timely manner the cropland and area indicator for the main crops at national level. This pre-operational system designed as a generic open source software relies on near real time acquisition of Sentinel-2a and Landsat-8 imagery. The crop type mapping also requires timely in situ data collection while cropland mapping can run either from in situ data or only from existing land cover map. A crop type area indicator corresponds to unqualified crop area estimate and is obtained by pixel counting corrected for possible bias as assessed by a confusion matrix.

These nationwide applications respectively in Ukraine, Mali and South Africa are planned in close collaboration with national partners, with the additional objective to transfer the system to the national entity. This is the reason why the Sen2-Agri system is operated in a centralized way on one hand and in parallel at national level closely engaging and empowering the national stakeholders. National stakeholder's workshops are organized to provide insights from a user's perspective as well as to assess the quality and the relevance of the delivered information. Five additional local sites were selected in Morocco, Sudan, France, China, and Madagascar covering up to 300 x 300 km in order to further increase the global representativeness of the demonstration findings.

The objective of this paper is to report the preliminary outputs of the Sen2-Agri system, mainly illustrated through the Ukraine demonstration case, and to discuss the first lessons learnt.

3. Methods

Being part of the ESA Data User Element programme, the product to deliver by the Sen2-Agri system was entirely driven by a user-oriented approach in order to address concrete user needs and requirements. A suite of four core products was defined as top priority and are delivered automatically along the growing season by the system which was designed to take advantage of the near-real time imagery acquired by Sentinel-2 satellites as well as Landsat-8. Before the launch of the satellites, systematic benchmarking of state-of-art methods led to develop specific processing chain for each product (Bontemps et al., 2016). Only the cropland mask and the crop type mapping are presented in this paper.

The dynamic cropland mask delivered several times during agricultural seasons consists of a binary map at 10-meter spatial resolution separating annual cropland areas from other areas. Cropland is defined according to the JECAM guidelines (JECAM, 2014) as follows: “the annual cropland from a remote sensing perspective is a piece of land of a minimum 0.25 ha (minimum width of 30 m) that is sowed/planted and harvestable at least once within the 12 months after the sowing/planting date. The annual cropland produces an herbaceous cover and is sometimes combined with some tree or woody vegetation”. There are three known exceptions to this definition. The first concerns the sugarcane plantation and cassava crop, which are included in the cropland class, although they have a longer vegetation cycle and are not planted yearly. Second, taken individually, small plots, such as legumes, do not meet the minimum size criteria of the cropland definition. However, when considered as a continuous heterogeneous field, they should be included in the cropland. The third case is the greenhouse crops that cannot be monitored by remote sensing and are thus excluded from the definition. This definition discards perennial crops and fallow, as they are less important to monitor from an annual perspective.

The mask is delivered for the first time after 6 months of data acquisition and is then updated monthly. The season start date is a parameter defined a priori by the user. From one year of data acquisition, the production is based on a 12-month moving window. The regular update is expected to lead to an accuracy progressively increasing along the growing season. The processing chains producing the cropland mask are respectively described by Matton et al. (2015) and Valero et al. (2016) whether in situ data are available or not.

The cultivated crop type map is a map of the main crop types (or crop groups) for the whole country at 10-meter spatial resolution. It builds upon the cropland mask to process the time series only over the cropland areas. The main crop types are defined as (i) those covering a minimum area of 5% of the annual cropland area and (ii) whose cumulated area represent more than 75% of the annual cropland area. A maximum of 5 crop types are considered by country in the demonstration. In an operational context, the user can map the crop types he wants, providing that he collects the corresponding in situ data. The crop type map is delivered twice during the growing season with user-defined season start and end dates. The first map is produced after six months of data acquisition, with a legend that might be slightly different from the final one depending on what can be discriminated during the early stages of the season (e.g., summer vs. winter crops, irrigated vs. rain fed fields, etc.). Its accuracy may be variable but is intended to provide the best current information critically needed for crop monitoring systems. The second map comes at the end of the growing season and is expected to have much higher accuracy. The product allows deriving an early crop area indicator, which consists of the proportion of each crop type reported on the map within a 1 km² pixel. In the case of significant bias, the proportions will be corrected using the information provided by the confusion matrix of the crop type map. The area indicator can also be delivered at the most convenient aggregation level from the user point of view, i.e. administrative or census entity.

Aiming at developing an operational processing system globally relevant and coping with the large diversity of agro systems is not straightforward (Bontemps et al., 2016). It raises several challenges. From the remote sensing point of view, being relevant over the whole range of agricultural systems require to deal adequately with the global diversity of surface reflectance values to extract meaningful land cover information. Furthermore, the local heterogeneity of the agricultural practices (rotations, unusual crops, grassland edges, etc.) and the agro-meteorological variability will prevent the use of expected trajectories for crop discrimination and will require methodologies able to account for specific local conditions.

As described in Bontemps et al. (2016), products relevance does not only depend on their accuracy but also on their timeliness. Indeed, the value of most agricultural information rapidly decreases over time, as the seasonal production cycle leads to a sequence of critical dates for information delivery. The challenge is to provide the capacity to handle rapidly the processing of whole country, with the associated large volumes of data and products. The demonstration study also addresses challenges from the methodological, digital and organizational points of view. Indeed, most operational monitoring systems rely on proxies and qualitative indicators based on medium to coarse spatial resolution sensors. While the potential of high spatial resolution imagery is widely recognized, most of the research activities in this area currently rely on one site, one crop and one sensor. Supporting the development of operational agriculture monitoring methods based on high resolution images will first require collecting both EO and in situ data coming for the same season. Second, enough in situ data are to be acquired over each country to allow both algorithm calibration and independent validation of each product.

Three national demonstration cases (table 1) have been selected according to criteria including the representativeness of the selected countries with regard to a large demonstration ambition. These concerned the type of agricultural systems to monitor (e.g. crop type diversity, spatial heterogeneity, croplands fragmentation and field size distribution) and the agro-climatic conditions defining the actual availability of valid cloud free observation at the critical periods of the growing season.

Table 1: *Summary of national demonstration cases.*

Country (study area)	Main characteristics	Main crops and calendar	National Stakeholders
Mali (447 948 km²)	➢ Northern hemisphere ➢ Sudano-sahelian climate ➢ Field size: 1–5 ha	➢ Millet, Sorghum, Rice, Maize, Cotton ➢ From June to October with field preparation in March/April;	➢ ICRISAT ➢ Ministry of Agriculture : IER and Cellule Planification et Statistiques
Ukraine (576 604 km²)	➢ Northern hemisphere ➢ Humid continental climate, with snow cover in February and March ➢ Field size: 30–250 ha	➢ Wheat, sunflower, maize, barley, soybean ➢ From September to July and from April to October	➢ Space Research Institute of National Academy of Science ➢ National agro-meteorological service (Ministry of Emergency)
South Africa (619 606 km²)	➢ Southern hemisphere ➢ Sub-humid to semi-arid climate ➢ Field size: 40 ha	➢ Maize, wheat, sunflower, soybean ➢ Major season from December to June; from April to November	➢ Agriculture Research Council (ARC)

4. Results

While the Sen2-Agri system is currently running at national scale for Ukraine, Mali and South Africa, the performances are here illustrated from the preliminary results obtained in Ukraine.

4.1 In situ data collection

The purpose of in situ data collection within the season is twofold in the context of Sen2-Agri: for the calibration to support the training of EO data processors (Sentinel-2, Landsat 8) and for the validation to assess the quality of the Sen2-Agri products. The validation sampling is spatially independent of the calibration samples. It will allow assessing the map accuracy by compiling a confusion matrix and deriving various accuracy metrics (Overall Accuracy, Precision, Recall, and F-Score) in order to document the quality of the Sen2-Agri products.

The objective of the calibration or training sampling is to cover the diversity of situations existing at national level in order to represent the range of possible signatures for croplands versus non croplands and for the five main crop types. In addition, discriminating and mapping these crops required also to collect data about the other crops. The samples are really targeted to establish all the links between a given target of interest and the range of its features used for classification (i.e. Sen2-Agri processors). Various types of sampling seem appropriate as long as it is fairly well distributed across the territory and containing enough information for each targeted class. In order to cover the diversity or gradient observed over large areas, it is recommended to stratify the croplands according to the interaction between agrosystem type – crop distribution – cropping calendar – biophysical context.

For each sampled parcel, the crop type must be identified from ground observation during the on-going growing season. As adopted by the JECAM network, a comprehensive 'windshield survey' along the main and secondary roads is found very efficient for in situ data collection for calibration purpose. A particular attention is required to reduce the bias related to the road proximity by getting off road regularly. For the calibration of the cropland mask, two options can be considered to sample non-agricultural land cover. If up-to-date very high resolution imagery is available from Google Earth or Bing geoportal for a large part of the area of interest, a systematic random sampling is proposed to collect by photo-interpretation a sufficient number of non-agricultural land cover types. Alternatively, the non-cropland samples can be selected during the crop type validation sampling by windshield survey along the same roads. The figure 2 reports the sample distribution of the nationwide field campaign completed in July 2016 by the field team of the Space Research Institute (NAS, Ukraine). In Ukraine, an agro-ecological zoning strongly correlated to crop distribution delineates four very distinct strata, which are classically use for agriculture reporting.

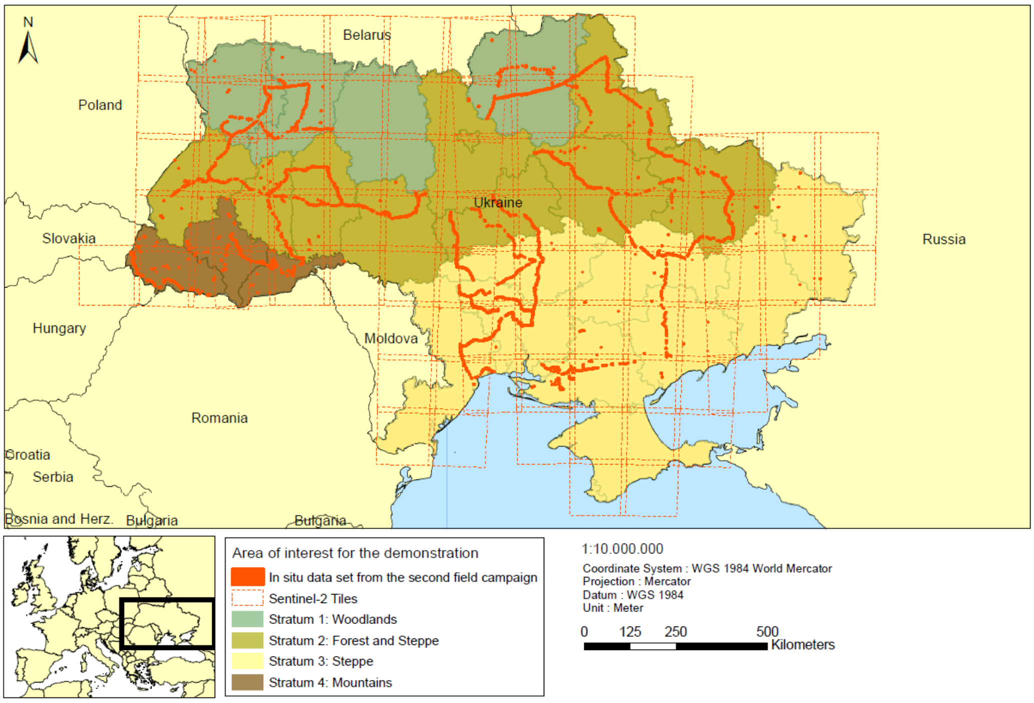

Figure 2: *Agro-ecological zoning of Ukraine used to stratify the Sentinel-2 time series processing and windshield sampling across the country for calibration purpose.*

4.2 Sentinel-2 data observation

Each Sentinel-2a acquisition has been processed from the 1st April to the 9th September 2016 in order to accumulate cloud free surface reflectance along the growing season. Using the MACCS module (Hagolle et al., 2010, Hagolle et al. 2015) included in the Sen2-Agri, a spatio-temporal cloud screening allows to detect the clouds and the associated shadows. The figure 3 shows the number of cloud free observation available over the 2016 growing season for each pixel of 10 m, highlighting the orbit overlap (in green).

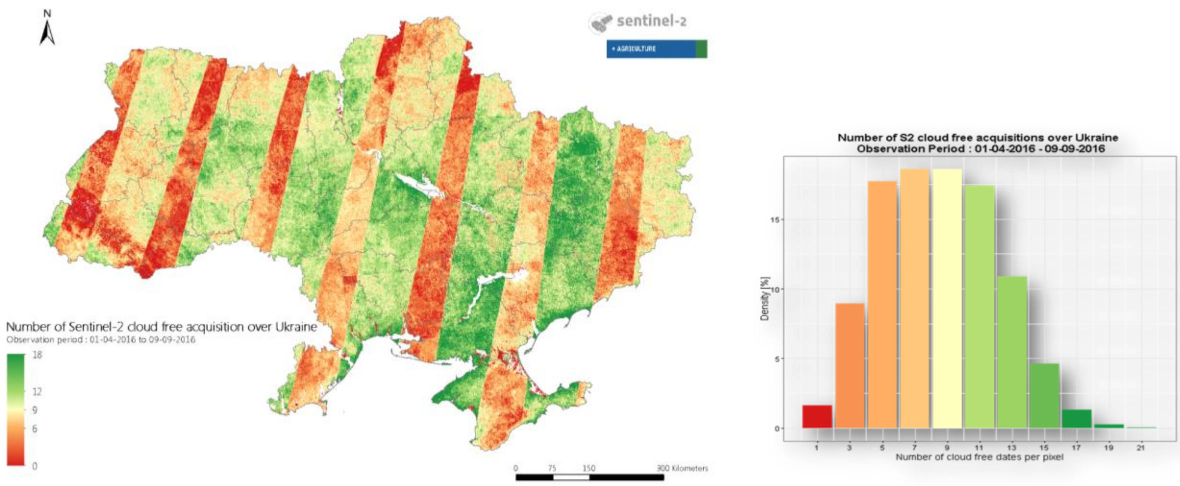

Figure 3: *Number of cloud free observation provided by Sentinel-2a over Ukraine during the 2016 growing season.*

4.3 Production and validation of crop mask

Once the field data quality controlled, they must be uploaded into the Sen2-Agri system to produce the crop mask and the crop type map. The figure 4 corresponds to a single tile (100 x 100 km) of the Ukraine territory to highlight the spatial details of the Sentinel-2 images acquired on 17 July 2016 and the associated in situ data.

The full time series of all Sentinel-2 observation acquired from April to September 2016 over the whole of Ukraine (more than 1,5 Tb of compressed input data) was automatically processed to surface reflectance (6 Tb of processed surface reflectance data). Thanks to the upload of the in situ data, the time series was then classified to derive the crop mask at 10 m resolution by early October for the on-going growing season over a national territory of more than 600,000 sq km. The figure 5 displays samples of this unique result of 10 m crop mask. This early estimate of the 2016 cultivated area can be compared with the available early statistics for 2016 compiled from the sowing area declaration by the farmers aggregated at oblast level.

The quality of the crop mask displayed on figure 4 is assessed by the set of accuracy metrics already mentioned. It is clear that the accuracy varies spatially according the fragmentation of the landscape, the crop diversity, the density of field data and, last but not least, as long there is only one Sentinel-2 in orbit (till 2017), the frequency of cloud free images along the season. Fortunately, these characteristics can be easily documented and therefore the area estimate uncertainty can be predicted.

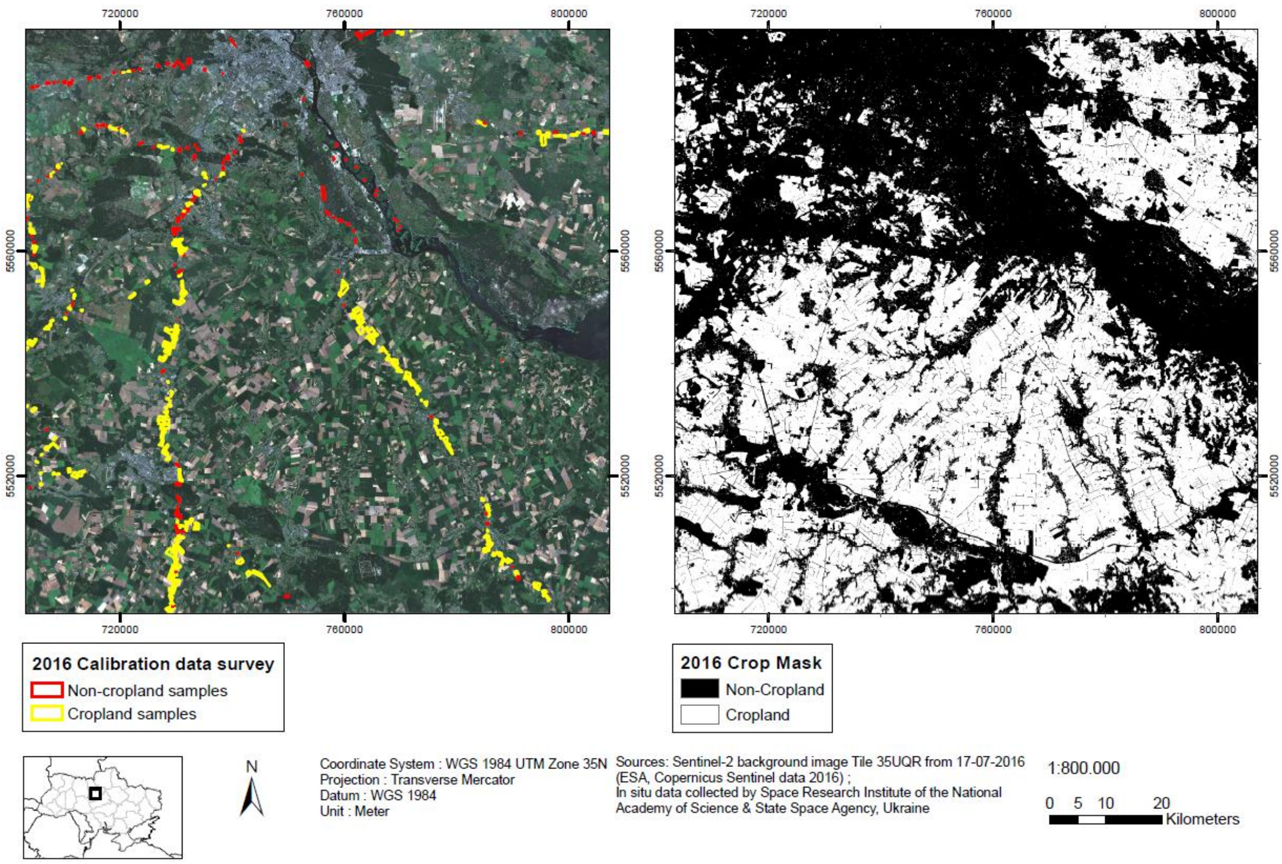

Figure 4: *Sentinel-2 10-m color composite acquired on 17 July 2016 over the South of Kyivs'ka oblast (on the left) overlaid by the field data used to produce the 2016 crop mask for the corresponding area (on the right side).*

4.4 Production of crop type map

Using the same in situ data, the Sen2-Agri system can also deliver a mid-season crop groups map and a more detailed crop type map by the end of the growing season. Zooms on the outputs obtained are displayed at figure 5. First, a map discriminating winter crops versus summer crops was produced while at the end of the season a more precise map of the different main crop types will be produced. Please note that the season was not over at the time of writing and the crop type map illustrated at the figure 4 is only an intermediary product.

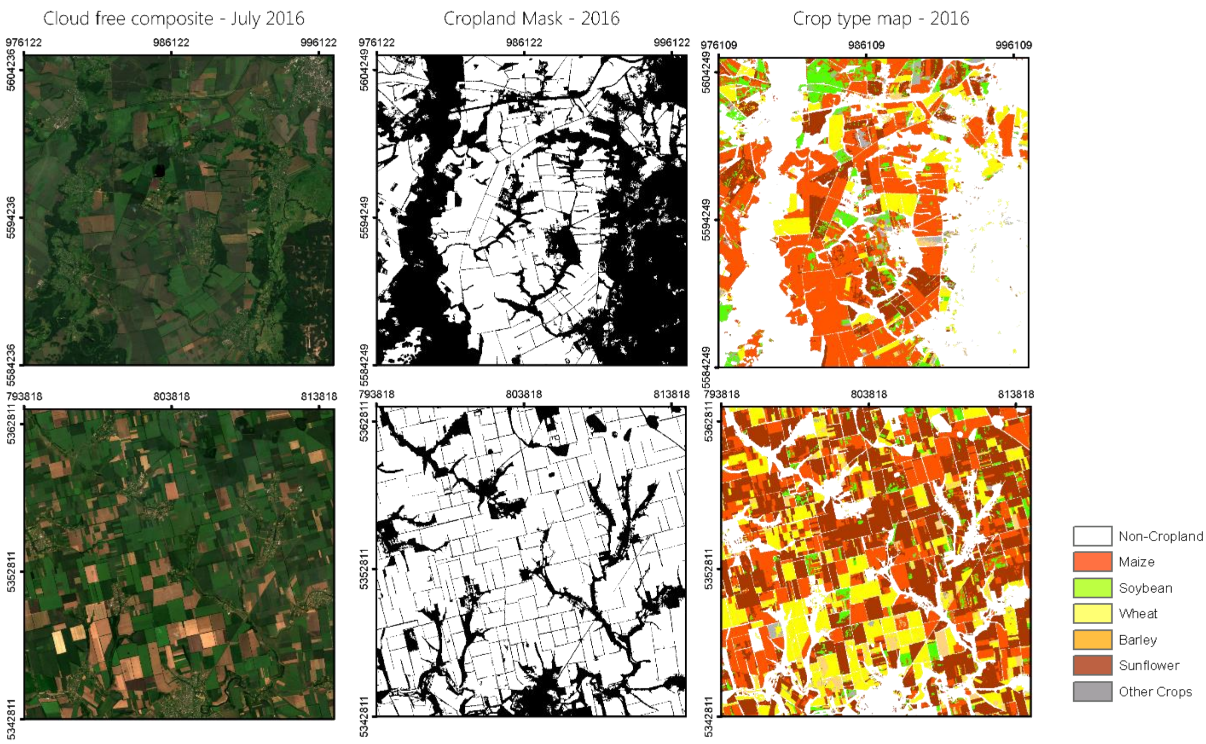

Figure 5: *Details of the 2016 cropland and main crop types map for two zoom in Ukraine.*

5. Perspective

The on-going demonstration of the Sen2-Agri highlights the significant impact of the availability of the Sentinel-2 time series on the capacity to deliver along the season various products including crop mask and crop type maps. The accuracy obtained for some of these products indicates that the early area estimate can be derived and be relevant as a complementary information to the official agricultural statistics. By the end of the growing season in the various demonstration countries, the final nationwide maps and derived area estimate will be available and compared with the existing official statistics. In addition, a user-oriented assessment, involving the national stakeholders such as the Ministry of Agrarian Policy and Food of Ukraine, will be reported in order to assess the Sentinel-2 demonstration products utility and benefit and the possible improvements.

ABSTRACT

Images collected by optical and radar satellite sensors represent a most viable solution for the extraction of biophysical parameters of the earth surface. The mid-resolution dataset acquired by Landsat and Sentinel satellites have recently become available free of charge for all users. At the same time, some software of image processing and GIS, like *QGIS*, *R*, and *ImageJ*, have reached a high level of maturity and a large community of users, thanks to their open source license. In this project free satellite images and open source software have been used for the assessment of the grassland biomass. The overall goal is the enhancement of the statistics of grassland production and dried fodder for the animal breeding. Currently the National Institute of Statistics collect this kind of dataset at the province level.

The project, still in progress, consists in some "in situ" surveys in a specific site in central Italy and in the building of a regression model between the grassland heights and the corresponding radiometric values of the most relevant image bands.

Keywords: biomass, Sentinel, Landsat, grassland

1. Study areas

During the planning phase, three areas have been identified for the collection of training and test samples, in the North, Central and Southern Italy. A specific mission in the National park of Murge, in Puglia, South of Italy, has shown however the unsuitableness of the local grassland for the model, due to the presence of stones and shrubs over the ground and the low number of pastures in the small, scattered and flatten areas. The collected samples of the grass height have also demonstrated the diversity of vegetation classes and the need to build a complex regression model considering the height of each class, or each group of classes, separately.

The foreseen campaign of measures in Northern Italy has not taken place until now due to limited time and resources. Therefore, the model has only been trained with the two-year campaigns carried out in Central Italy, in a site named Pian Grande.

Pian Grande is an upland karstic plain in the national park of Monti Sibillini, located between Umbria and Marche, in the Appennini mountains, in central Italy. It is a quite suitable site for the grassland production because of the lack of trees and shrubs over the flat plan, located at 1300 mt above sea level. The plain is the bottom of an ancient mountain lake, now dried up, and has a rectangular shape with an area of around 15 Km^2. From the vegetational point of view, it is possible to consider the existence of 4 types of homogeneous areas:

- areas with agricultural crops (grass meadows, barley and lentils) located in the nearby of Castelluccio village and below the slopes of Vettore Mt., corresponding to the class 2.1.1 (Non-irrigated arable land) of CORINE[1] Land Cover 2012 map;
- areas with natural grassland, equivalent to the class 3.2.1;
- areas with pastures, that occupies the central portion of the plain, corresponding to the class 2.3.1 (Pastures);
- bare rocks (3.3.2) or sparsely vegetated areas (3.3.3), located in the nearby of Vettore Mt.

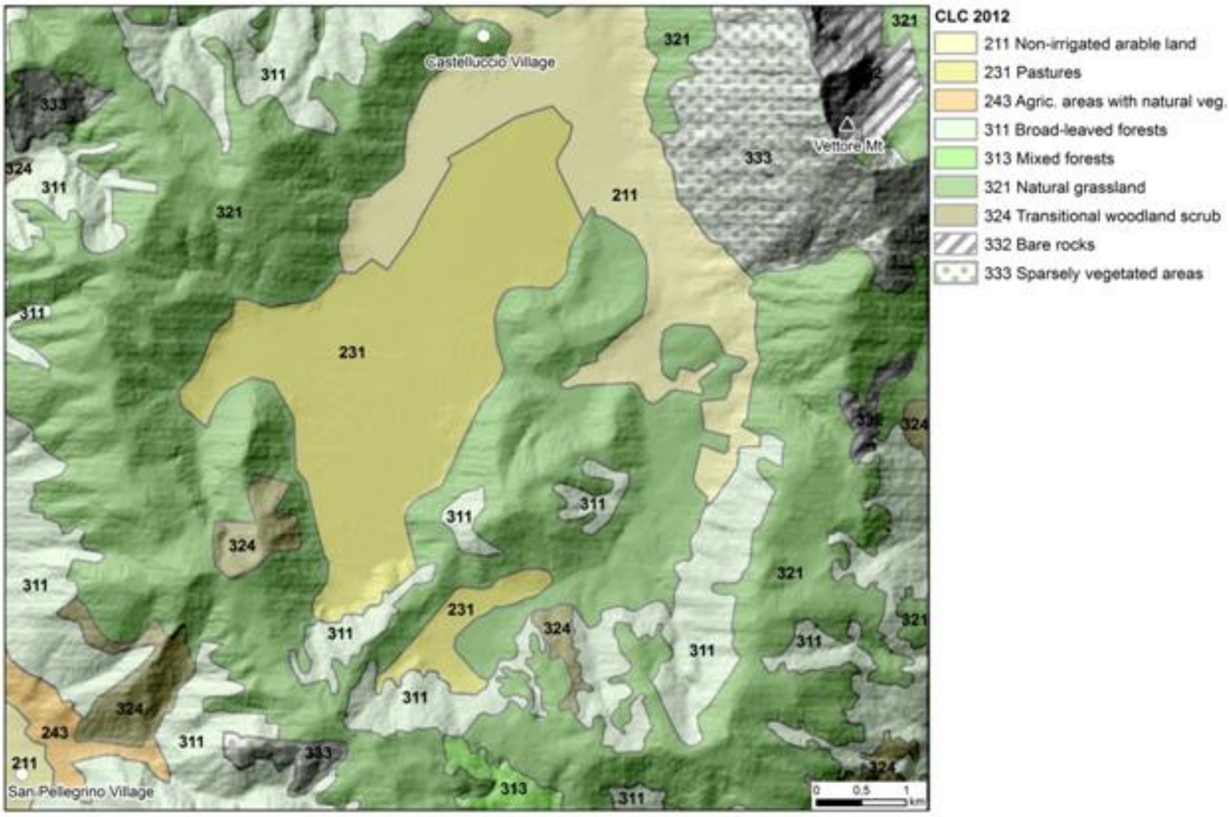

Figure 1: *CORINE Land Cover 2012 map*

The pasture reaches its highest growth at the end of June, depending on the temperatures, after a suggestive blossom, and produces high quality bales of hay. The best period for the field surveys is between the end of June and the beginning of July, just before the cut of the grassland. Two missions have been carried out in the past two years (2015-16) during the same period of the year.

[1] http://www.eea.europa.eu/publications/COR0-landcover

2. Sampling methodology

The need of collecting many samples as possible of the grassland height in a limited time and with the most possible accuracy, taking also into consideration the pixel dimension of the satellite images used for the model, has suggested to the use of the camera and to postprocess the images in order to derive the height with some image processing tools.

The assessment of the height has been executed with a white cardboard of 300 x 70 cm placed on the grass and used as a background for the photograph in order to derive just a linear section of the grass height. Every picture has been linked to the GPS position of the same sample point.

Figure 2: *Survey of a height of a section of grass*

The high contrast of the green vegetation over the white background has helped in the postprocessing of the photographs that has consisted in the extraction, rescaling to a standard width and measure of just the white area (c section in the figure 3) in terms of number of pixels. The division of that area by the fixed width produces its mean height and, by difference with the total height of the cardboard, the mean height of the grass.

The pictures have been analysed with an open source image processing software: *ImageJ*[2]. The software is written in Java and is available for Windows, Linux and Mac OS and OS X. Some of the software tools used in the software for the process are the *Colour Threshold*, for the selection of the white pixels, and the *Colour Pixel Counter*, for the determination of their number. In the 2015 survey a simpler brown cardboard has been used, but sometimes the colour separation and the extraction of grass has been difficult, above all in case of dry hay. Another lesson learnt during the first year of the project is to avoid measures in the second half of July, when the grass is usually cut and compacted in bales.

This method has allowed a very fast survey and a high number of samples collected during each day of measurements. 88 samples have been acquired in a two-day campaign on June 2016, while just 20 were the points surveyed in 2015 because of the partly mown pasture.

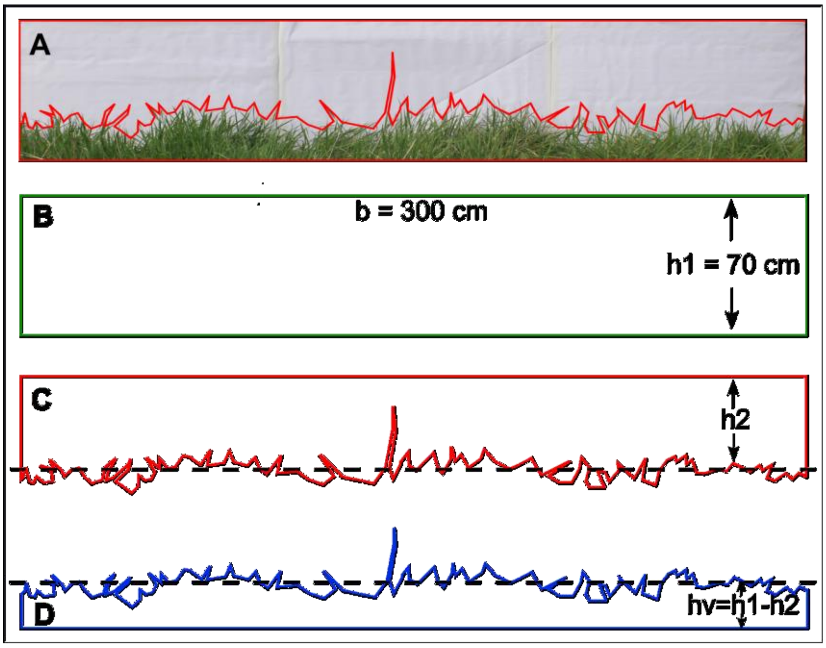

Figure 3: *Postprocessing of the pictures*

3. Satellite images

Currently two mid-resolution satellites acquire images from the earth surface with optical sensors and deliver them free of charge to all users: the Landsat 8 (Nasa) and the Sentinel-2 (Esa).

The OLI sensor of Landsat 8 has replaced the ETM+ one mounted on Landsat 7 but maintains the same bands and the same ground resolution (30 meters) of the previous satellites, allowing in this way the time series analysis. Sentinel-2A is one of the satellites of the Copernicus Esa observation programme and delivers images at a spatial resolution of 10 meters in visible - near infrared spectra. By the end of 2016 the new Sentinel-2B will join the Esa constellation, increasing in this way the revisiting frequency on the same area.

Radar images have also been considered for the correlation model: the Sentinel-1 satellites acquire polarised images in C-band with a spatial resolution of 20 meters. From the first results of the model it seems S-1 images are not so useful for the determination of grass height (see S1_VH and S1_VV in Table 1). Nevertheless, it has been planned to test the model with the high-resolution radar images of the *Cosmo-Skymed* Italian mission.

The values for every image and band have been extracted with the *QGIS*[3] *Zonal Stats* tool with a 20-meters buffer centred on each samples and by extracting basic statistics, like mean and standard deviation, from the overlapping pixel values.

4. Statistical analysis

Descriptive statistics are used to describe the basic features of the data by means of some numeric indexes: mean, standard deviation, standard error of the mean (SEM), coefficient of

[3] http://www.qgis.org/it/site/

variation, skewness and kurtosis. The univariate correlation has been considered too, with the evaluation of the Pearson correlation coefficients and the relative correlation matrix.

Furthermore, a multiple linear regression model has been implemented, based on ordinary least squares method, that is one of the most frequently used statistical approaches to model the correspondence between spectral and field data (Lu, 2006).

The regression model consists of a dependent variable, the vegetation height (Hv) measured in the in-situ survey, and the independent variables, represented by the spectral radiance levels of the bands from Landsat 8 and Sentinel 1-2 satellites. Adjusted R-square are considered as fitting parameters of calculated models.

A backward elimination approaches based on Akaike's Information Criteria (AIC) was used to identify the model that provides the best description of the data using the smallest number of parameters.

4.1. Sentinel

Descriptive statistics and correlation for Sentinel image are shown in Table 1 and Table 2. A positive correlation exists between the S2_NIR and S1_VV while remains negative for all the others bands. Table 3 shows the T-test between the most significant predictors for the model (Red, Green, NIR) and how they differ from each other.

The regression model with the least AIC is:

$$Hv = 71.186 - 0.168 * S2\_G + 0.083 * S2\_R + 0.010 * S2\_NIR$$

The overall significance of the regression model has been estimated with the F-test (F-statistic: 40.62 on 3 and 66 degree of freedom, p-value: 5.42e-15) and the model shows an Adjusted R-square of 0.63.

4.2. Landsat 8

Descriptive statistics and the correlation matrix for Landsat 8 image have been evaluated as well (see Table 4 and Table 5). The correlation is similar to Sentinel: positive between the grass height and the NIR band while remains negative for all the other bands. Table 6 shows the coefficients obtained with the T-test.

The resulting model is:

$$Hv = 161.094 - 0.042 * S2\_G + 0.024 * S2\_R + 0.002 * S2\_NIR$$

The F-test reports similar results of the previous case (F-statistic: 33.31 on 3 and 66 degree of freedom, p-value: 3.153e-13) and the model shows an Adjusted R-square of 0.58.

5. Statistics on grassland production collected by Istat

As part of official statistics, Istat disseminates several statistics on grassland in Italy. The Istat classification of grassland includes the following classes: grass meadow; alternated grassland; grasses; grazings. The Italian Agricultural Census allows to have an analysis with a high spatial detail of grassland areas (at municipal level), in hectares. The inter census sample survey “Farm Structure” provides the same information at the regional level.

The annual estimates of the areas and production quantities of grassland are recorded by: “Estimate of crop, flower and pot plant production and area”. This statistics are produced using expert information. Data are provided by local authorities that collect experts evaluations on area and yield of different crops. The auxiliary information could be included in expert's estimate, such as verifying the availability of external sources (e.g. professional bodies or associations of producers, administrative sources, auxiliary sources of data related to the cultivation being estimated). Crops under investigation are different for each month and take into account the phenological stage of cultivation. For this reason more than one estimate can be determined for each crop during the year (provisional, temporary or permanent).

As part of the official agricultural statistics, more general information are produced by sample survey “Early estimates for main fields crops”, carried out annually in order to provide preliminary estimates of the areas affected by the most interesting crops during the current crop year.

6. Results

The project is still ongoing but the first results show a poor correlation ($R2 \geq 0.6$) between the VNIR bands and the grass height. Radar Sentinel-1 images, even polarised, seems not influenced by different vegetation biomasses of upland pastures, perhaps due to the limited grassland height. From the statistical results seems the higher grass has a bigger component of red while green and NIR decrease. The validation of the model is still to be performed.

However, the sampling method permitted fast operational activities and has given good results. The model seems to work better for mid-height grassland (10-20 cm), perhaps because in case of very low grass the images receive signals from other visible elements, like small stones, dry grass, and the terrain itself, while the higher grass doesn’t change the same radiometric values acquired for mid-height samples.

USE OF OPINION POLLS FOR INFORMING FOOD SECURITY AND WELL-BEING MEASUREMENT

Session Organizer
A. Rzepa | Gallup | London | United Kingdom

ABSTRACT

As the curtain closes on the Millennium Development Goals, a variety of new mechanisms and instruments have been developed which may be appropriate for measuring the progress and health of societies.

Survey data and opinion polls are being put forward by many parties as key data sources for the Sustainable Development Goals (SDG) process in order to help enable the realisation of the HighLevel Panel's post-2015 vision of creating an information revolution by enabling the disaggregation of data "by gender, geography, income, disability, and other categories."

As demonstrated by the work of The Organization for Economic Cooperation and Development (OECD) and a number of national governments—including Bhutan and the United Kingdom—over the past half-decade, there have been a number of significant breakthroughs in the field of subjective well-being measurement via survey research and opinion polls. These developments have coincided with a growing acceptance of well-being's potential impact to influence policy and policymakers. The use of such survey instruments on a global scale allow new insights into the state of the human condition.

In parallel, the United Nations Food and Agricultural Organisation has developed and validated an experience-based measure of food insecurity (FIES) for global monitoring through its Voices of the Hungry (VOH) project. Once again its implementation through a global survey instrument provides an overview of food insecurity at global, national and sub-national levels.

This call requests papers that can help demonstrate the utility and use of opinion polls to inform the post-SDG framework on the topics of food security, well-being or other interrelated themes, whether in isolation or as part of the larger data ecosystem.

ABSTRACT

A large literature exists on the positive link between the consumption of fruits and vegetables and physical health. The World Health Organization and many western nations have adopted postures that suggest a healthy diet being one where individuals are advised to consume five portions of fruits and vegetables per day (2002). Not a lot of research has been done, however, on measuring the impact of a healthy diet on psychological well-being. Despite the increased interest both by scholars and governments in the study of life satisfaction as a proxy for progress in a nation or society as a whole, there has been little research on a very basic element of human life which is the impact of the people's dietary choices in their happiness.

Building upon the exercise made by Blanchflower and Oswald for the UK (2012), this study investigates on the existence of a link between the regular consumption of fruits and vegetables and life satisfaction in the United States. With the aid of Gallup-Healthways Well-Being Index, a unique data source that surveys 500 US citizens daily on well-being and health related aspects, a cross-sectional analysis was done to determine if regular consumption of the five portions of fruits throughout the week has an important role in emotional wellbeing of individuals. Controlling for different economic, demographic and other socioeconomic factors the data demonstrates that an increased number days having the correct amount of portions is accompanied by an increase in life satisfaction evaluations. Reverse causality remains possible. Limitations to the study, policy implications and further research are discussed.

Keywords: Gallup Healthways Wellbeing Index, Healthy Food, Positive Impact

1. Introduction

Through its year-round daily surveys, the Gallup-Healthways Well-Being Index provides the most up-to-date data and insights available on US citizens' purpose, social, financial, community and physical well-being. Gallup published nearly 60 articles in 2015 about US citizens' health, well-being and life-satisfaction. Some of the key findings showed uninsured rates among US adults falling, obesity surging, cigarette consumption among young adults decreasing significantly over the past decade or nearly two in ten people in the United States saying they take drugs to relax almost every day. Factors contributing to these findings include negative workplace environments and difficulty making positive health decisions about modifiable health behaviours like diet, exercise, and stress.

In that same line of trying to determine what impacts well-being and life satisfaction, this study uses the Gallup-Healthways Well-Being dataset to study what the impact of regular consumption of fruits and vegetables is on life satisfaction in the United States. A large literature exists on the positive link between the consumption of fruits and vegetables and physical health. The World Health Organization and many western nations have adopted postures that suggest a healthy diet being one where individuals are advised to consume five portions of fruits and vegetables per day (2002). Not a lot of research has been done, however, on measuring the impact of a healthy diet on psychological well-being. Despite the increased interest both by scholars and governments in the study of life satisfaction as a proxy for progress in a nation or society as a whole, there has been little research on a very basic element of human life which is the impact of the people's dietary choices in their happiness.

There are particular dietary constituents like vitamins and minerals that have proven to be beneficial to physiological health. Such a great benefit to the body creates the need to answer the question of whether these benefits also happen in the psychological realm. Rooney, McKinley and Woodward (2013) show in the most thorough literature review on the matter how more and more papers are suggesting that choice of food intake may have the potential to influence psychological well-being. Foods with complex carbohydrate content (like beans, peas and bananas), high on vitamin B (in particular folate (spinach, Brussels sprouts) and vitamin B6 (peas and bananas), antioxidants or minerals (iron, calcium and magnesium) contained in fruits and vegetables have been linked to improvements in brain functions including neural development and synoptic plasticity in neurons.

Although there are exceptions like Graham (2008) and Powdthavee (2009), there has not been a lot of work on how happiness interacts with health and dietary choices. Building upon the exercise made by Blanchflower and Oswald for the UK (2012), this study investigates on the possible existence of a link between the regular consumption of fruits and vegetables and life satisfaction in the United States. By using 2014 and 2015 yearly data, this study provides evidence of a positive association between the regular consumption of fruits and vegetables with psychological well-being, using life satisfaction as a proxy. The more days a week a person consumes the recommended 5 units of fruits and vegetables the greater their life satisfaction is. The nature of this relationship is evaluated across a series of controls and possible confounders like income, race or educational level and the results are robust. That is important in this setting, because so many 'healthy' attributes, including high levels of education and income, are likely to be correlated with the eating of fruit and vegetables. The study also finds that higher levels of fruit and vegetable consumption appear to be predictive of future life satisfaction of individuals.

A limitation to the study should be made clear from the beginning. The data set is cross-sectional. Even though the margin of sampling error for the study being 0.2 percentage points at the 95% confidence level, we cannot draw direct inferences about causality. Given the policy implications of this topic and the difficulty of obtaining daily individual food consumption datasets, it would perhaps be valuable to create future longitudinal data sets in which fruit-and-vegetable portions are measured.

2. Methodology

The data for this study comes from the Gallup-Healthways Well-Being Index. Quoting from their own methodology, in the U.S., the Gallup-Healthways Well-Being Index provides an ongoing assessment of Americans' health and well-being. By interviewing no fewer than 500 adults each day, the Well-Being Index gives the ability to analyse and monitor U.S. residents' health and well-being on a continuous basis, allowing for unique insights on how to create behavioural change to ultimately improve well-being and lower healthcare costs. The Gallup-Healthways Well-Being Index includes questions that fall into six sub-indexes: Basic Access, Physical Health, Emotional Health, Healthy Behaviours, Life Evaluation, and Work Environment. The Well-Being Index segments the data for respondents in adverse and optimum situations according to household income, location demographics (based on ZIP code), and personal health status.

Gallup daily tracking relies on live (not automated) interviews, dual-frame sampling (which includes random-digit-dial (RDD) list-assisted landline interviewing and RDD wireless phone sampling to reach those in wireless-only and wireless-mostly households), and a random selection method for choosing respondents within the landline household. Gallup stratifies the random-digitdial (RDD) list-assisted landline and the wireless phone samples to ensure that the unweighted samples are proportionate by U.S. Census region and by time zone within region. Gallup weights the data daily to compensate for disproportionalities in selection probabilities and nonresponse. For this study, yearly data for 2014 and 2015 was combined. The total sample available was of 353,983 individuals, aged 18 and up. The two sequentially asked questions in the survey that are used as key dependant variables in our study are the following:

- "Please imagine a ladder with steps numbered from zero at the bottom to ten at the top. The top of the ladder represents the best possible life for you and the bottom of the ladder represents the worst possible life for you. On which step of the ladder would you say you personally feel you stand at this time?"
- On which step do you think you will stand about five years from now?

These questions are self-reported measures of life satisfaction. The response distribution for the first question shows that more than 45% of the people gave a score of 8 or more with the mean score for the sampled individuals is 7.00 with a standard deviation of 2.00. For the second one, life satisfaction in 5 years' time, the mean score is of 7.81 with a standard deviation of 2.21.
The study uses one key question relating to fruit and vegetable consumption.

- In the last seven days, on how many days did you have five or more servings of fruits and vegetables

Possible responses to this question range from 0 (no days with 5 or more servings of fruits and vegetables) to 7 (having 5 or more servings every day). More than two fifths of the people claim to have less than 3 days with the suggested servings and an overwhelming 30% say they have the 5 servings every day of the week.
We are interested in the size and statistical significance of the coefficient accompanying the consumption fruits and vegetables variable. To allow for possible confounding effects and check for robustness, using a similar methodology as Blanchflower, a series of independent variables were incorporated to estimate equations of the general form of:

Life Satisfaction = (number of days with 5 portions of fruit and vegetables consumed; age; gender; education; income)

3. Results

Table 1 reports the simplest regression specification in which the dependent variable is a person's current life satisfaction on scale from zero to ten and the independant variables are dummies for the number of days with five serving of fruits and vegetables each person had. Everything is normalized against the case of no days having the five portions of fruits and vegetables. A strong positive correlation is noticed. The more days having the right amount of servings the greater the impact on life satisfaction. Those that eat 5 servings on a daily basis have a life satisfaction score that is almost 19 times bigger than those with only one day. (0.028 vs 0.568)

Table 1: *Number of days with 5 servings of fruits and vegetables on life satisfaction*

		B	Std. Error	T
1	(Constant)	6.631	.009	753.810
	1 day of fruit	.028	.018	1.546
	2 days of fruit	.168	.014	12.111
	3 days of fruit	.302	.013	23.892
	4 days of fruit	.451	.014	33.275
	5 days of fruit	.518	.013	40.512
	6 days of fruit	.610	.020	31.246
	7 days of fruit	.568	.011	52.976

Table 2 of is an adjusted version of the first specification adding demographic characteristics: this regression equation incorporates gender, race and age. Like in Blanchflower and Oswald (2008), there is also evidence here of a U-shape in age, lower levels of satisfaction among black people and higher ones for Asian and Hispanic populations (compared to White). The fruit-and-vegetable coefficients, despite decreasing slightly, remain large and statistically significant. It is worth mentioning that the coefficient accompanying daily consumption of the optimal servings has the highest coefficient of impact on life satisfaction.

Table 2: *Number of days with 5 servings of fruits and vegetables and demographic variables on life satisfaction*

		B	Std. Error	T
1	(Constant)	6.862	.021	333.971
	1 day of fruit	.034	.019	1.760
	2 days of fruit	.142	.014	9.933
	3 days of fruit	.255	.013	19.923
	4 days of fruit	.395	.014	29.159
	5 days of fruit	.437	.013	34.494
	6 days of fruit	.484	.019	25.627
	7 days of fruit	.490	.011	45.791
	Gender	-.099	.007	-14.569
	Black	-.171	.012	-14.572
	Asian	.087	.023	3.764
	Hispanic	.034	.012	2.893
	Under 20	.135	.021	6.539
	Under 30	-.061	.021	-2.980
	Under 40	-.120	.020	-5.907
	Under 50	-.190	.020	-9.612
	Under 60	.106	.020	5.356
	Under 70	.234	.021	11.402
	Under 80	.215	.023	9.353

Table 3 shows the most encompassing equation. On top of the already added demographic variables, socioeconomic and other lifestyle habits were added. Income (normalized by household size), employment status, marital status, education level, excessive alcohol consumption, smoking, exercising regularly, having insurance and controlling for having experienced happiness in the previous day were added as controls. The majority of these variables have been used in previous papers that try to explain wellbeing and are used to correct for the possible confounding factors. It is important to consider these variables and control for them as the consumption of fruits and vegetables can be highly correlated with many of these socioeconomic variables. If many of these covariates were not included, it could be argued that the relationship could be spuriously driven by omitted factors like eating healthier by becoming richer, or eating poorly due to a difficult personal situation like a divorce or becoming unemployed.

The coefficients accompanying fruit and vegetable consumption fall, but still remain meaningful and statistically significant. To put the impact into context, having daily consumption of the required amount of fruits and vegetables has a similar impact 0.183 (0.017) on life satisfaction as being married 0.221 (0.016) or exercising regularly 0.237 (0.013). Not surprisingly, a big impact on current life satisfaction is the current state of happiness. Those who claim having experienced happiness in the previous day have a life satisfaction of almost 1.1 points more than those who have not. Being unemployed -0.594 (0.034), smoking -0.298 (0.015) or using drugs on a regular basis to relax -0.234 (0.012) have a strong negative impact.

Table 3: *Number of days with 5 servings of fruits and vegetables, demographic variables and other socioeconomic controls on life satisfaction*

		B	Std. Error	t
1	(Constant)	6.489	.048	135.384

	Unemployed	-.594	.034	-17.629
	In the Labour Force	-.079	.015	-5.425
	Chronic Illness	-.305	.012	-25.337
	Married/Living together	.221	.016	13.552
	Divorced/Separated	-.107	.021	-4.973
	Widowed	-.014	.028	-.503
	High School	-.040	.016	-2.480
	Bachelor	.096	.014	6.713
	Post Graduatate	.266	.016	16.830
	Have Health Insurance	.429	.021	20.493
	Binge Drink	.017	.020	.856
	Exercise Regularly	.237	.013	18.493
	Smoke	-.298	.015	-19.495
	Experienced Happiness	1.095	.019	58.179
	Had drugs to relax	-.234	.012	-20.279

To check for robustness of the results, the same specifications were used to measure the impact of fruit and vegetable consumption on future life satisfaction evaluation. Even though the scale of the impact of fruit and vegetable consumption is smaller, it remains statistically significant and it goes in the same direction as the evaluation of current life satisfaction. Even when current life satisfaction was entered as an independent variable, the results maintained. Controlling for current satisfaction (which not surprisingly comes into the equation with a large, positive and statistically significant coefficient) a greater number of days consuming the optimal amount of servings has a greater impact on the future life evaluation score.

4. Conclusions, limitations and further discussions and policy implications

With many issue like the rise of diabetes or obesity, many laboratory and other studies have shown the two way relationship between experiences of negative affect and food consumption. People eat more and less healthy food when going through negative experiences and it is through poor eating that other diseases like obesity occur - having a negative impact on life satisfaction. This paper tried to look to the other side of the balance. Other cross-sectional research has shown that healthy eating is associated with lower lifetime prevalence of depression and anxiety (White 2013) but there is not a lot of research showing if healthy eating also has an effect on the day to day evaluation of life satisfaction. This study was meant as a start to bride this gap. This study is meant to be an assessment of whether regular healthy eating, using fruits and vegetables as a proxy, has a positive connection with individual self-measured life satisfaction. Even though no direct causality can be established, the relationship between these two variables is strong and positive, even after controlling for many possible confounding factors. This study corroborates the findings of Blanchflower and Oswald's 2012 study for the UK, and even though this pattern cannot be considered as universal, it shows that in Western developed nations fruit and vegetable consumption can be seen as a determinant of life satisfaction.

Despite the significance of the findings – healthy eating is a good investment for current and future evaluations of life satisfaction – they should be interpreted with caution due to the cross sectional nature of the dataset. Correlation does not imply causation and the lack of panel data or a long term randomized controlled trials where different levels of fruits and vegetables are the sole treatment cannot allow us to suggest that eating more fruits and vegetables will make you happier. Even though the Gallup's dataset is one of the most robust ones for the purpose, given the large amount of confounding factors that can be controlled for, any sort of suggestive causal relationship must be taken with care. A bigger, longitudinal randomized controlled trial could be a way forward, but again, this would present limitations in the implementation of its own (external situations affecting emotions and satisfaction for example could not be controlled for). Asking for more detailed food consumption habits – not just fruits and vegetables – like red meat, fish, or other foods could also help the robustness of the results.

There is relevance for policy and further research that is derived from this study. The positive relationship between healthy eating and happiness found in this study can support the current widespread view of the importance of eating fruits and vegetables on a regular basis. Governments should try to find ways of fostering this type of behaviour. However, as claimed by Graham (2008), it is not obvious that policies that are beneficial from a public health standpoint would make the majority of the population happy. Another alternative for policy, similar to what Blanchflower and Oswald propose, could be using the findings to push the medical community to continue looking for linkages between subjective wellbeing like human optimism and the presence of certain substances in the blood and brain derived from vitamins/minerals/antioxidants that come from fruits and vegetables. If a medical link can be established, the validity of this study increases substantially As for further research, trying to find the funding to have longitudinal data or an RCT could be the way forward. In the meantime, trying to replicate the findings not just with developed nations, but in a wider context for countries with different socioeconomic factors could support or dismantle the universal validity of the findings of this paper.

ABSTRACT

This study uses Gallup World Poll data to estimate the impact of food insecurity on SWB, and the extent to which it has different impacts across the world. We focus on a simple but potent food access question: “Have there been times in the past 12 months when you did not have enough money for food?” A negative answer to this question is associated with devastatingly low levels of SWB, particularly when SWB is measured asan overall life evaluation (Cantril ladder scale) and, to a lesser extent, when SWB is measured on the basis of negative experiencesin the last 24 hours. In addition we explore heterogeneity among 10 broad regions of the world, 126 countries and individuals within a multilevel framework. We identify significant heterogeneity across regions and countries, with greater impact in regions and countries with low levels of SWB. An analysis of income levels at purchasing power parity for the food insecure in different parts of the world suggests that individuals in richer areas may interpret the item in terms of general economic hardship, whereas individuals in poorer areas respond to the food insecurity question in a more literal sense. Future studies should further explain the multilevel structure identified in our exploratory analysis, particularly geographic variation in impacts of food insecurity and the extent to which this variation is due to measurement inequivalence or cultural differences.

Keywords: Food Insecurity, Subjective Well-Being, Gallup World Poll

1. Introduction

Food insecurity is a many-headed hydra that arises from a network of complex interactions between stable factors such as markets, climate, or infrastructure, and unpredictable factors such as natural disasters or wars. Likewise, the consequences of food insecurity are multi-pronged. Most research has focused on its deleterious effect on health (e.g. Olson, 1999), and the costs that negative health outcomes represents throughout an individual's lifetime, as well as society at large. Food is one of the basic needs that must be met before advancing to higher levels of self-actualization (Maslow, 1943). From the wider perspective of human motivation theory, Tay & Diener (2011) identified basic needs, including food and shelter, as a major determinant of life evaluation, even if the impact on SWB of each need was independent of whether other needs were fulfilled, in contradiction with Maslow's hierarchical model.

Even though there is a wide body of literature on the relationship between human needs and SWB, few studies to date have focused specifically on the impact of food insecurity on subjective well-being (SWB). Akpalu, Christian, & Codjoe (2015) recently conducted one such study using data from three urban poor communities in Accra – Ghana, finding a weak correlation between food security and household income. The study also found that income compensating differentials are greater for food insecure households than food secure households, suggesting that the deleterious effect of food insecurity on subjective well-being goes above and beyond the effect of poverty.

A broader study was conducted more recently by Guardiola & Rojas (2016), this time focusing on the relationship between food deprivation and SWB in Latin America. Their findings corroborate those by Akpalu et al. (2015) regarding the greater impact of food deprivation relative to income. The authors also identify several sources of heterogeneity suggesting that religion and relational goods may enhance SWB in Latin America relative to other regions, even among the food insecure. Tsai & Senah (2014) identify additional individual-level sources of heterogeneity in their sample of Ghanaian households, concluding that male heads of household give greater importance than females to usage of land, owning of livestock and amount of food spending.

The current study aims to build on these prior local and regional-level efforts, and expand them to an international level. More specifically this study aims to estimate the average global impact of food insecurity on SWB, and whether the size of this impact varies by country, age group, educational attainment and urban vs. rural setting.

2. Methods

All data come from the Gallup World Poll (GWP), a global research project conducting nationally representative surveys annually since 2006, in more than 160 countries and more than 140 languages. In most of the developing world, GWP surveys are conducted using in-person interviewing and an area sampling frame design. In the developed world, random-digit-dialling or a nationally representative list of phone numbers is used, generally including landline and mobile phones stratified by region. With some exceptions, all surveys, either telephone or face-to-face, are probability based and nationally representative of the resident non-institutionalize population aged 15 and older[1].

---

[1] See http://www.gallup.com/178667/gallup-world-poll-work.aspx for further methodological details

We consider in this study cognitive and affective measures of SWB (Diener, 2000): Life Evaluation and Experienced Well-Being. Life evaluation (LE) are measured with the Cantril Self-Anchoring Striving Scale (Cantril, 1965). The question uses a scale from 0 to 10 and asks respondents:

> *Please imagine a ladder with steps numbered from zero at the bottom to ten at the top. Suppose we say that the top of the ladder represents the best possible life for you, and the bottom of the ladder represents the worst possible life for you. On which step of the ladder would you say you personally feel you stand at this time, assuming that the higher the step the better you feel about your life, and the lower the step the worse you feel about it? Which step comes closest to the way you feel?*

Experienced Well-Being is created using experiential measures of emotions, including two positive experience questions (smile or laugh, enjoyment) and three negative experience questions (worry, sadness, anger). These measures were selected out of a larger list of affect measures in the GWP on the basis of providing the largest possible number of country/year observations while maintaining a balanced list of positive and negative measures. The questions are introduced as follows:

> *Now, please think about yesterday, from the morning until the end of the day. Think about where you were, what you were doing, who you were with, and how you felt:*

The positive affect questions are:

1. *Did you smile or laugh a lot yesterday?*
2. *Did you experience the following feelings during A LOT OF THE DAY yesterday? How about enjoyment?*

The negative affect questions are:

1. *Did you experience the following feelings during A LOT OF THE DAY yesterday? How about worry?*
2. *How about sadness?*
3. *How about anger?*

All five affect questions were dummy coded as 1 for a “Yes” answer and as 0 for “No,” “Don’t know” or “Refused” answer. The dummy-coded items were summed to obtain the overall positive and negative experiences index.

We want to estimate the effect on these two SWB measures of a simple but potent food access question: “Have there been times in the past 12 months when you did not have enough money for food?”with Yes = 1, and No/Don’t Know/No Response = 0. Food insecure households are however likely to exhibit a variety of other features that make them prone to lower SWB. They are likely to be poorer, but also to have a diminished ability to cover other human needs or have access to relational goods. An increasingly exhaustive set of covariates is used in order to control for these confounding influences. The first basic control is annual per capita household income, transformed for international comparability into international dollars adjusted for purchasing power parity. The resulting income variable was then log transformed to account for the marginal diminishing returns of income on SWB measures (e.g. Sacks, Stevenson & Wolfers, 2010).

Then universal needs are considered, as operationalized by Tay & Diener (2011), whom in turn examined needs derived from Maslow (1954), Deci and Ryan (2000), Ryff and Keyes (1995), De Charms (1968) and Csikszentmihalyi (1988). We exclude the "basic needs", which include the food security item of interest in the current study. The final list of needs include:

1. Safety and security:
   - Felt safe walking alone
   - Did not have money and/or property stolen during the past 12 months
   - Were not assaulted during the past 12 months
2. Social support and love[2]
   - Have others they can count on for help in an emergency
3. Feeling respected[3]
   - Felt they were treated with respect
4. Mastery[4]
   - Had the experience of learning something
5. Self-direction and autonomy[5]
   - Experienced freedom in life

All itemsare answered on a dichotomous yes/no scale. For the purposes of model estimation, needs were dummy coded, with yes = 1, and No/Don't Know/No Response = 0. Items available for the human needs approach represent a relatively low threshold, meaning that any one needwill be covered for most people. For this reason a second theoretical framework based on well-being domain satisfaction is considered to account for confounding variables. We use the five essential elements identified by Gallup (Rath, Harter & Harter, 2010), including the following itemsfrom the Gallup-Healthways Well-Being Index (GHWI)[6]:

1. Purpose WB
   a. Like What You Do Each Day
   b. Learn or Do Something Interesting
2. Social
   a. Someone Encourages Your Health
   b. Friends/Family Give You Positive Energy
3. Financial WB
   a. Have Enough Money
   b. Worried About Money

---

[2]Tay & Diener (2011) also include in their "Social support and love" needs the item "Experienced love yesterday", which is not available for this study's reference period.
[3]Tay & Diener (2011) also include in their "Feeling respected and pride in activities" needs the item "Were proud of something yesterday", which is not available for this study's reference period.
[4]Tay & Diener (2011) also include in their "Mastery" needs the item "Did what she or he does best at work". This item is excluded from the current study, as its inclusion would effectively eliminate from the sample those outside the employed population.
[5]Tay & Diener (2011) also include in their "Self-direction and autonomu" needs the item "Choose how their time was spent", which is not available for this study's reference period.
[6]http://www.gallup.com/poll/175694/country-varies-greatly-worldwide.aspx

   c. Feelings About Household Income[7]
4. Physical
   a. Felt Active and Productive
   b. Physical Health Near Perfect
5. Community
   a. City or Area is a Perfect Place
   b. Recognition for Improving City or Area

After eliminating cases with missing data on any of the analysis variables, the final sample includes 126 countries in 10 broad regions of the world, with a total of 120,582 individual respondents. To estimate an unbiased impact coefficient of food insecurity on SWB we follow recommendations from Ferrer-i-Carbonell & Frijters (2004) and Kristoffersen (2010), and estimate LE and AB using an OLS regression approach:

$$SWB = \beta_0 + \alpha D + \beta F + \varepsilon \quad (1)$$

Where β_0 is a constant term, D is a vector of control variables with unknown coefficients α, F is our food insecurity variablewith unknown coefficient β and ε is the unexplained part of the model. To provide a robustness check on the OLS estimates, we also estimate the effects on SWB using Propensity Score Matching (PSM), which does not require strong linearity assumptions (Rosenbaum &Rubin, 1983). We use nearest neighbor matching based on logit distance in propensity scores using R MatchIt package (Ho et al., 2004). Propensity scores are the true probability of unit i being food insecure, given covariates Di, calculated via logistic regression, where Y is a dichotomous variable which is defined as:

$$Y = \begin{cases} 1 & \textit{for those without money for food} \\ 0 & \textit{for those with money for food} \end{cases}$$

And the probability of Y =1 is given by:

$$Pr = \frac{1}{1+exp[-(\beta_0+\beta_i D_i)]} \qquad (2)$$

Where β_0 is a constant term, and D_i is a vector of covariates with unknown coefficients β_i. Using one-to-one nearest neighbor matching without replacement, the individual the food insecure group is chosen as a matching partner for an individual in the food secure group that has the closest propensity score. All impact estimations take into account the multi-stage clustered nature of the sample, including the effect of sampling design in all variance estimations using SPSS Complex Samples 18.0 with linearization via Taylor series.

Finally, this study explores heterogeneity of impacts across a typical set of demographic factors, including, gender, region, urban or rural setting, educational attainment, age, and religion. In order to

[7]Not part of the GHWI ítems, but included for its high explanatory power, see Diego-Rosell, Tortora & Bird (submitted).

account for the nested nature of the data, we turn to a multi-level modelling framework. In the interest of brevity we refer to the matrix notation suggested by Albright & Marinova (2010),

$$SWB = X\beta + Zu + \varepsilon \qquad (3)$$

where X is an nxp matrix containing fixed effects regressors, $\beta$is a vector of fixed-effects parameters, Z is an nxpmatrix of random effects regressors, u is a vector of random effects, and ε is avector of errors (p.10). All multilevel models were estimated using the xtmixed program in Stata 12.0.

3. Results

Table 1 presents the survey-weighted coefficients for "Lack of Money for Food" under a series of increasingly stringent models, starting with a bivariate regression coefficient with no controls, which is equal for all models presented, continuing with a model including log of income as a control variable, and then showing the effect of adding needs and WB domains. The PSM approach was only partially successful in eliminating differences in covariates between the food insecure and the matched food insecure group, as seen in figure 1. Differences in income remain after matching on the full set of 19 covariates (Cohen's d = 0.56), as do smaller differences in other covariates. For this reason we include a third, further stringent estimation approach that uses the propensity score matched sample, and applies the same regression controls as in the OLS model (shown as PSM +OLS on Table 1).

In spite of these highly restrictive conditions, the effect of food insecurity on SWB remains significantly different from zero at the 95% confidence level across all specifications, going in the expected direction for all three SWB outcomes. However the size of the effect varies considerably depending on the SWB outcome and model specification. The simple bivariate model with no control variables shows that being food insecure lowers life evaluation scores in a 0-10 scale by 1.43 points (t = -26.16, p<.00). This effect is reduced to -0.82 points (t = -16.84, p<.00) after controlling for income in an OLS regression, and further down to -0.75 points (t = -14.68, p<.00) in the OLS+PSM model. The most stringent specification, controlling for income, needs and WB domains in an OLS+PSM model leaves the effect at -0.33 points (t = -6.80, p<.00).

We can calculate the income compensating differentials of food insecurity, considering that the coefficient for the log of income in this same OLS+PSM model is .643 (t = -17.31, p<.00). the ratio of coefficients shows that eliminating food insecurity would have an impact equivalent to more than a half-point increase in the log of income (0.33/.643=0.52), which would be equivalent to more than a trebling of income (10**0.52=3.3). Since the average per capita income in international dollars for the food insecure was $2,680 in 2015, the effect on LE of eliminating food insecurity would be equivalent to a cash transfer of $2,680*2.3 = $6,164 to each food insecure individual, a sum that is arguably much larger than the cost of actually eliminating food insecurity in practice.

The impact of food insecurity on experienced well-being is lower than for LE. Excluding the unrealistic model with no statistical controls, effects range from a high of t = -11.25 (p<.00) to t = -2.18 (p<.05) for positive experiences. Food insecurity has a larger effect on negative experiences than on positive experiences, ranging from t = 17.07 (p<.00) to t = 8.36 (p<.05).

Let us turn now to the exploration of heterogeneity of impacts from a multilevel perspective. We are interested in identifying differences in impacts across regions, with a further analysis of urban/ rural, age, education and gender differences in impacts within regions. For this nested modelling approach an empty, intercepts-only respondent-level model is estimated as the starting point,

$$SWB_{ij} = \beta_0 + U_{0j} + e_{ij} \qquad (4)$$

where SWB outcomes for respondent i in region j are equal to thetotal population mean β_0, plus a region-specific effect Uf or each region j, plus an individual-level error e_{ij}. The region effects U_{0j} are assumed to follow a normal distribution and center around 0, with a variance σ_{u0}^2. Individual errors follow the same assumptions and are denoted by σ_e^2.

The overall mean β_0 (across regions) is estimated as 5.52 for life evaluation, 1.40 for Positive affect and 0.80 for negative affect. The between-region variance in LEis estimated as σ_{u0}^2= 0.80, and the within-region between-individual variance is estimated as σ_e^2= 4.85, for a total variance of 0.80 + 4.85 = 5.65. The intraclass correlation coefficient (ICC) is 0.8/5.65 = 0.14, indicating that 14% of the variance in LEcan be attributed to differences between regions.Following the same calculations, ICC for positive affect is 0.05, and 0.02 for negative affect. Given the relatively low ICC for the two experienced affect variables, this study focuses on LE for the rest of the multi-level modelling exercise.

Region-level effects U_{0j} for LE and their standard errors are presented on figure 2, showing that Sub-Saharan Africa and South Asia are significantly below the overall average in Life Evaluation scores, whereas the EU+ region and the US+Canada+ Australia+New Zealand region are significantly above the overall average. In order to explore regional level variation of food security coefficients we add to equation (4)fixed effects for food security and all the individual-level covariates in the prior models, represented by two new terms, $\beta_1 F_{ij}$ and $\beta_i X_{ij}$,

$$SWB_{ij} = \beta_0 + \beta_1 F_{ij} + \beta_i X_{ij} + U_{0j} + e_{ij} \qquad (5)$$

where $\beta_1 F_{ij}$ represents a fixed coefficient for food security, and $\beta_i X_{ij}$ represents a vector of fixed coefficients β_i on covariates X_{ij} (income, needs, WB domains). We want to test the hypothesis of random food security coefficients across regions, so we add the term $U_{1j} F_{ij}$ to equation (5)

$$SWB_{ij} = \beta_0 + \beta_1 F_{ij} + \beta_i X_{ij} + U_{1j} F_{ij} + U_{0j} + e_{ij} \qquad (6)$$

where $U_{1j} F_{ij}$ represents a vector of random coefficients U_{1j} for the food security indicator F_{ij}. We can use a likelihood ratio test to test whether the food security effect varies across regions. The log-likelihood value for model (5) was -250381.64, and for model (6) was -250296.64 so the likelihood ratio test statistic is LR = 2*(-250296.64 --250381.64) = 170 with 1 degree of freedom (because there is only one parameter difference between the models), which is greater than 3.841, the 5% point of a chi-squared distribution with 1 DF[8].

The food security effect $\beta_1 F_{ij}$ for region j is estimated as -.415, and $U_{1j} F_{ij}$, the between-region variance in these slopesis estimated as .028. For the ‘average’ region we estimate that food insecurity has an impact of -.415 points in LE, with a 95% confidence interval of -.415 ± 1.96*0.08 = -0.5718 to -0.2582. The negative covariance estimate of -.010 means that regions with a high

[8]http://sites.stat.psu.edu/~mga/401/tables/Chi-square-table.pdf

intercept (above-average LE for the food secure) tend to have a lower-than-average effect. Similarly, regions with a low intercept (below-average LE for the food secure) tend to have a more marked increase in LE with food security.

Finally we want to explore whether the impact of food security varies depending on individual-level demographic factors. We continue with our model nested within regions, and add another level of nesting for country, location (urban vs. rural), gender (female vs. male), age (15-29 vs. 30+) and educational attainment (primary or less vs. higher). In order to test the need for a three-level model start with the intercept-only model

$$LE_{ijk} = \beta_{00} + U_{0j} + W_{0jk} + e_{ijk} \qquad (7)$$

where LEfor respondent i in region $j$and country $k$is equal to the total population mean β_{00}, plus a region-specific effect U for each region j, plus a country-specific effect W within each region j, plus an individual-level error e_{ijk}. ICC for country as a third-level nesting variable is 0.21, indicating that 21% of the variation in LE can be attributed to the nesting of countries within regions, with a marginal ICC of 0.10 that is exclusively attributable to the country level, above and beyond the regional effect. Marginal ICCs are also sizeable for educational attainment (0.07), but much lower for the remaining nesting variables we tested, including location (0.03), age (0.02), and gender (0.00). We thus focus on the effect of country and education for the rest of the three-level modelling exercise. We add linear fixed effects for food security and all the individual-level covariates in the prior models, so we add two new fixed terms, $\beta_1 F_{ijk}$ and$\beta_i X_{ijk}$ to equation 7, plus the term$U_{1j} F_{ij}$ for random slopes within regions.

$$LE_{ijk} = \beta_{00} + \beta_1 F_{ijk} + \beta_i X_{ijk} + U_{0j} + W_{0jk} + U_{1j} F_{ij} + e_{ijk} \qquad (8)$$

Equation (8) is equivalent to (6), which showed the significance of region-varying food security effects, but this time with the addition of country/educational effect W_{0jk}. We are interested in the hypothesis of random food security coefficients across countries within regions and across educational levels, so we add the term $U_{1jk} F_{ijk}$ to test for random slopes within countries and education levels

$$LE_{ijk} = \beta_{00} + \beta_1 F_{ijk} + \beta_i X_{ijk} + U_{0j} + W_{0jk} + U_{1j} F_{ij} + U_{1jk} F_{ijk} + e_{ijk} \qquad (9)$$

The LR test for the two equations is significant for random slopes by country (LR=167.14, p<.00, 1*df*), and by education level (LR=28.36, p<.00, 1 *df*).

4. Discussion

The impact estimates we find for food insecurity are significant across all model specifications and sizeable, particularly when considering the income compensating differentials. Our findings are consistent with prior literature, showing that the effect of food insecurity is larger than income equivalent(Guardiola & Rojas, 2016). From the perspective of SWB components, we find that food insecurity has a largest effect on life evaluations, followed by negative affect, and a relatively small effect on positive affect. This is consistent with Tay & Diener (2011), who found a similar pattern for a "Basic Needs" component including food and shelter insecurity indicators.

Our multilevel modelling results show that the impact of food security varies significantly by region, with poorer regions having a more marked increase in LE than richer regions when individuals move from being food insecure to food secure. This finding is surprising considering that our models control for income expressed in international dollars.

A potential hypothesis to explain this finding is that respondents interpret “having enough money for food” differently in different regions. As Figure 3 shows, the average income for food insecure households is, at the global level, almost 4 times lower than that of food secure households. This ratio is lower at the regional level because food insecure households are very unevenly distributed, with Sub-Saharan Africa and South Asia accounting for more than half of all food insecure households. The income ratio between food secure and food insecure households at a regional level is between 1.4 and 2.1, with the ratio increasing with the level of development of each region.

Based on a literal interpretation of our food insecurity question, we would expect that the cut-off point in income where households turn from “having enough money for food” to “not having enough money for food” would be the same in all regions, since income is adjusted for purchasing power differences across countries, and so the same level of income should be needed in all countries to achieve basic food requirements, yet individuals in richer regions have a higher income threshold for reporting food insecurity than those in poorer regions.Taking the East Asia region as an example of a rich region, average annual per capita income among those with “enough money for food” is $18,835 at PPP, compared to $9,065 for those with “Not enough money for food”. In Subsaharan Africa, average income among those with “enough money for food” is $1,791 at PPP, compared to $885 for those with “Not enough money for food”.

While the income gap between the food secure and the food insecure is consistent across all regions, it seems that “not having enough money for food” is interpreted more literally in the poorer regions, whereas it may be just an indicator of general economic hardship in richer regions. These potential measurement equivalence issues highlight the importance of valid and reliable scales of food insecurity such as the Food Insecurity Experience Scale (FIES) developed by FAO (Ballard, Kepple, & Caffier, 2013).

Our current study is not without limitations. Data availability constraints mean that some big countries had to be excluded from the sample, most notably China. Other large countries had a small number of cases (e.g. USA, n=104). Finally, while we strived to adjust our standard errors to account for the stratified clustered sample design of the GWP, the xtmixed program in Stata 12.0 does not allow for survey design adjustments, which probably results in an underestimate of standard errors for the multilevel models. Future studies should try to further explain the multilevel structure identified in our exploratory analysis, particularly variance of impacts of food security at the regional and country levels, which show the largest ICC of all the nesting variables explored.

ABSTRACT

Literature on human experience in green environments has widely demonstrated how the direct and indirect experience with nature has positive impact on individuals' well-being. Experience with nature reduces psychophysical stress, induces positive emotions and facilitates the renewal of cognitive sources providing both physical and psychological benefits. In addition, many studies on psychological restoration have shown that green spaces have a greater capacity of promoting human health and well-being than built-up areas.

With the increasing interest in the use of urban green space for promoting human health, it is interesting to gain knowledge and development on this important topic, focusing also on the related methodological issues. Indeed, perceived well-being is generally assessed indirectly and a set of proxy variables (i.e. indicators) are used to measure it, thus leading to the definition of well-being as a latent composite construct. As a novelty in the analysis concerning the relationships between perceived well-being and green environment, this study aims at investigating this issue by referring to the Partial-Least Squares Structural Equation Modelling (PLS-SEM) within the framework of Attention Restoration Theory (ART).

We selected three typologies of urban and peri-urban green spaces in Central Italy, characterized by different physical features (e.g. presence of natural and built up elements). A questionnaire including measures of length and frequency of visits, perceived restorativeness - introduced according to the ART - and self-reported benefits of the visit to the green spaces was administered *in situ* within five sites. By adopting the PLS-SEM approach, we explored the relationships between restorative components and psychological and physical self-reported well-being. PLS approach allowed us to verify also the existence of mediator effects in order to better understand these interactions.

Keywords: PLS-SEM, Well-being, Restorativeness, Urban forest

1. Introduction

Environment and environmental conditions have a significant effect on human health and quality of life (EEA 2013). Indeed, direct and indirect experience with nature have positive impacts on individuals' well-being since natural environment helps to recover psychological and physiological resources (Hartig 2004). There is a wide body of literature dealing with the effect of natural elements such as trees, woodland and green spaces on physical, psychological and social well-being (e.g. Ulrich et al. 1991, O'Brien 2005, Carrus et al. 2015; Scopelliti et al. 2016; Tomao et al., 2016). They provide empirical evidence of attention restoration and stress reduction from the experience of nature. Furthermore, some of these studies (e.g. Carrus et al. 2015) report how green spaces promote a higher level of well-being if compared to built-up areas.

The restorative effects of green areas can be assessed based on different theories, including the stress reduction theory (Ulrich et al. 1991) and the Attention Restoration Theory (ART) (Kaplan 1995). In particular, the ART proposes that regenerative environments are characterized by four components: (i) *being-away*, (ii) *extent*, (iii) *fascination*, and (iv) *compatibility* (Kaplan 1995). *Being-away* is linked to the experience of being in an environment physically different from the one of daily routine, where cognitive efforts are requested. The *extent* relates to the physical characteristics of an environment that has to be wide enough to promote exploration without cognitive effort. *Fascination* refers to regenerative aesthetic stimuli of environments. *Compatibility* is the property of places able to support individual expectations.

With the increasing interest in the use of urban green space for promoting human health, our study aims at investigating the relationships between perceived well-being and green environment by proposing a Partial-Least Squares Structural Equation Model (PLS-SEM) and distinguishing between direct and indirect effects related to physical and psychological benefits deriving from urban green space. To the best of our knowledge, this is the first study that combines these two aspects of well-being, the PLS-SEM methodological framework and the ART restorative components.

2. Research hypothesis

Bearing in mind the complexity of ART theory and by considering that the components of restorativeness can be considered as predictors of perceived well-being (Carrus et al. 2015; Tomao et al. 2016), we formulated the following Research Hypotheses (RHs):

RH1: Restorative (ART) components as well as well-being[1] (WB) can be considered as latent variables and can be measured by using manifest variables within the PLS approach.

RH2: Restorative (ART) components have a direct effect on psychological and physical WB.

RH3: Restorative (ART) components have an indirect effect on well-being deriving from visiting green areas and woodlands in urban context.

[1] In this study we refer to well-being as the overall benefits obtained while visiting urban green areas.

3. Method and model specification

3.1 Data

The exploratory study refers to a sample of 200 individuals (50% women; mean age = 41.6 years; Standard Deviation - SD = 15.4). In order to increase the range of knowledge on urban and peri-urban green areas as well as their relationships with human well-being, we selected five sites in accordance with three typologies of green spaces characterized by different physical features: a botanic garden (Rome), two urban parks in Rome (Villa Borghese and Villa Pamphili) and two peri-urban forests (the pinewood of Castelfusano - Ostia, RM - and a high forest beech stand located in Soriano nel Cimino -VT-). A total of 28 visitors in the botanical garden, 66 in the urban parks, 69 in the pinewood of Castelfusano and 37 in the beech forest in Soriano nel Cimino have been involved, requesting them to fill a questionnaire during the visit of the green area. Specific items derived from the Italian version of the Perceived Restorativeness Scale (PRS; Pasini et al. 2009) were included in the questionnaire as manifest variables for measuring restorative components. Specific questions aimed at measuring psychological and physical benefits while visiting study sites were included according to Carrus et al. (2015). All variables were measured through a 5-point scale ranging from 1 to 5.

3.2. Modelling FW within the PLS-SEM approach

According to the ART framework, we modelled perceived subjective well-being and restorative components of green areas by referring to the PLS–SEM approach.

The PLS path modelling is a variance-based technique recommended during the first stages of research in order to test and validate exploratory models, especially when variables cannot be easily determined or measured directly. These types of models well fit human (subjective) well-being whose measurement is generally obtained indirectly by means of data gathered using questionnaires.

A PLS path model consists in two components (Hair et al. 2014). The first is a structural model (the inner model) which illustrates the specified constructs and focuses on the relationships (paths) between them. The second is the measurement models (the outer models), that shows the relationships between the constructs and the indicators also known as manifest variables. Furthermore, while structural and measurement models are present in all types of SEMs with latent constructs, the weighting scheme represents the third specific component of the PLS approach (Monecke and Leisch 2012) and is used for estimating the inner weights linking latent constructs. Table 1 illustrates the Latent Variables (LVs) of the specified structural model (first column) and the related indicators used in the measurement model (second column).

Table 1: *Latent variables and manifest variables*

LATENT VARIABLE	MANIFEST VARIABLES
COMPATIBILITY	Q1. Being in this place is in accordance with my personal interests Q2. In this place it is easy to do what I want
BEING AWAY	Q3. Spending the time here allows me to distance myself from my daily routine Q4. In this place I can run away from the things that usually require my attention
FASCINATION	Q5 This place is fascinating Q6 There is much to explore and discover in this place
EXTENT	Q7 It's like this place had no boundaries Q8 There is a clear order in the physical layout of this place
PSYCHOLOGIAL WELL-BEING	Q9 Do you feel psychological benefits during the visit to this place? Q10 Do you think you will feel psychological benefits during the visit to this place?
PSYSYCAL WELL-BEING	Q11 Do you feel physical benefits during the visit to this place? Q12 Do you think you will feel physical benefits during the visit to this place?
WELL-BEING	Q13 How much do visiting this place make you feel better than before? Q14 After visiting this place, how much do you believe you will feel better if compared to how you usually feel?

In our model *Compatibility*, *Being away*, *Fascination* and *Extent* are exogenous LVs since they do not have any predecessor in the structural models while the other three LVs (psychological, physical WB and well-being) are specified as endogenous LVs. Figure 1 illustrates the structural model specified in our analysis and the relationships between the latent variables.
Figure 2 reports the complete (inner and outer components) specified model, which reflects the RHs. In order to test this model we used SmartPLS 3 software and applied the path-weighting scheme.

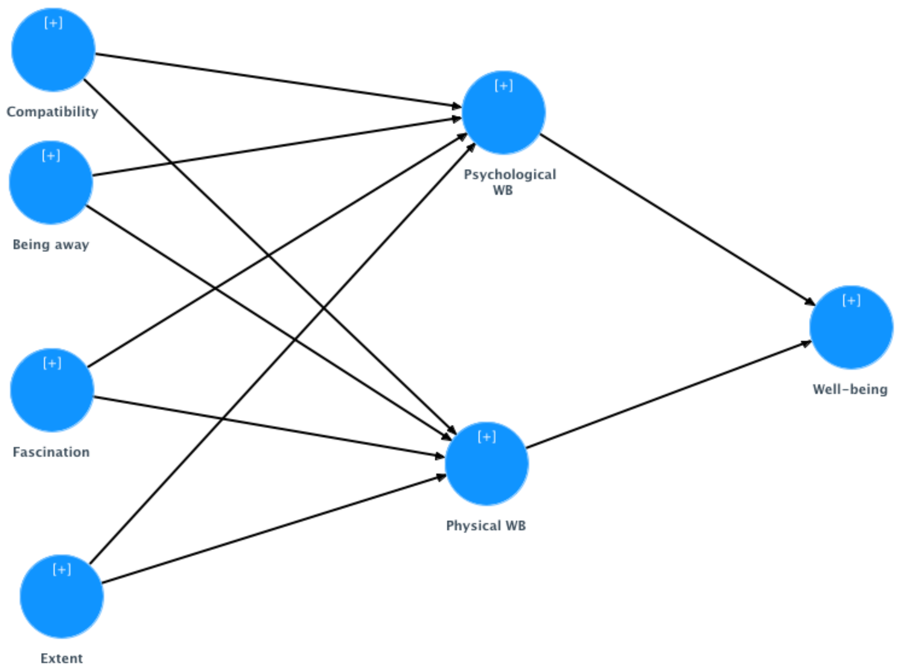

Figure 1: *The specified structural (inner) model*

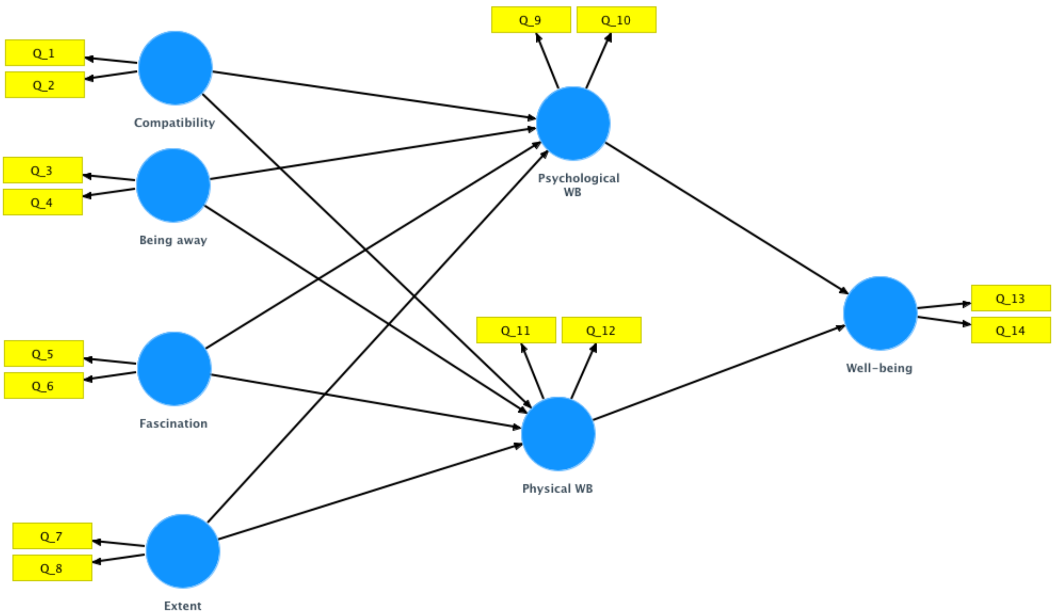

Figure 2: *The specified inner and outer models*

3. Results

The analysis of results was carried out by following recent guidelines for PLS-SEM by Hair et al. (2014). Firstly, we examined the measurement models by evaluating item and construct reliability as well as convergent and discriminant validity of the constructs. Secondly, we evaluated the structural model by verifying its ability to predict the endogenous constructs in terms of goodness of fit, cross-validated redundancy and path coefficients. Once the validity of the models was assessed, we analyzed estimated direct and indirect effects.

The reflective measurement models were evaluated for reliability and validity. Item reliability of our model is higher than 0.7 in almost all of the cases. Only two items (Q2, Q8) have outer loadings between 0.55 and 0.7. However, the Average Variance Extracted (AVE) values, defined as the grand mean of the squared loadings of the indicators associated with the construct, are higher than 0.5 for all the LVs, indicating convergent validity for all the constructs. Composite reliabilities for the 7 constructs range between 0.72 to 0.95, satisfying the requirements suggested by Hair et al. (2014). The values of Variance Inflation Factors (VIFs) are lower than 10 for all the constructs, demonstrating that our structural model results are not affected by collinearity.

Table 2 shows the results concerning the coefficients describing the relationships between latent variables (standard errors were obtained from bootstrap).

The results of direct structural relationships reveal that four out of the ten relationships hypothesized are statistically significant at 1% level (p-value<0.01) and two of them are statistically significant at 5% level (p-value<0.05). In particular, restoration components - except for *extent* - have a direct and positive effect on psychological WB. On the other hand, only *compatibility* has a direct effect on Physical WB. Both psychological and physical WB show a positive and highly significant effect on well-being.

Besides, direct effects on both physical and psychological WB, restorative components – and specifically compatibility, fascination and being away – proved to have indirect significant effects on well-being via both psychological and physical WB.

Table 2: *Estimated direct, indirect and total effects*

	Direct effects		Indirect effects		Total effects	
	Estimate	Sign	Estimate	Sign	Estimate	Sign
Being away -> Psychological WB	0.227	***			0.227	***

4. Discussion and concluding remarks

Findings of this study support the evidence emerged from other studies that mental and physical benefits can be obtained by visiting urban and peri-urban green areas (Hartig 2004; Carrus et al. 2015; Tomao et al. 2016).

We applied PLS-SEM models to self-reported well-being considering it as a latent variable (RH1). Results on item reliability showed how subjective well-being as well as restorative components can be estimated by the selected proxy variables as well path-modelling can be considered as an appropriate framework for linking well-being and ART components. This evidence also confirms that the manifest variables identified by the Italian version of the PRS (Pasini et al. 2009) can be successfully used to evaluate restorativeness, even using PLS procedures.

Our results show that all the intrinsic restoration properties of the green areas have a positive and direct effect on both psychological and physical WB (RH2), even if *extent* is not statistically significant. This evidence highlights how components of restorativeness can be considered as important predictors of well-being, confirming the findings of other previous studies (e.g. Carrus et al., 2015; Marselle et al. 2016; Tomao et al., 2016). On the other hand, the dimensions of green areas, wide enough to capture the individuals' attention, seem to have a more marginal role in well-being perception. This is probably due to the perception, in many cases, of the so called "grey infrastructure" elements (buildings, roads, etc.), that can be seen outside, but also from inside the boundaries of the green areas.

Compatibility has been the only one component having a significant influence on both psychological and physical WB. It also showed a highly significant indirect effect on overall well-being (RH3), suggesting that the characteristics of places able to support individual expectations are very good predictors of well-being and for this reason should be considered in managing and designing public green areas.

Our preliminary and explorative results represent a good starting point for deeper analysis, required to better understand the complex issue of well-being evaluation. In particular, an interesting improvement can be the evaluation of the effect of the "site quality" on well-being perception, for example by comparing scores of latent variables obtained for each green area. Moreover, variables related to the demographic and economic characteristics of the users of green areas could be also introduced in the model in order to verify if and to what extent context variables may affect directly or indirectly perceived well-being.

ABSTRACT

Reliably measuring food security (FS) is of paramount interest today, as food insecurity plagues individuals even in those countries with a surplus in food supplies. With GDP as an indicator of society's progress proves embattled, well-being indicators such as life evaluation (LE) have edged in to affect (inter)national policy formulation. Numerous studies show females are over-represented among the global food insecure (FI) population, however little research has examined if FS affects men and women's reported LE, and if this effect differs by region and food insecurity severity. The exploratory nature of this paper seeks to analyze whether gender is a global risk factor for experiencing mild, moderate, or severe FI, and to explore how the effect of FI on LE may be more pronounced by severity of FI, and if this association is moderated by gender. Through a collaboration with FAO, this study utilizes data collected through the Gallup World Poll® (GWP), which has included the Food Insecurity Experience Scale (FIES) since 2014. The FIES is an eight-item scale, with the current paper categorizing respondents as FS (zero affirmative responses), mildly FI (1-3), moderately FI (4-6), or severely FI (7-8). A single GWP question (adapted from Cantril's Self-Anchoring Striving Scale) comprises the LE variable, with possible answers ranging 0 to 10, with '0' signifying worst possible life, and '10' signifying best. A multivariate logistic regression model was estimated to examine the likelihood of reporting lower LE based on gender, food insecurity severity and region. Results using 2014 cross-sectional data from 148 countries shows that 45.5% of the population was FI. Of this total, 19.3% were mildly FI, 12.6% moderately FI, and 13.6% severely FI. Significantly more women were found to be mildly, moderately, and severely FI (52.6%, 52.7% and 52.6%, respectfully) than men. Those who were categorized in any FI severity showed significantly lower odds of rating "best possible" LE compared to FS counterparts, with severely FI individuals least likely to rate "best possible" LE (OR: 0.08, 95% CI= 0.07-0.09). Globally, women are less likely than men to rate "worst possible" LE, while simultaneously being significantly more likely than men to experience any level of food insecurity.

Women had consistently higher mean LE responses compared to men at the FS, mild FI, and moderate FI levels, but severe FI level showed nearly equal LE responses between genders. The novel finding that men and women's average LE responses balance only at the severely FI severity points to identifying these factors as crucial for understanding how FI is experienced differently by men and women before FI reaches its most severe level. The need for reliable measurement is evident, and requires a change in methodological approach to ensure both men and women benefit from policy and programmes to address food insecurity.

1. Background

Although it has been widely accepted that there is enough food produced globally to meet the world's population needs (WFP, 2011), no country can claim complete food security (FS) for each of its citizens. The 1996 World Food Summit established the currently most cited definition of FS as, "..when all people, at all times, have physical, social and economic access to sufficient, safe and nutritious food which meets their dietary needs and food preferences for an active and healthy life," (Food and Agriculture Organization of the United Nations, 1996). The exact number of FI individuals, and the extent to which they suffer, remains unspecified within countries (Cafiero et al., 2014), as currently there is no "gold standard" for measuring FI (Coates et al., 2006) but rather an array of measurement instruments exist and are needed to monitor the multiple dimensions of FI.

The need to measure FS deeper than national level has driven an increased use of population surveys that can better reflect direct evaluations of a household or individual's access to food (Cafiero et al., 2014). Experience-based food insecurity scales, such as the U.S. Household Food Security Survey Module (USDA, 2014), the Household Food Insecurity Access Scale (Coates et al., 2007), and the harmonized Latin American and Caribbean Food Security Scale – ELCSA (Pérez-Escamilla et al., 2007), served as models for the creation of the Food Insecurity Experience Scale (FIES) developed by FAO's Voices of the Hungry1 (VoH) project in 2013.

[1] http://www.fao.org/in-action/voices-of-the-hungry/

The unique contribution of experience-based FI scales is the ability to capture psychosocial aspects, such as anxiety or uncertainty, as well as behaviors relating to the ability to procure enough food at the individual level. The FIES is based on the premise that the evidence of universal dimensions of experienced FI (Swindale, A. & Bilinsky, P., 2006), as well as accumulated research showing the cross-cultural validity and applicability of previous measures, support the use of a standardized measure enabling international comparisons. The FIES is a psychometric scale similar to other widely accepted scales measuring unobservable traits, such as intelligence and depression. Brunelli's 2014 analysis explored if the eight FIES items worked similarly between men and women, as significant discrepancies in item severity could imply the existence of a gender-based difference in the interpretation of that item. Only one item out of the eight item FIES scale was found to have statistically meaningful Wald test p-values that differed between genders, the question being, "...hungry but did not eat because there was not enough money or other resources for food," (Brunelli et al., 2014). Comparability of FIES results across countries was achieved through the Item Response Theory (IRT) models (Nord, 2014; Brunelli et al., 2014). The FIES was constructed using the One Parameter Logistics Model (or Rasch Model) based on IRT. When the model is applied to FI measurement, the probability that a respondent with FI responds positively to a scale item characterized by severity level can be modeled as a logistic function of the distance between these two aspects (Brunelli et al., 2014). This provides a theoretical base and a set of statistical tools that can assess the suitability of a set of questions for constructing a scale, and then compare the performance of the scale in various populations and survey contexts (Nord, 2014).

Globally, women face weaker decision-making within the household, observe differential feeding and caregiving which favor boys and men, and poorer health and nutrition outcomes compared to male counterparts (Asian Development Bank, 2013). Studies show that women in South Asia are served and often eat after other household members, and are less likely than men in the same household to consume preferred foods such as meats and fish, which are often the most nutrient-dense (Brown et al., 2008). Brown et al (2008) also found that during times of crisis in low income countries, women and girls are often expected or forced to reduce their intake of higher quality foods or total food quantity in favor of male household members. NHANES datasets from 2001-2008 show intra-household differences in FS, consistent with concurrent literature: US women were more likely to experience FI than US men of similar age in households with the same FI and income (Nord, 2011). Through psychology, economy, public polling, sociology, and other fields, well-being as a subjective experience has been objectively measured, assessed, correlated with observable brain functions, and shown to reliably reflected the characteristics of individuals and societies (Helliwell et al., 2012). While objective metrics such as life expectancy at birth, diabetes prevalence, and gross domestic product have been used to assess overall wellbeing at the national level for decades (Drewnowski & Popkin, 1997), the 2012 World Happiness Report concluded that measures of subjective well-being provide an alternative yardstick of progress that is grounded in people's experiences, oftentimes differing from other important, conventional metrics that focus on access to resources (Helliwell et al., 2012). This disparity is desirable, as it offers nuanced evidence apart from the economic and social indicators such as income or employment typically used to assess a person's well-being. Hadley Cantril's "Self-Anchoring Striving Scale" is a prominent and widely accepted indicator of LE, which asks respondents their perceptions of where they stand on a hypothetical vertical ladder (Cantril H, 1977). It was concluded that the Cantril Ladder was a pure measure of LE, with Kahneman and Deaton (2010) considering the Cantril Ladder a serious global contender for the best tool for measuring the degree to which individuals view themselves as achieving their overall goals. Currently the Cantril Ladder covers the widest span of countries of any well-being indicator (Helliwell et al., 2012). At the group or national level, reliability is very high for measures such as the Cantril Ladder, due to individual-level random variations and personality fluctuations being averaged away, and underlying circumstances that may change from year to year changing modestly over longer time frames (Blanchflower et al., 2004;

Helliwell et al., 2012). Revised Cantril LE measures carried out using the individual as unit of analysis show that in most high-income countries, women report higher LE than men (Helliwell et al., 2012). When comparing men and women's LE over time, women's well-being ratings do not increase as consistently as those of men (Blanchflower, 2008). Where women report higher life satisfaction than men, all other factors equal, women report more psychological stress and mental illness than men, too (NolenHoeksema et al., 1999).

1.2 Study Rationale and Objectives

Measuring LE in conjunction with FS can offer invaluable information about a society's resiliency and social protection networks, or even signals of underlying crises to come. Assessed at the individual level, measuring LE alongside FS can foster a more complex understanding of the way men and women may have different experiences between and within FI severities.

This exploratory paper seeks to analyze whether gender is a global risk factor for experiencing mild, moderate, or severe FI. The secondary objective is to explore how the effect of FI on LE may be more pronounced by severity of FI, and if this association is moderated by gender.

2. Methods

This quantitative study uses a cross-sectional survey design, conducted through a collaboration with the co-authors as well as the VoH team at FAO, which holds the data license. With few exceptions, all samples used by the GWP are probability-based and nationally representative of the resident population, beginning at age 15. Each country surveyed is covered entirely within sampling, including rural areas. Random respondent selection is achieved by using either the latest birthday or Kish grid method. The GWP uses a standard set of core questions that have been translated into the major languages of the respective country. Data were analyzed using IBM® SPSS® Complex Samples version 21, to improve the validity of statistical inferences by accounting for sample design in survey data analysis. Sampling weights were provided by Gallup. Using only year 2014 dataset, 148 countries with 153,209 respondents comprise the present study.

The FIES comprises the FI indicator, incorporated into the GWP in 2014. The FIES consists of eight questions worded to be as concise and universally relevant as possible. The GWP aims to ensure that the questions, as formulated in the language of administration, faithfully capture the concepts underlying the FI scale. To obtain prevalence rates that are comparable across the large number of countries, the FIES global standard scale is defined as a set of item parameters based on the results from application of the FIES in all countries covered by the 2014 GWP survey. By calibrating each country's scale against the FIES global standard, the respondent severity parameters obtained in each country are effectively adjusted to a common metric, thus allowing the production of comparable measures of severity for respondents in all countries (FAO, 2016).

Respondents were categorized based on the individual's sum of affirmatively answered FIES questions (raw score), a characterization developed in collaboration with the VoH team. Those responding "no" to all eight FIES questions (raw score of zero), are classified as "FS". Those with 1-3 raw score were classified as "mildly FI", 4-6 as "moderately FI", 7-8 as "severely FI".

The LE indicator is adapted from the Cantril Ladder measure, administered in the GWP Core Questionnaire: "Please imagine a ladder with steps numbered from 0 at the bottom to 10 at the top. The top of the ladder represents the best possible life for you and the bottom of the ladder represents the worst possible life for you. On which step of the ladder would you say you personally feel you stand at this time, assuming that the higher the step the better you feel about your life?"

3. Results

50.9% of the total sample (81,528 unweighted count) was female. Of the total sample, 54.5% were found to be FS, 19.3% mildly FI, 12.6% moderately FI, and 13.6% severely FI. Over half of all severely FI respondents reside in Sub-Saharan Africa (58.4%), with this region holding the highest proportion of moderately (33.8%) and severely (22.9%) FI individuals of any region. Europe and Asia had the highest proportions of FS individuals at 75.5% and 65.8% respectively, although Asia's severely FI proportion (6.7%) was nearly double Europe's (3.6%). LE responses follow a Gaussian distribution centering at "5", typically found when using Cantril Ladder item variations. More women reported a LE rating of 8, 9 and 10 than men (11.5 vs 11.2%, 4.3 vs 4.2%, and 5.3 vs. 4.6%). Significantly more women were found to be mildly, moderately, and severely FI (52.6%, 52.7% and 52.6%, respectfully) than men (Table 2), hence proportionally more women (47.1%) than men (43.9%) categorized with any level of FI. 14.1% of all women were categorized severely FI, a statistically significant find, versus 13.1% of all men. Without using Complex Sample calculation (Table 3), women consistently had a higher mean LE response than men did at the FS, mild FI, and moderate FI levels. Only at the severe FI level do LE responses even off between genders. Of the total population who rated their LE "worst possible", 46.1% were severely FI (Table 4). This is compared to those who rated LE "best possible", where 10.4% were severely FI.

Table 1: *Region Frequencies*

Region	Frequency	%	Food insecurity			
			FS	Mild FI	Mod FI	Severe FI
Europe	34,051	22.2	75.5	14.6	6.3	3.6

Table 5: *Prevalence of "worst possible" life evaluation for each food insecurity by gender*

"Worst possible" life evaluation	Food insecurity							
	FS	95% CI	Mild FI	95% CI	Mod FI	95% CI	Severe FI	95% CI
Men	18.0	16.1-19.9	18.2	16.3-20.2	19.9	18.0-21.9	43.9	41.5-46.4
Women	15.0	13.4-16.8	14.8	13.1-16.5	22.1	20.2-24.2	48.1	45.8-50.5

p value <0.001

Of the total number of women who rated LE as "worst possible" (Table 5), 15% were FS (versus 18% of men). 48.1% of women who rated "worst possible" LE were severely FI, higher than their severely FI male counterparts (43.9%) though CI ranges slightly overlap. Women were significantly more likely than men to rate LE > 5, notably "best possible" (OR: 1.36, 95% CI= 1.24-1.50). The likelihood of rating LE as "best possible" significantly declines as FI severity increases (compared to FS), controlling for gender, income, region, marital status and education (Table 7).

Table 6: *Association between women and LE*

Life evaluation	OR	95% CI
1	.983	.890-1.086
2	.988	.903-1.080
3	.990	.911-1.075

Severe FI vs. FS	.079	.068-.091

p value <0.001

4. Discussion

These findings are consistent with recent literature on gender disparities in FI, while enriching this body of knowledge with the current findings of women more likely to be FI at each severity level. Men and women who rated their LE as “worst possible” experienced different FI severities, with proportionally more FS and mildly FI men, and proportionally more moderately and severely FI women. Globally, women are less likely than men to rate “worst possible” LE, while simultaneously being significantly more likely than men to experience any level of food insecurity. This study cannot infer what factors, and to what extent, influence women’s higher mean LE. However, the novel finding that men and women’s mean LE responses balance only at the severely FI severity points to the need for identifying these influences before FI reaches its most severe level. Women’s higher likelihood of any FI is interlinked with their globally limited access to education and employment opportunities (Asian Development Bank, 2013). These barriers affect not only individual FS, but household members who depended on that woman for income or food.

This analysis supports Brunelli et al. (2014) and others in the appeal for studying FS at the individual level to better explore differences in how FI may affect other aspects of a person’s life, and how these differences can be seen between the genders. This paper views surveys as a useful method for studying LE, as they allow a direct and easily administered measure where people can report on their own perceived LE (Helliwell et al., 2012), as well as implement well-being and FS assessments in unison to understand how FI affects LE in specific economic and social contexts. The need for reliable measurement is evident, and requires a re-structuring of food security monitoring at individual level, to ensure both men and women are adequately benefiting from FS policy and programmes. Further research is necessary to explore why LE is viewed differently by men and women and what nutritional and well-being consequences result.

ACKNOWLEDGMENTS

The authors acknowledge the opportunity to collaborate with the VoH team in their development and use of the FIES, and in their supportive role as license holders of Gallup datasets.

The authors are also grateful to Gallup for access to data from the 2014 Gallup World Poll.

USE OF ADMINISTRATIVE DATA FOR AGRICULTURAL STATISTICS

Session Organizer
N. Keita | FAO | Rome | Italy

ABSTRACT

A large proportion of the data being currently produced in developing countries comes from administrative sources, mainly as a by-product of activities of extension workers and other administrative processes and this situation is likely to stay for a long time because of resource and capacity limitations in many of these countries to conduct proper sample surveys. Also because of the growing need for very low geographical level data and for early warning and pre-harvest crop forecasting data to inform governments on the prospective food situation which is mainly derived from crop monitoring and other auxiliary information produced by field staff. Furthermore, data on livestock, fishery, forestry, land and water is usually derived from administrative reports prepared by subject matter specialists. In developed countries, budget restrictions, respondent burden and availability of new tools and methods are prompting many countries and institutions to undertake research in new ways of producing agricultural statistics with a more important role of administrativesources. However, several studies have underlined the limitations of data from administrative sources in terms of their low quality for a number of technical reasons. This session will present and discuss findings from research undertaken on the improvement and use improvement and of administrative data for a cost effective agricultural statistics system both in developing country and developed country context. Papers can focus on successful research or implementation of methods and tools for use of administrative data in agricultural statistics in a country.

ABSTRACT

One of the key priorities of the Research Plan of the Global Strategy to Improve Agriculture and Rural Statistics is "Improving the methodology for using administrative data in agricultural statistics" (World Bank, 2010).The School of Statistics and Planning of Makerere University, Uganda (SSP) and the Center for Survey Statistics and Methodology of Iowa State University, USA (ISU), were engaged by FAO in a collaborative research effort with the aim of developing strategies and methodologies for improving the collection and management of data from administrative sources and of their use in an integrated agricultural statistics system in developing countries.

Literature shows that statistics agencies in developed countries have done a lot of research in this area especially with regards to uses of administrative records. On the other hand, the review on developing countries shows that despite questionable agricultural administrative data quality, many countries are collecting and using administrative data. Administrative data requires fewer resources and therefore a more sustainable source. These sources also provide high frequency data and can better generate small area statistics and data on rare commodities based on technical and cost considerations. However, while administrative data may be of acceptable quality for executing administrative functions, concerns have been raised regarding performance and infrastructural issues identified in the gap analysis need to be resolved before data its quality for official purposes especially in developing countries. A comprehensive analytical framework using a structure, conduct and performance paradigm was used to review the administrative sources in terms of production, quality and use of this data; to identify strengths, weaknesses and suitability of the existing agricultural data systems and review and analyze gaps. The structural, conduct, performance and infrastructural issues identified in the gap analysis need to be resolved before data from this source can be integrated in the agricultural statistics system. The field tests have made an attempt to address these issues. Findings from the pilot are given.

Keywords: Sources, Quality, Methodology, Experiences

1. Introduction

The Global Strategy to Improve Agriculture and Rural Statistics adopted by the United Nations Statistical Commission in 2010 aims to improve statistics in agriculture, livestock, aquaculture and agro-forestry production in developing countries and ensure sustainability of their maintenance. One of the key components of the Global Action Plan is its Research Plan whose priorities include "Improving the methodology for using administrative data in agricultural statistics" (World Bank, *2010*).

The major objective of the research is to improve the quality and use of administrative data. It aims at developing strategies and methodologies for improving the collection and management of agricultural data from administrative sources and of their use in an integrated agricultural statistics system in developing countries. The expected primary products of this research include (i) a technical report that includes a country-tested and validated methodology to improve and make available administrative data for producing agricultural statistics and (ii) a proposed strategy on how to use administrative data in cost effective agricultural statistics systems.

A number of definitions of administrative data have been made, including Brackstone (1987), Pronab (undated), UN (2011). However, the working definition of administrative data for this research is *"information collected primarily for administrative (not statistical) purposes by government departments and other organisations usually during the delivery of a service or for the purposes of registration, record keeping or documentation of a transaction (Administrative Data Liaison Service UK, 2015).* This involves routine data collected by agricultural extension workers/chiefs and includes data from farm assistance programs, cattle tracing, veterinary visits and farm inspections; farmers' associations; farm transactions; agricultural inputs dealers, parastatals, etc.

A four-step approach was proposed for this research, namely,

(i) a thorough review on the quality and use of administrative data to improve agricultural statistics in developed countries;
(ii) an analysis of the country assessment surveys and other documentation to identify methodological issues in using administrative data in developing countries;
(iii) based on the findings in (i) and (ii) and experiences in developed countries, develop a general methodology for integrating administrative data and other sources of auxiliary information with survey data as part of an integrated national statistical system;
(iv) three developing countries selected for in-country testing to validate and improve the methodology developed in (iii), after which final guidelines for developing countries to integrate administrative data into agricultural statistics would be produced.

2. Methodology of analysis

The work so far has involved the analysis of (i) **Country assessments reports** with information on the main sources of core agricultural data (Africa and Asia-Pacific regions); (ii) **Literature review** of research activities, empirical studies and country experiences on the sources, production, quality and use of administrative sources for statistical purposes in developing countries; (iii) **Key informant interviews;** (iv) Responses from a **questionnaire** administered to the National Statistical Offices (NSOs) in Africa during the Africa Symposium for Statistical Development held in January 2015, in Uganda; (v) **further analysis** of the data for Africa and the Asia Pacific region assessments (FAO, 2015c); **gaps**; and **in-country testing** in three selected developing countries.

A review of the analytical framework for assessment of Agricultural Market Information Systems developed by Kizito (2011) showed that it is comprehensive and can be used for review of other systems' structure, conduct and performance. The framework was modified for the purpose of assessing the Administrative Data Systems for Agricultural Statistics (ADSAS) in countries.

3. Findings from the Literature Review and the Gap Analysis

3.1 Benefits of Administrative Data

Administrative data is cheaper to use, reduces response burden and improves public image of the NSOs. They can be collected more frequently, are more timely and up to date, can cover the whole target population. Indeed, in many developing countries; it is the only data available-especially for lower level administrative units and rare commodities. Finally, administrative data can also help the NSOs cope with their mandate despite budget limitations.

3.2 Sources of Agricultural Administrative Data

Sources of administrative data identified which have application to agricultural statistics, include: Regular returns/reports by agricultural field/extension staff, agricultural production and inputs manufacturers and distributors, farmers' associations, private businesses data, meteorological data, parastatals handling the major commercial/cash crops and traceability data (e.g. traceability livestock data). Tax data, land ownership records, farm registers and other registration or licensing systems are potential sources of this data but are rarely used in developing countries because of quality and coverage issues. Most of the institutions producing agricultural administrative data are public/government but there is also a lot of potential for the private sector, farmers' and traders' organizations as well as agricultural research organizations.

3.3 Uses of Administrative Data

Common uses to which administrative data is put in developed and developing countries included: sampling frame construction and sample design; covering data gaps from surveys and censuses; forecasting, planning, provision of small area estimates and administrative uses including policy and decision making. While developed countries tended to use scientific approaches for adjusting or improving administrative data before use, developing countries tended to use simpler subjective methods like expert opinion, screen surveys, eye estimation etc. The experiences of developed countries in the use of administrative data therefore give important lessons for developing countries (FAO, 2015a, b).

3.4 Data Processing and Accessibility to Administrative Data

A lot of data from this source remain in raw form and are not turned into usable information in developing countries. Apart from exports and imports as well as agricultural price information which are often published widely, like data from other sources, a lot of other agricultural administrative data are not widely disseminated for use as it is not fully analysed. Data dissemination is often limited to office reports and workshops.

3.5 Data Quality:

Assessment of the quality of administrative data is subjective in most developing countries and the assessments are not detailed enough to cover the different quality dimensions; yet the appropriate form of quality analysis depends on the intended use of the administrative data. Much of the agricultural administrative data is usually collected and compiled without using standard statistical procedures or personnel with training in statistical methods. Documentation of administrative data collection and processing methodologies as well as agricultural data quality parameters is also poorly done.

3.6 Institutional and Organisational Capacity

As a result of decentralization in most developing countries, there are more lower reporting levels, most of which have limited capacity, leading to delayed information flow. Data is often only collected intermittently. There are also frequent institutional changes in the administrative units. Operational constraints make it difficult for extension staff or chiefs in some cases, to cover their areas of jurisdiction to collect data. They have several other responsibilities and are not, normally, and legally under the statistics authorities. Agricultural returns by agricultural extension staff are based on non-standard data collection forms which can lead to reporting errors and inconsistencies. Sadly, in some cases there are even no standard reporting formats.

3.7 Summary of Potential Limitations in the Use of Administrative Data

Limitations of administrative data in developing countries include: Changes in administrative processes leading to inconsistencies in estimates across time, or reduced data availability; non-standard definitions of variables, units and identifiers making synthesis of multiple sources a challenge; under-coverage; reporting errors; and the challenge of maintaining confidentiality. Other challenges include: The NSOs using administrative data source for a purpose different from the one for which the data was originally collected; limited involvement of the NSOs in data collection and analysis; access problems including legal restrictions, policy considerations, organizational arrangements and technical standards; and diverse sources for the same data with undocumented methods leading to conflicting estimates. Reduced contact of the public with the NSOs, timeliness, missing data, and resistance to change are the other limitations.

3.8 Gap Analysis

A gap analysis was carried out (See Table 1) in order to identify areas of possible methodological improvement and solutions for using administrative data in an integrated agricultural statistics system (FAO, 2015d).

Table 1: Gaps Identified and Proposed Solutions to Fill the Gaps

<table>
<tr><th></th><th>COMPONENT</th><th>GAPS</th><th>PROPOSED SOLUTIONS</th></tr>
<tr><td>1.</td><td>Administrative Data Collection and Management</td><td>• Divergence in figures from different sources on the same data item – lack of consistency, coherence and comparability.
• Missing data.
• Poor application of statistical standards and methods.
• Limited use of ICT for data collection and management.
• Use of non-uniform formats across different administrative units.
• Poor data collection tools – questionnaires and manuals.
• Subjective reporting of crop area, production, forecasts of production and yield.</td><td rowspan="2">• Set up a robust Routine Agricultural Administrative data system linked to other agricultural statistics sub systems.
• Produce a comprehensive administrative data systems manual with proper guidelines covering all aspects of the data collection and management system.
• Improve specificity of definitions.
• Standardize data collection instruments.
• Support field supervision on a regular basis. Best practice from India: The Improvement of Crop Statistics (ICS) to supervise data collection and verify the accuracy of the data collected. The Timely Reporting Scheme (ITS) to improve the timeliness of the data (Ministry of Statistics and programme Implementation, India, Undated).
• Introduce and enhance use of modern technologies e.g. GPS tools, mobile phones, PDAs, scanners, etc.
• Train and equip staff to use modern technologies for data collection and management.
• Learning from best practice of other countries.
• Developing protocols for metadata documentation and for correcting data inconsistencies.
• All Agricultural Administrative units should have at least one statistician as part of their staff team.
• Establishment of a Technical Working Group to monitor the process of administrative data production.</td></tr>
<tr><td>2.</td><td>Structure of Organisations Collecting Administrative Agricultural Data</td><td>• Failure to sustain good data collection systems.
• Many & frequent changes in the administrative structure that affect data collection and management.</td></tr>
</table>

	COMPONENT	GAPS	PROPOSED SOLUTIONS
3.	Coordination and Supervision	• Poor coordination or lack of co-ordination between the NSO and the various administrative agricultural data collection and management institutions. • Inadequate statistical infrastructure • Field staff often not well supervised. .	• Establish legal frameworks that support good coordination between the NSO and other players managing administrative agricultural data. • Put in place or improve MoUs to facilitate data sharing. • Best Practice – India: Well established countrywide infrastructure; a permanent village reporting agency (Ministry of Statistics and programme Implementation, India, Undated). .
4.	Human Resource / Incentives to ADSAS staff	• Lack of qualified staff & low staff retention mainly due to poor working conditions. • Poor incentive structures among employees. • High Rate of staff attrition of trained and experienced staff from the government service. • Regular training is not common in most countries. • Extension staff who often collect the administrative agricultural data have many other functions.	• Assess human resource and training needs to identify basic skills requirements. • Improve terms of service. • Incorporate finances required to recruit and train staff into the national budget and those of MDAs, including local governments. • Reduce overlap; streamline activities to clearly make data collection part of the job description. • Training Best Practice: Tanzania Agricultural Routine Data System (ARDS) on: ➢ the common reporting formats, ➢ the Village/Ward data collection format, ➢ data management, ➢ data handling and analysis at district level.
5.	Quality Control Procedures	• Quality assessments for agricultural administrative data systems in developing countries are rarely done. • Most ADSAS in developing countries do not put emphasis on documenting agricultural data quality parameters, and where they exist, they are subjective.	• Set up a Technical Working Group to ensure quality control measures and data validation mechanism/processes are put in place and adhered to. • Determine the data quality dimensions that are more relevant for assessing quality of administrative data. • Develop quantitative indicators of the relevant quality dimensions.
6.	Institutional Capacity	• No interface for dialogue between data producers and users. • Where they exist, channels of communications are not well set up and/or not regularly used as required leading to weak data relevance. • One third (30%) of the African countries for example operate below average of the expected level of the primary institutional infrastructure to produce agricultural statistics (AfDB, 2014).	• The interface for dialogue between data producers and users should be set up where they do not exist and strengthened where they are weak. • Monitoring mechanism should be established to ensure the interface is used on a regular basis. • Institutional infrastructure (physical, statistical, GIS capability, statistical methodologies and classifications) should be strengthened where they are weak. This may require providing technical support to the countries. • Best practices should be drawn from the Asia-Pacific countries of Australia, Japan, Mongolia, and New Zealand (APCAS 2012) that performed well in this dimension.
7.	Adequacy of Resources	• African Countries have inadequate resources to run the agricultural statistics systems effectively and efficiently. This is	The Countries need: • Financial support in terms of greater budgetary allocations for Agricultural Statistics in their national budgets as well as

	COMPONENT	GAPS	PROPOSED SOLUTIONS
		in terms of ➢ Finances ➢ Human resource and ➢ Physical infrastructure including technology. • These result into late or irregular collection of information, inability to hire and retain well trained staff, failure to ensure sustainability and production of poor quality data. • Lack of information on cost effectiveness of agricultural routine data collection systems.	external funding where possible. • Capacity building in human resources for their agricultural activities. • Technical assistance or share technical expertise through staff exchange programmes and study tours. • To use more cost-effective methods. • Lobby governments to provide more financial support for the system (worked well in Asia Pacific to gain access to the national budget for the routine data collection systems (Maligalig, 2015).
8.	Data Use	• Limited use of the agricultural administrative data (especially due to quality concerns). • Limited use for: ➢ Improving frame construction and sampling designs. ➢ Improving efficiency of survey based estimators. ➢ As covariates in constructing model based small area estimates and forecasts. ➢ Crop forecasting	• Use of cross checks and corrections made through survey data. • Combining multiple data sources with complementary strengths and weaknesses. • Use calibration and construct area frames. • Develop methodology for record linkage and evaluation of measurement errors. • Develop good identifying variables. • Make the agricultural statistics production process more objective and transparent through digitisation and automation. • Review and revise the legal framework to cover administrative sources.

3.9 Approach to In-Country Testing

Two types of pilot testing were done – one field-based and another, desk-top. The School of Statistics and Planning (SSP), Makerere University, Uganda led the field piloting in Tanzania and Côte d'Ivoire, while the Center for Survey Statistics and Methodology (CSSM), Iowa State University (ISU), USA led the desk-top data analysis in Namibia. This paper refers to the field-testing. (FAO, 2016e).

3.9.1 Strategy Adopted in the Pilot

The Agricultural Routine Data System (ARDS) in Tanzania identified as one of the best agricultural administrative data collection systems in Africa, due to consistency and coverage, was used as basis for the pilot. The strategy adopted was to identify what improvements were required and then pilot these. For example, there was no primary source of data from the agricultural households. Therefore a household level questionnaire was designed and piloted. In Côte d'Ivoire, there was no routine reporting system. Therefore, a similar system was set up in four villages in Cote d'Ivoire on a pilot basis.

The routine reporting system of Tanzania and the data collected by administrative agencies in Côte d'Ivoire were evaluated, reviewed, and strengthened with respect to a number of dimensions corresponding to different issues as identified in the gap analysis. These included: coordination and supervision; skills and knowledge in agricultural data management and analysis; usage of comprehensive methodologies and technologies in data collection and management; conversion factors for agriculture (crops and livestock); presence of an agricultural statistics dissemination strategy; quality control; linkages between data from administrative sources with surveys and censuses; and cost of the administrative data.

A mini-survey to come up with conversion factors in the pilot areas was also carried out in Cote d'Ivoire as there were no conversion factors. The pilot also included introduction of new technologies like data collection using Tablets, area measurement using the GPS tools and collection of crop production using crop cards.

3.9.2 Visits to the Pilot Countries

There were a total of four visits to each of the pilot countries by the SSP Team. Each visit had a checklist of issues. A pre-pilot (first) visit was made to Tanzania and Côte d'Ivoire by an SSP team of two; to better understand the agricultural administrative data systems of these two countries.

A second visit by the SSP team was at the beginning of the pilot where a number activities were conducted including: Confirming the current coordination structure of the agricultural statistics system and the mandates of partners (NSO and Ministries) in collecting agricultural-related information; finding out current supervision arrangements; launching the pilot including briefings to all concerned; designation and training of respective staff to participate in the pilot; and agreeing on the dates for the third and fourth visits by the SSP team with stakeholders.

During the third (pilot mid-term) supervision visit, it was established whether the study countries had conversion factors; discussions were also held on the adequacy of funding, a review of data returns and flow at various levels was also done and other potential sources of administrative data identified. The fourth and final visit to wind up the field tests was also used to ensure that the issues identified in the gap analysis were all responded to. Measurements were compared: farmers' estimates of area against measurements obtained using GPS equipment; farmers' estimates of production versus actual record keeping through the crop card. The uses of modern technologies in data collection, in this case the tablets, was explored to speed up data collection and transmission at the local level and contribute to generation of real time data.

3.9.3 Findings

The introduction of a questionnaire, the crop card and the respective instructions' manuals as well as the tablet were considered to be very good innovations in both countries. The farmers themselves noted that the benefits were two-way in that the enumerators got the information they wanted while the farmers got extension advice and also got to know the exact size of their fields.

The main challenges included the fact that most of the plots were far away from the villages and scattered and not easily accessible; continuous harvesting especially where the crop card was not administered; farmers who did not want to be identified because they are squatters; synchronization of the data and sometimes lack of internet and; provision of area and production estimates by illiterate farmers. There were clear over-estimates of areas by the farmers when compared to the GPS estimates. Farmers production estimates were also over-estimates compared to the crop card. The facilitation given to field staff and supervisors was also greatly appreciated. The challenge is whether it is sustainable.

It was proposed to have intensive sensitization of the farmers before the pilot, to give more time for the training of field staff, to program the Crop Card on the mobile phone so that farmers can report regularly and electronically and, to geo-reference the plots as well since they are quite far from the homesteads. The collaboration between the NSO and MoA in Tanzania, in administering, coordinating and supervising the ARDS is a best practice that can be replicated in other countries including Cote d'Ivoire.

The existence and adherence to quality control measures and data validation mechanism/processes were examined; which data quality dimensions are more relevant for assessing quality of administrative data and their quantitative indicators (measurement of dimensions); and find out whether performance assessments of the system are done, review them and make recommendations.

As far as cost of administrative data is concerned, it is well known that establishing costs is a difficult but important task. With costs diffused throughout the data collection process, the goal was to estimate respective costs at each level of the process and make the process more cost-effective.

4. Conclusions

The Literature Review clearly shows that statistics agencies in the developed counties have done a lot of research in this area especially with regards to the several uses of administrative records. On the other hand, the Literature Review on Developing Countries shows that despite questionable administrative data quality, many countries are already collecting and using administrative data in a number of situations. In fact, administrative data are the major source of data in many developing countries, especially for agricultural statistics. There are also new potential sources of data, especially from the private sector. This is partly due to the privatization of formerly official functions and the growth of the private sector. The major problems are mostly data quality and infrastructural issues. Increased use of administrative data will therefore require these issues to be addressed. The field tests, whose analysis has started, have attempted to address these issues and tested strategies and methodologies that would improve the generation and use of administrative data.

Use of administrative registers for strengthening the geostatistical framework of the Census of Agriculture in Mexico

ABSTRACT

For a few years now the statistical use of administrative registers has been fostered, as they have been an important tool to reduce costs in producing information and the burden on respondents, for this reason the institutions responsible of producing statistics have boosted capacity building, in order to increase knowledge on the use of administrative sources and ensure the quality of the data produced.

In Mexico, INEGI has established agreements with various institutions to take advantage of the information produced by the administrative registers they produce, with the aim of producing demographic, economic and social statistics.

Regarding the agriculture and forestry sector, in Mexico some of the main sources of administrative registers have been identified, among which the following are worth mentioning: the Ministry of Agriculture, responsible of regulating the actions related to the agricultural and fishery activity; the National Forestry Commission, in charge of fostering the conservation and restoration of forests; and the National Agrarian Register, responsible of controlling and updating part of the rural property in the country.

In this context, there have been collaboration agreements with the Ministry of Agriculture and the National Agrarian Register, who provided inputs such as vector files of land plots and tables of producers from their respective programs, with the objective of analyzing them to determine their utility for strengthening the list and area frames of the Census of Agriculture.

In the beginning, incorporating the tabular and cartographic information into the geo-statistical framework of the Census of Agriculture, was thought to be simple, since it was easy to use digital files; however, the process has not turned out this way, given that there are many considerations to take into account for using the information obtained.

Thus, before incorporating the vector and tabular information to update the list and area frames of the Census of Agriculture, it is necessary to consider important aspects like: the projection in which the land files were produced, the geodetic reference system, as well as the standardization of the vector files obtained from different sources. Whereas for the tabular data, it is very important to obtain the minimum information necessary for the identification of both the producer and his address, independently from the structure that defines every agency.

Key words: administrative registers, census of agriculture, geostatistical frame, list frame, area frame.

1. Introduction

One of the viable alternatives for obtaining data with statistical purposes is the exploitation of administrative registers generated by federal agencies and private entities. In this regard, INEGI has reached agreements with public sector institutions that collect information from individuals and legal entities for using it as a data source to produce statistics with a geographic breakdown.

INEGI currently produces and publishes statistics from exploiting administrative registers in the following matters: economic (mining, foreign trade, and public administration), social (culture, labor relations, suicides, security and public order and health) and demographic (births, deaths and marriages).

Concerning the exploitation of administrative registers from the agricultural sector, INEGI has established alliances with some institutions in order to use their tabular and cartographic information, with the purpose of strengthen the permanent updating of the geostatistical framework of the Census of Agriculture.

2. Analysis of administrative registers from RAN and PROCAMPO to strengthen the geostatistical frame of the Agricultural Census

As a result of the 2007 Agricultural Census conducted in Mexico, the digitalization of approximately 70% of the land plots, where agricultural activities are held, was obtained. The remaining 30% of the land plots is not accurately demarcated since their specific boundaries are unknown, however, they are identified by INEGI in a “control area” (one section of the 187,326 parts that INEGI used to divide the national territory). Additionally, as a result of the Census of Agriculture, it was determined that 49% of the producers are linked with their land plots as production units, while the other 51% production units are not linked.

With the purpose of increasing this 49% of production units, several attempts have been made for incorporating information from administrative registers into the Agricultural Census’ information; nevertheless, most of the registers of producers' associations were discarded, since they contained heterogeneous and incomplete information, and they could not be used for this aim.

During the review of different sources, it was identified that RAN and PROCAMPO registers’ have three basic characteristics that allow a better and detailed analysis:

1. - They contain the producer’s table (a list of several variables that includes the name and address of the producer and other information)
2. - The land plot of the producer is a located territory and has defined boundaries.
3. - Both elements are in digital format; the first one is in database file (.DBF) format and the second one is in shapefile (.SHP) format.

Considering the necessity of being provided with the largest number of rural land plots, properly identified and linked with its producer, INEGI glimpsed the possibility of strengthening the sampling frame of the Census of Agriculture, by exploiting RAN and PROCAMPO information.

In view of the above, it was necessary to train INEGI staff in the use of GIS. With these systems, spatial comparison of the vector files of the land plots from the Census of Agriculture and those from the mentioned sources could be made by using different tools. Besides, high resolution satellite images (with a spatial resolution of 2.5 and 1.5 meters) were used and added into the GIS, in order to use them as a background. Satellite images were used to support the correct location of the boundaries of land plots that normally coincide with roads, rivers, and some other physical boundaries. Additionally, batch processing of geographic information is allowed by the GIS, which reduces the required time to compare land plot files and its databases.

Although digital files are easy to use and integrate into other sources of data, it is important to consider the following aspects before the analysis, and exploitation of administrative data:

1. - Geographic information must be in the same geographic and reference systems and in the same cartographic projection; for all cartographic elements, it is important for the register to be generated with the reference geodetic system's parameters and with the projections that are officially managed in the country, as well as using the parameters that are normally published in official journals for public knowledge, in order for the matching to be as accurate as possible.

Figure 1: *Shift effect observed by the different geodetic reference systems in shape files.*

2. - Database information must have the same structure (size and content of fields must be normalized). Concerning tabular files, it is required that they have basic information needed for the identification of both the producer and his address, regardless of the structure defined by each agency. It is therefore recommended for the name of the producer to be split by the last name of the father, the last name of the mother, and the name itself, in separate fields as it is common for the full name to be included in a single field, which makes information difficult to handle. It is also recommended for the information on the address to be organized according to the technical rules generated for its standardization; these rules usually specify the minimum information on streets and surrounding streets that allow locating addresses; furthermore, localities must be properly identified with the name and geostatistical code that have been assigned to them. Normalization of the database structure will prevent any problem in the process of the information and it will also allow the interchange of data between databases.

3. Analysis of information from the RAN

The measurement and certification of land plots and plans from each "ejido" in México, (shared lands of social property), was done between 1993 and 2003 and backed up on magnetic media by the RAN. The technical works of measurement were carried out by INEGI until 2003; after that, RAN has kept on updating its information. Now INEGI considers important to use these administrative registers to update its information as well.

INEGI obtained the vector files of land plots and producer's tables from RAN, with the purpose of analyzing them and determine if they were able to be used for complementing the information produced by the 2007 Agricultural Census. The criteria set to analyze the information were the following:

1.- The land plots that spatially coincided with information that INEGI already had, were not used to add information to the area frame of the Census of Agriculture; they were only used to verify that INEGI's data is updated.

2.- RAN's land plots, located inside one of INEGI's land plots, were considered as a subdivision, as long as they coincided with its boundaries. In this case, RAN's land plots were considered as part of the updating of the area frame of the Census of Agriculture.

3.- RAN land plots that are subdivisions of a land plot from INEGI, but whose boundaries overlap INEGI's boundaries, will be visually analyzed in detail to determine if they will be used for the updating process.

From a total of 5 685 450 land plots received in shapefiles format, approximately 94% were part of the land plot shapefiles of the Agricultural Census. The high coincidence of land plots from this source is explained because INEGI initiated the social property land plot certification task in Mexico in 1993 and then, in 2003, the activity completely became RAN's responsibility. The remaining 6% corresponds to the land plots incorporated and surveyed by RAN from 2003 up to date and they are divided as follows:

3.31% of the remaining land plots correspond to lands that can be directly incorporated in the shapefile format of the Agriculture Census' land plots, or with minimal editing; these land plots corresponded to subdivisions of larger areas that were already defined in the Agricultural Census, or to common use spaces of the "ejidos" that were divided and distributed among the landowners.

Figures 2 and 3 show different examples of RAN's land plots that were incorporated within the boundaries of a large land plot of the Census of Agriculture, with the respective information of producers.

Figures 2 and 3: *Examples of information of RAN incorporated into Census frame*.

The remaining 2.71% corresponds to land plots whose configuration does not match exactly with the spaces bounded by the Agricultural Census, making it necessary to perform a detailed visual reviewing using the satellite image to determine whether the land plot is incorporated or omitted. In some cases even when land plots do not match, RAN's land plots have a better definition of boundaries (see Figure 4), so they are used to update INEGI's frame. INEGI is currently in the process of determining the land plots of this segment that could be incorporated in the land plot shape.

Figure 4: *Review of RAN's Land plots using satellite image*

Furthermore, the review of the tabular file associated to the shape, allowed identifying the name of the producer along with the information about the “ejido” he or she belongs to, as well as the number of the land plot; however, the tabular file lacks producer’s address (street, number, name of locality, etc.), which is a fundamental data to locate the producers during a census or survey. In this regard, INEGI is in the process of comparing the names with the names included in the Agricultural Census in order to associate the corresponding addresses in case of matches. At the same time, INEGI is requesting RAN to complete producer’s information.

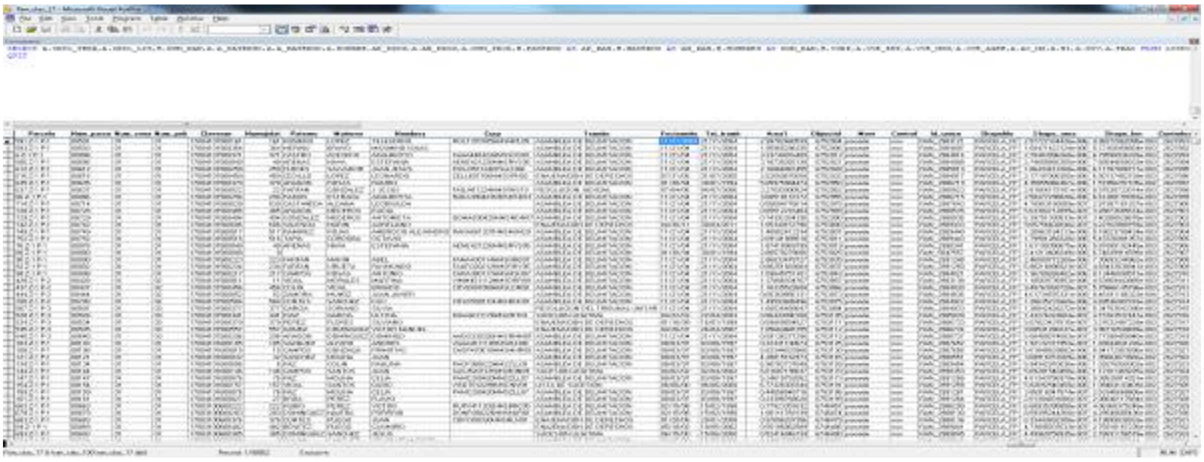

Table 1: *RAN´s information structure, without address data*

4. Analysis of information from PROCAMPO

Information generated by SAGARPA was also considered to be used, specifically data coming from the support programs for farmers that cultivate specific products in their lands. This is the case of PROCAMPO; to keep this register, SAGARPA identifies the land plot being supported; then determines its area and obtains the producer’s information to whom the economic resources are being allocated to; the tabulate and cartographic information collected were also backed up in magnetic media, and it is also considered potential information for updating.

The review of the cartographic information revealed some differences in the configuration of the land plots; the most important was that data from PROCAMPO included land plots with boundaries classified in the Agricultural Census as “big land plots”, without an inner subdivision. PROCAMPO’s boundaries, in most cases, can be considered divisions of the Agricultural Census’ original land plots, however there are some cases where PROCAMPOs’ land plots corresponded only to the cultivated area supported economically by the program. In those cases, where minimal edition is required, will be reviewed before making the decision of integrating them or not.

Besides, there are land plots whose shape differs from the shape in the Agricultural Census, so a one to one detailed review is needed in order to decide which land plots can be incorporated and which are eliminated. This could be done by using the satellite image as background. Figure 5 shows a group of land plots from PROCAMPO that fill a “big land plot” of the census frame with detailed information.

Using the same criteria applied to RAN’s information, from a total of 3 308 038 land plots received from PROCAMPO, 83.9% were already in the land plot layer of the Census of Agriculture; 8.3% corresponded to land plots that could be included with a few modifications; and finally, 7.8% were land plots that must be reviewed, one by one, and then decide upon their incorporation.

Figures 5: *Land plots from PROCAMPO (pink) to be incorporated into Census frame.*

In the case of the tabular information of PROCAMPO, the review reflected lack of data, although the directory contains the names of the producers that are supported by the program, and, in most cases, the street name and number. It also lacks the locality and the address, so INEGI is working with SAGARPA in order to obtain the complete information.

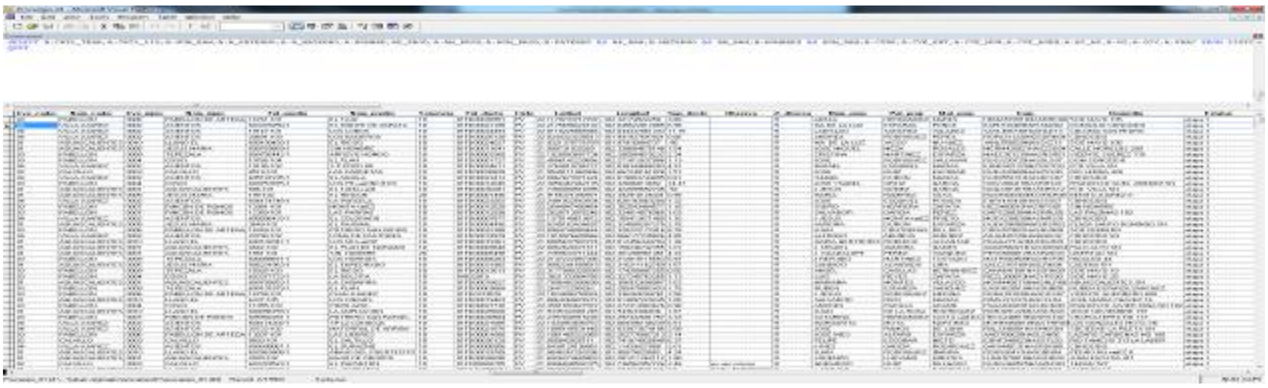

Table 2: *PROCAMPO´s information structure, without accurate address data*

Even though producers' names from PROCAMPO are not included in INEGI's information, they were used to update the information of the Census of Agriculture, since the information of the census corresponds to 2007 and PROCAMPO information is updated to 2012-2013.

5. Conclusions

The use of specialized software of GIS and high resolution satellite images, represents a huge advantage for analyzing, exploiting and managing cartographic and database information produced by institutions in the public and private sectors. Those advantages have been exploited by INEGI to compare vector data from different sources and to use them for strengthen the geostatistical framework of the Census of Agriculture.

Exploiting information from public institutions, as RAN and SAGARPA, represents a great opportunity for INEGI to update the list frame and the area frame of the Census of Agriculture; however, it is very important that information increasingly meets established standards in order to ease this task. The differences of the structure of the databases and the different reference systems of geographic and cartographic information are the main things to keep in mind while working with this kind of data.

With this work, it was possible to increase the percentage of production units (producers linked with their land plots) from 49% to 59%. Concerning the amount of land plots with delimited boundaries, the 295, 155 land plots that RAN added to the shape of the Census of Agriculture, compared with the 2 719 500 land plots that have not been delimited, corresponds to 11%.

Concerning PROCAMPO' data, the 189 853 land plots that were identified for possible addition in the area frame, are still in the process of detailed reviewing to decide whether they will be used to complement the shape of land plots of the Census of Agriculture or not. This amount represents 7% of possible land plots to be added.

ABSTRACT

The Agriculture Statistics Program at Statistics Canada (Statistics Canada) has undertaken a project to increase the use of administrative data: to replace current survey and census data, to fill data gaps, and for census and survey data validation. Overall the Administrative Data project aims to reduce response burden and increase program efficiencies.

This project involves first identifying specific sources of administrative data that have attributes that make them well suited for further use. Secondly, an assessment is conducted of their usefulness to replace survey or census data, to enhance data validation, or to assist into frame maintenance alongside an assessment of the requirements for their integration into the program.

This paper will present some of the findings resulting from this project, some of the long-term considerations required, as well as the methodology used to evaluate the quality of the sources that have been identified.

Keywords: Administrative data, validation, quality, respondent burden, efficiency

1. Introduction

Following the last major review of Statistics Canada's Agriculture Statistics Program[1] (ASP) in 2010-12, the agency has explored new processes with the objective to reduce respondent burden and continue to provide high quality information on agriculture (Smith J. 2011, Smith et al. 2013)).

One of these initiatives was to integrate more administrative data[2] in order to reduce respondent burden further, to improve quality of survey estimates and to reduce data collection costs. The ASP uses more than 200 sources of administrative data. The primary objectives are to validate collected information and to avoid collecting data already gathered by other agencies and programs. The APS's vision is to continue the acquisition of administrative data for replacing traditional survey data collection methods.

Section 2 is presents new administrative datasets that were assessed and used. Section 3 describes the evaluation guidelines for using administrative data with a specific dataset, AgriInsurance. The last section concludes by looking forward on initiatives to expand the use of new administrative data into the Canadian ASP.

2. Administrative data sources (including Earth observation)

2.1 Taxation data

The ASP uses a census of farm tax filer records annually to estimate detailed farm revenues and expenses. In 2011, the Census of Agriculture (CEAG) program undertook the Agriculture Taxation Data Replacement Initiative. The purpose of this feasibility study was to evaluate the robustness of taxation data as a replacement to detailed operating expenses provided by respondents. The project, completed in 2012, concluded that from most operations in Canada, detailed expenses could be obtained from taxation data. As a result, the 2016 CEAG removed detailed farm expenses from its questionnaire as this information is available from the taxation data.

2.2 AgriStability

In Canada, the AgriStability program was established in 2008 as part of the Growing Forward policy framework implemented by Agriculture and Agri-Food Canada (AAFC). The purpose of the AgriStability is to provide income stability to farmers by managing risk inherent to the agricultural sector (AAFC, 2013).

As the evaluation of AgriStability datasets are still in early stages, the potential of using this program data for replacement in surveys is still unclear. An initial assessment indicated that the AgriStability datasets contain highly detailed income, expenses, and commodities data. However, the data availability is not timely enough to replace survey data. The lag time between the end of a program year and reception of a full dataset is approximately 2 years.

---

[1] ASP includes mainly a suite of primary agricultural programs on commodities, farm financial and practices based on surveys, Census of Agriculture and administrative data.

[2] Information that is collected by other organizations and departments for their own purposes, and is sought, at the micro or aggregate level, by Statistics Canada in respect to the objects of the *Statistics Act*. It excludes data that do not pertain to the Canadian society or economy. By definition, Statistics Canada's use of this information for statistical purposes is secondary to the objective of the original collector of the information.

2.3 Remote sensing[3] to derive crop area and yield

For a number of years, the ASP has used remote sensing data for data confrontation against data collected from the field crop surveys and the CEAG. For survey data replacement, the Remote Sensing and Geospatial Analysis (RSGA) team produces two major outputs. The first output is the generalized crop area estimates based on AAFC Annual Crop Inventory data. The AAFC spaced-based annual crop inventory data map the expected extent of annual and perennial crops as well as land use and cover classes covering the agricultural regions of Canada with a spatial resolution of 30x30 m pixels (AAFC, 2015). The second output incorporates CEAG coarse resolution satellite data, survey yield[4] estimates and agroclimatic data to produce Model-based Principal Field Crop Estimates as at August 31.

The first yield model estimates were published on September 17, 2015, three weeks in advance of the traditional September crop survey publication. After an extensive evaluation of the modelled and survey results for 1987 to 2015 period, the decision was made to terminate the September crop survey and replace it with Model-based Principal Field Crop Estimates. This successful implementation was a concrete example where crop survey data could be replaced with modelled data derived from administrative data and historical survey data.

2.4 Animal traceability

Animal Traceability in Canada has been developed as a cooperative effort between agricultural industry organizations and the federal, provincial and territorial governments. The goals of traceability are the identification of animals, recording and reporting animal movements, and premises identification. Traceability facilitates accurate tracking of animal locations during disease outbreaks, and provides information to contain negative impacts associated with such emergencies.

While hog traceability has been fully implemented, other livestock sectors in Canada are at various stages of implementation. The *Health of Animals Regulations* (revised in 2015) are currently being amended to include full identification and movement requirements for cattle, bison, sheep, goats and cervids. Traceability data will be required under Part XV of the regulations. These data are held by the Canadian Food Inspection Agency (CFIA), and is intended for regulated traceability use only (unless consent is given by regulated parties for other uses).[5] Statistics Canada could use traceability data to validate or replace part of the Livestock survey data.

2.4 AgriInsurance

The AgriInsurance program in Canada has been in place since 1959, to provide crop insurance to producers. The program helps to reduce producers' losses by supplying funding where natural hazards have negatively affected production. The program data are acquired by the ASP by agreement with provincial program administrators.

---

[3] Earth Observation and remote sensing are used interchangeably in this paper.

[5] For information on uses of this information, as well as privacy restrictions, please contact Eric Aubin - National Manager for the Livestock Traceability Program (CFIA) at 1.613.773.6173.

AgriInsurance covers a wide variety of crops including field crops (corn, wheat, oats, barley, soybeans, etc.), horticultural products, and other non-traditional products such as bees and maple syrup. Currently the ASP acquires operator information for each insured operation, individual crop type acreage, yield, and associated field management practices. The level of detail varies by province, but data provided for the Prairie Provinces (Alberta, Manitoba, and Saskatchewan) are generally more detailed. These three provinces account for 48.5% of all farms reporting land in crops based on the 2011 CEAG, and accounted for 81.6% of all total crop area of the Canadian Prairies. AgriInsurance programs do include livestock plans, although the current scope of the ongoing project focuses solely on the crop portion of AgriInsurance. Table 1 illustrates the current and potential use of AgriInsurance data.

Table 1: *Current and potential uses of AgriInsurance data within the ASP at Statistics Canada*

	Validation or ground truthing	Replacement	Frame maintenance	Combined with other data
Census	Current	Potential – 2021	Current	Potential – 2021
Crop surveys	Current	Potential – 2018	To some extent	Potential – 2018
Remote sensing	Current	Potential – 2017	n/a	Potential – 2017
Livestock	Potential	unknown	To some extent	unknown

3. Evaluation guidelines for using administrative data

At Statistics Canada, the Directive on Obtaining Administrative Data for Statistical Purposes, governs the quality evaluation of administrative data. This directive establishes an agency-wide approach to administrative data quality, mandates support for its quality evaluation and ensures that the quality information is documented centrally. Quality is measured using Statistics Canada six dimensions of data quality: relevance, accuracy, timeliness, accessibility, interpretability and coherence.

An evaluation framework, along with evaluation tools and procedures have been developed and tested at Statistics Canada. Unsuitable administrative data sources are quickly rejected early in the evaluation process.

The framework is composed of two phases. The Exploration Phase collects background information (for example, variables available and data format) from the administrative data holder without requiring the acquisition of the complete dataset. Following this phase, a recommendation is issued to continue with more in-depth evaluation.

This second phase, the Initial Acquisition Phase, is where the data itself is accessed and evaluated. This evaluation results in a recommendation whether to proceed or not with a full acquisition of the administrative data source.

The tools developed at Statistics Canada to collect information for the evaluation framework are a standard questionnaire, a toolbox of suggested methods and indicators, and compilation tables where the evaluation results are summarized. The sections below outline the information that is gathered through the use of these tools. In order to highlight the application of the Directive, AgriInsurance data is used as a case study given its level of detail and breadth of information.

3.1 Exploratory phase

The replacement strategy begins with an overall review of potential sources of administrative data available to respond to a statistical need. Once a potential source has been identified, learning about the data from the supplier without accessing the data is the first step.

3.1.1 Target population and coverage

This step includes an evaluation of whether the target population is stable over time and documents the sources of under-coverage and over-coverage. The reference period(s) of the administrative data is recorded, noting when there are differences between that of the population covered and those for the existing Statistics Canada products.

3.1.2 Timeliness of acquisition

In addition, information on the tentative date of acquisition is collected, including dates when various versions (preliminary and final) of the data could be received. Timeliness varies widely across datasets, but is always a concern given the trade-off that often occurs between timeliness and accuracy.

For example, although highly accurate, AgriInsurance data is not available until more than halfway through the calendar year for planted area, while harvested area is not available until well after publication of official yield statistics. This limits the datasets use for direct replacement in crop surveys while having little effect on both the Remote Sensing and Census programs. However, the ASP continues to work towards developing methods that would mitigate the trade-off between timeliness and accuracy. Working towards the utilization of smaller subsets of data which are available in a timely manner have the potential to be useful towards building a quality product. The different data subsets obtained at different time of the growing season are assessed against benchmark estimates to determine which one will produce more accurate estimates.

3.1.3 Content assessment

Further, an initial assessment of the coherence is done for each variable between the administrative data and the statistical concept. For example, any farm operator registered under the AgriInsurance program would provide information similar as the one collected by the survey (type of crop, cultivated area, etc.).

3.1.4 Collection, processing and non-statistical considerations

Next the collection procedure is evaluated, taking into account any processes which may have an impact on the intended use such as the legal authority under which the data are collected and the frequency of collection. Similarly, the data processing (e.g. coding, imputation) by the provider is assessed, paying particular attention to whether the data may have been modified in the course of these various operations.

The subsequent section of the Exploration Phase takes into account other non-statistical considerations associated with using the administrative data. An estimate of the costs from acquisition or from increased processing is balanced against savings in collection costs. Likewise, a review of the human resource requirements associated with using the data is undertaken. In addition, the impact that using the administrative data will have on response burden is assessed.

3.2 Initial acquisition phase

3.2.1 Initial contact for access

Once an identified potential administrative dataset meets the criteria described above, initial contact and discussion on access start with dataset holders. Engaging potential data providers is key at this early stage to develop trust and to illustrate the added value of a data sharing agreement to all parties, and in particular to the farm operators. These contacts are occasions to share information about the goal and the intended uses of the data, the legal requirements and existing safeguards in place to guarantee the confidentiality and protection of the administrative dataset. For example, Statistics Canada has the legal authority to collect and obtain information and its obligation to protect the confidentiality of information is outlined in the *Statistics Act*. Under Section 13 of the Act, Statistics Canada has the authority to obtain any documents or records maintained by a government department, a business or an organization.

The Exploratory phase continues with a formal request for the data (or a subset used as a pilot project) and metadata such as record layout of variables in the administrative dataset in order to identify potential linking keys.

If the evaluation in the Exploration Phase has led to a decision to proceed further with the quality review, acquisition of the administrative data file is required. In this phase, a number of calculations and indicators are produced, mainly with regard to data accuracy.

3.2.2 Unique linking keys

The initial assessment starts with finding unique linking keys between administrative files and the current information existing in the statistical agency census and business register. On any administrative dataset, there are multiple variables used as identifiers (e.g. program, participant name, address…). The development and use of a unique key will expedite the linking of datasets over time.

The need for linking datasets varies depending on the program. Commodity surveys and CEAG data all require precise linkages for potential replacement of variables with administrative data. By comparison, area and yield model estimates produced using remote sensing do not require linkages at the individual operator or farm. The linkage could be done at an aggregated geographical area (representing several fields or plots). AgriInsurance data contains such linking keys, and therefore meets the basic minimum requirement for replacement moving forward.

3.2.3 Coherence

Although a full assessment requires a completion of the linking process, preliminary assessments of the AgriInsurance file indicates a high level of coherence of concepts between the administrative file and the statistical concept of the data to be replaced. All field crop types currently collected on the crop surveys, the CEAG, and in the area and yield model are present in the AgriInsurance dataset. They require little to no aggregation or disaggregation of variables. Data is reported at both the field level and operator level, meeting the specific needs of the Remote Sensing program, and the survey and CEAG programs.

3.2.4 Fitness for use

In terms of fitness for use, Statistics Canada requested the AgriInsurance data to be delivered in a raw format (as capture initially without imputation). This provides the opportunity to identify where potential issues may exist with regard to data quality, and usability. For example, an initial assessment of AgriInsurance datasets resulted in the identification of double counting. This double counting was largely unavoidable due to the manner in which AgriInsurance programs collect data. Awareness of these potential errors allows the RSGA to easily remove cases of duplication.

3.2.5 Accuracy

Accuracy is defined as the degree to which information correctly describes the phenomenon it was designed to measure. The evaluation of accuracy is achieved by looking at potential sources of error, which include coverage error, non-response error and error due to reporting, measurement or processing. Coverage error is assessed through the identification of under-coverage or over-coverage of the target population. Non-response error is evaluated through the amount of missing data for one or more variables relevant to the intended use.

Accuracy could be assessed at the aggregate level (e.g. the total crop area under crop insurance compared with official area estimates).

A comparative analysis between satellite imagery and AgriInsurance data has been done for two provinces for seeded area by type of crop. Where there was a field identified on AgriInsurance, the satellite successfully identified the same type of crop.

The analysis could also be done at the farm level data where reliable linking keys were identified to compare the divergence of information reported to the program data with the survey data. Reporting, measurement and processing errors are identified when the value of a variable in the administrative dataset is different from the survey value; understanding the reasons behind the differences would support adequate decisions during the evaluation. These types of errors are evaluated by identifying items such as invalid, inconsistent or imputed data for relevant variables.

4. Discussion – looking forward

Administrative data is recognized as a key component of the integrated survey framework promoted in the FAO Strategy to Improve Agricultural and Rural Statistics. *Governmental interventions such as subsidies, regulation, and legislation often require agricultural holders to report production information. Land ownership and cadastral surveys provide useful information for constructing registers. Food inspections, animal health inspections, and trade data provide input to the utilization accounts.*

The ASP already uses over 200 administrative datasets in collecting, processing, analyzing and publishing its statistics. These datasets are mostly supplied to Statistics Canada at the aggregated data level. They are extremely valuable as a supplement to data collected from more costly surveys and censuses. While administrative data will not eliminate the need for a CEAG, the investigation found that some administrative sources have the potential to replace part of a future census or to be used in ongoing agricultural surveys.

Recently, Statistics Canada successfully negotiated long-term data sharing agreements with provincial program administrators and national bodies of supply managed industries for. To promote increased use of administrative data and to meet its statistical requirements, Statistics Canada has also continued to support national initiatives, such as that led by the CFIA, which has oversight of the certified organic industry through the Organic Products Regulation of the *Canada Agricultural Products Act*, as well as the national traceability program.

Statistics Canada will continue its efforts to obtain and assess administrative data for the purposes of data confrontation, imputation, and enhancing or replacing some content of the agriculture surveys or for future censuses. Most of the successes in the use of new administrative data were related to the acquisition and integration of crop insurance data with remote sensing data for modelling field crop yield and production estimates. These estimates were used as official statistics in the 2016 field crop survey report.

Looking forward these different initiatives raise questions as to what else could be done to reduce respondent burden and data collection costs. One area that requires more investigation is non-public sources of data. For the first time, the 2016 Canadian CEAG is going to measure how many farm operators use new technologies such auto-steering, precision agriculture, GIS and smart-phone devices. This is an opportunity to assess the potential use of big data often created with these new technologies and to innovate with new data collection tools.

ABSTRACT

It is an important and difficult task to make sure that the quality of statistics obtained from administrative sources is sufficient for statistical needs. In recent years several studies have been made investigating quality frameworks for administrative registers. These includes the quality of the register itself, the possibilities of integrating administrative registers into statistical registers and how to document the quality of the statistics produced.

The aim of this paper is to discuss how quality frameworks can be used to improve and declare the quality in the statistics obtained from administrative sources. The frameworks will be discussed in relation to where in the statistical production process it can be included. The usefulness of two frameworks will be compared, i.e. the framework published by Statistics Netherlands (Daas et al. 2009) and the framework published by Laitila et al. 2011.

The paper will end in a discussion on the usefulness of the quality frameworks for administrative registers to improve the quality of the statistics and make suggestions for additional aspects that will have to be taken under consideration.

The case of using administrative registers from the control bodies to produce statistics on the structure of organic farms and on the amount of organic production will be used. The case will show how the quality frameworks can be used to discuss the statistical quality when using administrative slaughtering registers to producing animal production statistics. The case will also show how several registers; the registers from the control bodies, the farm register, the cattle database and the slaughter register, can be merged in order to get the statistics required.

Keywords: Administrative registers, Quality frameworks, Organic

1. Background and aim of the paper

It is a difficult decision whether to conduct a survey or derive statistics from administrative registers. This is especially true for official statistics, which must be a source everybody can trust.

A few years ago the demand for statistics about organic farming grew high. The Swedish Board of Agriculture (SBA) faced different alternatives. One alternative was to continue to publish figures from the three different audit bodies that make sure a farmer meets all of the requirements for organic farming. That alternative, however, would mean many drawbacks would persist. The figures were not comparable with the other agricultural statistics that we publish. The figures were shaky when broken down beyond national level. The advantage was that we already had a system to handle the data.

The second alternative was to conduct a sample survey of organic farms. There were, however, some disadvantages to this choice as well. To send out a questionnaire and to register all of the responses would incur an annual cost. We were also considering the burden for the respondents to fill out the questionnaire. The advantage was that the statistics would be comparable with all of the other agricultural statistics.

The third alternative was to derive the statistics from registers. The disadvantage was that it would take us some time to figure out how to do it. Also, we had to make sure that the administrative registers were of good quality. The advantage was that, once done it could be used year after year with minimal costs. The farmers with organic production would not have to fill out an extra questionnaire, hence the response burden would be zero.

After considering the pros and cons, we started to investigate how to proceed with alternative 3, to derive the statistics from administrative registers. We figured that the best way of producing comparable statistics was to link the statistics with the Farm Register (FR). If we could link the Organic Register (OR) with the FR, we could not only derive statistics for the whole country but also for any other geographical subdivision which might be requested. But we needed a framework to put our registers in.

In recent years several studies have discussed quality frameworks for using administrative registers for statistical purposes. The aim of this paper is to discuss the concepts developed by Daas et al. 2009 and Laitila et al. 2011 for the decision whether to use administrative registers to produce statistics about organic production.

2. The case of the statistics on organic animals

In all we found that we had three different registers to use. The first register is the FR, which contains information about all of the holdings in Sweden. Most notably for this exercise the number of animals of different kinds on the first Thursday in June every year. There is also information about social security numbers (SSN) of the holders and of other persons sending information to different registers at the Swedish Board of Agriculture (SBA). There is also information about the Production Location Number (PLN), i.e. the place where animals are held, the address and the phone numbers to the holding. Every third year we conduct a census updating all of the holdings in the register. Among the things that we update are the unique client id for all clients connected to one of the three control bodies certifying organic farming in Sweden. The FR is regulated by Swedish legislation.

The second register is the slaughter register (SR) that contains information about the number of slaughtered animals and their weight. The register contains information about the SSN of the persons reporting the slaughtering to the slaughterhouses and also from which PLN the slaughtered animals were coming from. The SR is regulated by Swedish legislation.

The third register contains information about holdings with organic production, the Organic Register (OR). This register is a combination of the registers of the three control bodies. The SBA receives these registers and merge them. This register contains information about what kind of organic animals that are raised on the holding. However, the way the animals are counted differs. For some animals it is the average number of animals during the year and for some it is the maximum number of animals during the year. There is information about the SSN, address and phone number of the holder. The holding's client id with their respective control body is also included in the register.

The aim is to combine all of the three abovementioned registers in order to extract the number of organic animals and the amount of organic slaughtering.

2.1 Setting up the frame

The idea for the number of organic animals is that we would match the OR with the FR. If a holding had organic cows in the OR, then all of the cows in the FR would become organic. And if a holding had organic pigs in the OR, then all of the pigs in the FR would become organic. We had to make one exception for poultry, because the different kinds of poultry are so different. If a holding had organic broilers in the OR then the broilers in the FR would become organic, but all of the other types of chickens would not become organic.

One of the big advantages with using the number of animals in the FR is that the data is fully comparable with the other figures from the FR. With the FR we can also determine an exact geographical point where the animals are located.

Some of the difficulties were that one holding in the FR could be two holdings in the OR, so there was not a one-to-one ratio. Some manual work was required to establish a link between the holdings in the OR and the corresponding holding in the FR, as this could not be done automatically. Overall the matching was not much of a problem though.

The idea for the organic slaughtering was the same as the idea for the organic animals, but we also had to include the SR. If a holding had cows that were present in the OR and also had slaughtering of cows, then all of the cows slaughtered would become organic.

Both Laitila et al. and Daas et al. contains suggestions of a system of indicators for quality assessment of administrative data, so that one can get an overview of the registers. On indicator level the concepts of Laitila et al. and Daas et al. are to a large extent overlapping. However, there are some differences in the way indicators are systemized and how quality is assessed. Daas et al. sees three dimensions: the administrative register in itself, metadata about the source and the data in the source. Indicators are developed within each dimension. Laitila et al. discusses indicators in three dimensions: output data quality, input data quality and production process quality. However, they group the indicators related to the work process, i.e. indicators related to information from the administrative authority, indicators related to data editing of the source, indicators related to integrating the source with the statistical register and integrating the survey with similar variables.

The indicators in the hyper-dimensional described in the text are summarized in table 1. The SBA is the supplier of the data sources of the FR and the SR. The supplier of the OR are the three control bodies that supplies one separate register each to the SBA.

Table 1: *Evaluation of registers according to the hyper-dimensions of Daas et al. 2009 and Laitila et al. 2011*

B4. Missing values	+ + + + +	+ + + + +	+ +
B5. Wrong values	+ + + +	+ + + + +	+ +
B6. Output of preliminary data	+ + +	+ + + +	+

What we found is that the FR and the SR are of very high quality. The OR, however, does not have the same quality standards. The FR is the base in Swedish agricultural statistics and contains all of the base variables. It is updated yearly.

Regarding the dimension of supplier (S1) the FR and the SR are situated at the SBA. The OR is sent to the SBA from the three control bodies. The knowledge of the OR is OK. Regarding the dimension of relevance (S2), the relevance of the units (A2) and the relevance of the variables (A4), the slaughter statistics is a register where the slaughterhouses report the number of animals that have been slaughtered and their corresponding weight each day. However, the register does not have any information of the animals slaughtered on the farms. The OR stems from the audit bodies that control that a farm meets the requirements of certified organic production. However, the OR contain a few variables of interest to us, namely what kind of animals are certified as organic and information to conduct our matches with other registers.

The privacy and security (S3) for the FR is very good. Nobody outside the statistical department at the SBA has access to the data. It is also protected by Swedish law. As for the SR nobody outside the SBA has access to the data. The situation is somewhat similar for the OR. Addresses might be disclosed but the number of animals will not be disclosed.

Regarding the delivery (S4), procedures (S5) and updates & punctuality (A8), then for the FR and the SR there is not much of a problem, because these registers are situated at the SBA and historically they have always been delivering data in time. There are usually no major errors in the material and if found, they are corrected swiftly. We are of course very familiar with how the data is collected and if we should have any questions they will be answered in a short period of time. The OR, however, usually requires more work. When the registers arrive they must be checked for errors and requests must be sent to the control bodies for them to correct the errors.

For the clarity and comparability (M1, M2) and the relevance of the variables and time (A4, A5), the base variable is holdings in the FR. Linked to these holdings are the number or animals from the FR and the number of slaughtered animals from the SR. The auxiliary variables come from the OR, i.e. what kind of organic animals are on the farm. In the FR the number of animals are counted on the first Thursday in June, but in the OR the number of animals could be either the maximum or the average during the year. Regarding the relevance of time, there should not be any problem, because all of the registers have strict codes regarding when a year begins and ends.

As for the unique keys (M3), primary keys (A1) and doublets (B3), there is some concern for all of the registers, because we know there are doublets in the material for the FR and the OR. For the FR, this is less of a problem in the census years and more so in the years between censuses. Holdings with organic production can choose between one of the three accredited control bodies and sometimes they change control body between the years. Since the registers of the control bodies are not fully up to date, one holding can be present in more than one register. As mentioned before, the holding is the primary unit in the FR, but in the other two registers, holding is not a primary key but instead a person. In some cases, two or more units from the SR or the OR must be put into one holding in the FR.

Data treatments (M4) are conducted on the FR every year before it is being published. There are checks whether the holding is part of the population, checks for extreme values, do all holdings have a holder, and is the data consistent and so on. For the SR, the holdings should report the animals that are being slaughtered. The same information should also be reported by the slaughterhouses. This form of double reporting should indicate that there are very few posts that are faulty. The OR is kind of different, because the audit bodies do not seem to put that much effort into data treatment. There are not many missing values (B4) but there could be substantial amounts of wrong values (B5). This of course, is a burden put on the SBA.

The third hyper-dimension introduced by Daas et al. 2009 is the data dimension that focuses on the quality aspect of the data in the source. Laitila et al. 2011 focus on the indicators of input data and production process quality. Hence Laitila et al. 2011 focus on register level, but Daas et al. 2009 assume that we base our analysis on the overall performance combining all of our registers and in the end receive the statistics. The quality is therefore assessed on the whole approach and not only on the registers themselves (Table 2).

Table 2: *Quality of the data for statistical purposes according to Daas et al. 2009 and Laitila et al. 2011*

Daas et al.	Model of the number of organic animals and organic meat production	Laitila et al.	Model of the number of organic animals and organic meat production
Q1. Technical checks	+ + +	D1. Relevance of variables as such	+ + + +
Q2. Over coverage	+ + + +	D2. Relevance of variables as auxiliary information	+ + + +
Q3. Under coverage	+ + + +	D3. Relevance of variables to improve statistics	+ + + +
Q4. Link ability	+ + + +	D4. Under coverage in administrative registers and in FR	+ + + +
Q5. Unit non-response	+ + + +	D5. Over coverage in administrative registers and in FR	+ + + +
Q6. Item non-response	+ + +	D6. Duplicates in administrative registers	+ + + +
Q7. Measurement	+ + + +	D7. Wrong units in administrative registers and in FR	+ + +
Q8. Processing	+ + + +	D8. Missing values	+ + + +
Q9. Precision	+ + + +	D9. Wrong values or wrong units, cross section data	+ + + +
Q10. Sensitivity	+ + + +	D10. Wrong values or wrong units, longitudinal data	+ + + +

Regarding the technical checks, there are no problems reading the data of the FR and the SR. The OR comes from the three audit bodies and is of worse quality. However, the data is fully readable after some extensive manual labor (Q1).

The variables in the OR are used as auxiliary variables and variables to improve the statistics (D2, D3). From the register we know which holdings are conducting organic farming. Since a holding can be both organic and conventional, we also use the information of what animals are organic. So if a holding is raising organic cattle, then all the cattle on the holding and all of the slaughtered cattle are assumed to be organic. In our model, it has worked out very well and the information has been very useful.

Over coverage in the SR is estimated to be negligible because of the double reporting conducted by the farmer and the slaughter houses. In the OR there could be over coverage if a holder is not removed from the register even though they have ceased producing organically. However, the over coverage is assumed to be very small. Over coverage in the FR is negligible for the years when we conduct a census (Q2, D5). For the years between there can be some over coverage since we do not send out questionnaires to every holding. It must, however, be emphasized that the over coverage is small and will not lead to any big overestimation. For all three registers combined, the over coverage is assumed to be very small.

The under coverage is assumed to be small for all of the registers and the linkability is assumed to be high (Q3, Q4, D4). The newly started holdings almost certainly will apply for subsidies and will therefore be incorporated in the FR. Less than 0.1 % of the animals in the SR are not linked to the FR now. For sheep there has been a few years where we could not link as much as 1 % of the slaughtered animals. In the OR there are usually 1-3 holdings that we cannot link, but those holdings could very well be closed down. There must be some mismatches between the registers, but we do not believe that the number is very high. It is of course hard to give a specific number, but from what we have seen, it is most certainly quite low.

Regarding the unit non-response and the item non-response (Q5, Q6, D8) we have a response rate of about 97 % in the FSS and in the livestock surveys. In the SR the response rate should be very close to 100 % because of the double reporting and in the OR the response rate should also be very close to 100 % because otherwise the farmers will not receive any subsidies or be able to sell the meat as organic. The item non-response, however, is harder to measure since we do not know if a holding has forgotten to fill in the number of sows under the pig section in the FSS or the livestock survey. For the bigger holdings we might find out that information is missing, but for the smaller ones it is very difficult.

The number of organic animals in our model is compared with the number of organic animals reported by the Swedish organization KRAV. The number of organic animals are about the same in both our model and KRAV:s figures (Q7). We also compare the amount of organic meat with other organizations to see if our figures are in line with them. There can of course be some small random errors. The systematic errors are assumed to be small, but we are underestimating the number of slaughtered animals due to the slaughtering on the farms. However, the slaughtering at the farms are close to insignificant.

In the processing (Q8) there are almost no adjustments and imputations made, because we see the FR and the SR as already finalized. Hence, there are no checks for outliers. In the OR there may be occasional adjustments and imputations made. Since we have figures for all of the holdings, there is no standard error in our estimates (Q9). However, when we made a time series from 2009-2013 for the variables involved, we noticed smooth trend lines (D10).

In the process we have made comparisons between the OR and the FR (D1, D9). The data in the two different registers are not totally comparable since the FR measures the number of animals the first Thursday in June every year and the OR measures animals differently. For example, the OR measures the total number of broilers produced during the year. However, in this case we divided the number of broilers with the production time and received a number that we could compare with the FR. Our comparisons turned out well and even though there could be differences, we concluded that the material from the OR was of good quality.

In our model there could be missing values or duplicates in the OR, but we believe that the numbers are small (Q10, D6). The total bias of the totals is assumed to be low.

2.2 What is the result?

After some testing and evaluation, we came to the conclusion that we had a very good model. The figures are in line with other sources and we can easily update the model each year with new figures. The response burden on the farmers is zero, because we use administrative registers and the cost for us is very low since we do not need to make another survey.

3. Discussion

The two frameworks have proven to be an excellent help in deciding the direction of the work with organic meat production. We wanted to use registers to obtain the organic meat production, but we weren't sure of if the registers were good enough. Both of the frameworks are thorough and takes every detail into account. They are also an objective and a standardized way of determining the quality of the registers that you are about to use. They have helped us to really consider what options there are, as well as declaring the quality of statistics obtained from administrative sources.

We found that the FR and the SR were registers of good quality and with the two models by Daas et al. 2009 and Laitila et al. 2011 we could quantify just how good they really are. However, these registers are maintained by the SBA and are thus in our own control. The OR was less good, but sufficient enough to be used in our model. Since the OR is not in our own control, we depend on the three organizations that maintain the register, and as we could see, there were some problems with the register. When we combined all of the registers however, the framework proved to us that our model was of very good quality. We were also able to see where the model could be improved.

The two frameworks are similar. One advantage of the framework of Daas et al. 2009 is the focus on the procedures for accessing data and the legal prerequisites. One advantage of Laitila et al. 2011 is the focus on the production process indicators as a separate step.

It is obvious that the quality frameworks can be used to determine whether to use administrative registers or not. For us the frameworks have proven to be very helpful in our decision-making.

ABSTRACT

Resumé: Administrative sources provide huge amount data that could be directly or indirectly introduced in several phases of the statistical process. The use of administrative data for statistical purpose often requires matching records, due to the fact that an administrative source alone is unlikely to be enough to produce high quality results with negligible or admissible errors. One of the first purposes of combining administrative data is to collect a statistical register of the target population or at least a master frame for sampling: in some developed countries, census has been totally substituted by a set of high quality administrative registers. In general, the use of administrative data in official statistics seems a crucial step for modernizing the existing processes. This paper focalises the coverage aspect connected to the use of administrative data in census context, in particular because in this case the perspective is moving from the traditional census under-count issues to the strong relevance of over-count related to the use of administrative sources.

Keywords: Coverage errors, Register and sampling frame, Linkage errors

1. Introduction

Nowadays administrative data represent a great opportunity for agricultural statistics: their use allows to meet the increasing needs of knowledge and information even at local level, by means of already available data, without further collection cost and response burden. Administrative sources provide huge amount data that could be directly or indirectly introduced in several phases of the statistical process in order to improve the overall quality of information. However, the complete and conscious utilization of administrative data for statistical purpose requires to positively answer to questions related to their quality according to the statistical perspective and the effect of their usage on the overall quality of the statistical results.

The use of administrative data for statistical purpose often requires matching records, due to the fact that an administrative source alone is unlikely to be enough to produce high quality results with negligible or admissible errors. One of the first purposes of combining administrative data is to collect a statistical register of the target population or at least a master frame for sampling: in some developed countries, census has been totally substituted by a set of high quality administrative registers. In general, the use of administrative data in official statistics seems a crucial step for modernizing the existing processes. In evaluating the impact of the use of administrative data when building a statistical register (both for substituting traditional census or for preparing a master frame for sampling), with respect to the coverage issues, the perspective is moving towards the strong relevance of over-count of administrative sources. In fact, administrative data essentially ensure a broad coverage of the interest population thanks to several separate sources, even if a little degree of under-coverage for particular population subgroups could still remain. Conversely, over-coverage is expected to be the more substantial problem. Further coverage problems could be generated by the record linkage procedure utilized in order to match all the information related to the same units reported in the different data sources. This could dramatically happen when administrative sources refer to units that are associated only indirectly to the statistical units of interest.

This paper focuses on the effect of administrative source use, with particular attention devoted to over-coverage errors and matching errors. The work reports examples from the 2010 Italian Agricultural Census. In this context the target is to estimate the unknown total amount of farm

2. The coverage issues

Data collection is inevitably subject to error, whatever is the method used to collect it. Therefore, it is necessary to devise a mechanism to assess the quality and reliability of data sources, in order to make robust adjustments and to improve the quality of the resulting estimates. Coverage error in data collection can be classified in two main groups: under-coverage (units which are completely missed by the data collection process but should be included in the population definition) and over-coverage (additional erroneous units which appear in the collected data source but which should not be included in the population). For agricultural census, example of over-coverage might include, together with duplicate records, big kitchen garden erroneously classified as little farm; farm not more operating (death farm) but not cancelled on the list.

In the traditional census, coverage issue is primarily concerned with estimating and adjusting for under-coverage. This is generally achieved through an independent coverage survey (the PES, Post-Enumeration Survey) and a capture-recapture or Dual System model (Wolter, 1986) aiming at estimating those units which have not been enumerated both by the census and the survey. The capture-recapture (CRC in the following) model is subject to some strong assumptions:

1. the interest population is closed;
1. records from both data sources can be matched without errors;

3. units have the same capture probabilities within each sources (homogeneity probability assumption);
4. over-count in both sources is negligible;
5. the two sources of data are independent.

In formula, say N_{11} the units enumerated in both the census and the PES, N_{1+} the units recorded in the census and N_{+1} those captured in the PES, the Dual System estimator (DSE in the following) of the unknown total amount of the population N is:

$$\hat{N}_{DSE} = \frac{N_{1+} \times N_{+1}}{N_{11}} \quad (1)$$

Several extensions and adjustments of the DSE have been proposed over the time in order to avoid biases due to any failure of these assumptions – resulting in the DSE under-estimates or over-estimates of the true total amount of the population. For instances, without being exhaustive, the main methods used to include dependencies between sources and heterogeneity of captures are extensions of log-linear model (Fienberg 1972; Cormack 1989; Chao 2001, Agresti 1994), conditional multinomial logit model (Chen and Kuo 2001; Zwane and van der Heijden 2005), latent class model (Bartolucci and Forcina 2005) and Bayesian capture-recapture model (Ghosh and Norris 2005).

As far as the matching errors is concerned, Ding and Fienberg (1994) propose simple method to achieve “linkage error unbiased” estimates of population total by explicitly modeling the two types of matching errors. Generally, linkage errors are commonly subdivided in two groups: false matches when records referred to different entities are linked, and missing matches when records that really represent the same unit are erroneously left unmatched. False matches directly deflate the population totals, causing under-coverage of the census list, while missing matches directly inflate the population totals, causing over-coverage of the census list.

Recent works take into consideration bias due to the over-coverage of sources, particularly relevant when dealing with administrative data, affected by significant level of list inflation due to different reasons. Meeting the assumption of close population should help to reduce the over-coverage. It is clear that matching errors will determine bias in over-coverage adjustments, with inflation of over-coverage in case of missing matches and deflation of over-coverage in case of false matches. More and more complicated is the case in the farm field, because of farm demography, changing in organization and operational status, difficulties in verifying farm definition for small farms, etc. All these factors directly and dramatically affect the linkage results, with consequence impact on over-coverage assessment.

Large et al. (2011) propose an adjustment to the DSE in order to correct the census totals by the over-coverage components. For household and population census, they consider four types of over-count:

- duplicate returns at the same location (for example, a paper and internet return for the same household)
- duplicate returns from different locations (for example, students at their term-time and parents’ address)
- a return counted in the wrong place (local over-count),
- erroneous returns (units which should not be in the census population such as a baby born just after census day and included on the return).

Therefore, they estimate the correct number of census returns by both local and duplicate over-count and include it in the DSE.

The US Census Bureau carries out a further sample survey (the E sample) in the same areas of the PES in order to estimate erroneous records, that should not have been collected in the census. Due to US level of erroneous enumeration, a dedicated survey is considered in order to determine the correct enumeration, via field work in E sample survey. Therefore, the erroneous records are removed before DSE is calculated. In 2010, the estimation procedure uses logistic regression. These models allow the use of more variables, and therefore produce better estimates of percentage undercount by single demographic characteristics. Three logistic regression models were developed, according to the following dependent variables:

- the probability of being a 'data-defined' enumeration (the data source for estimating the model parameters is all census people in housing units)
- the probability of being a correct enumeration (the data source for estimating the model parameters is the people in the E sample)
- the probability of being matched (the data source for estimating the model parameters is the people in the P sample)

Predictions are then made by inputting the values of the independent variables for each census case into the estimated models. This enables the prediction of correct enumeration rate (with E sample) for census and match rate (with P sample) for census at person level and use these predicted values in the DSE estimation. The approach adopted for the E sample seems the most feasible to view out-of-date or incorrect administrative source records, that could be considered being equivalent to erroneous enumerations in the US census. This means to carry out two separate independent under-coverage and over-coverage surveys, and their records should be matched each other's prior to DSE being calculated.

3. Lesson learned by the 2010 Census of Agriculture in Italy

Coverage issues related to the usage of administrative archives for census purpose have been dramatically experienced in carrying out the PES for the 2010 Italian Agricultural Census. The last Italian agricultural census was register-assisted, that is a preliminary list was provided before the census field operations in order to assist to census mail out. This preliminary list was obtained by matching at unit level several (more then 10) agriculture-related lists: the main ones were agricultural benefit registers, fiscal registers, chambers of commerce registers, cadastral archive, the previous agricultural census list. The goal was to build a list of farms as complete as possible; each record on the list includes name, address, and telephone number of the farm operator plus additional information on the agricultural place, as the address of the farm headquarter and the size in acres of the farm. Most names on a newly acquired list were already on the building frame so those found were set aside and a score of activity status were assigned to each unit. A huge matching work has been done in order to recognize the same farm across the several administrative registers, each of them may report only partial information on the farm size, the farm operator, the land owner or someone involved in the farm operation (for instance a member of the family, a partner, an administrator…); however, with respect to the most ambiguous case, the pre-census list were built admitting some over-coverage. Then, the Census proceeded with field operations on the basis of this preliminary list.

Independently from the census and its preliminary list, to measure the census coverage errors, a PES was designed keeping in mind mainly the under-coverage issue, as usual in the previous census round. However, the linkage step of the PES data highlighted some evidence with respect over-coverage and further record linkage activities were carried out, matching PES data with all the administrative sources which contributed to the pre-census list. This complex linkage procedure allows to identify the main components of under- and over-coverage. The former ones were:

1. “non-response or kitchen garden”, farms included in the census list but hesitated as non-respondent or refusal or not eligible due their size (i.e. kitchen garden) after the census operation;
2. “in pre-census list”, farms that were in the pre-census list, but were classified as not eligible before the Census operations;
3. “in administrative archives”, farms stemmed in one of the original administrative sources but that have been excluded in the pre-census list;
4. “not present in any lists”, PES farms not linked with any units in Census, in pre-census list or in others available archives;

While the forth category represents under-coverage with respect to all the available information, the previous ones explain the under-coverage according to lists as less focused on farms as the number of the category increases.

As far as the over-coverage is concerned, the category “farm with multiple links” was used to represent the over-coverage risk, identifying those farms for which the linkage procedure proposed as correct link more than one unit in the census. Those multiple links (from n units in one file to m units in the other) couldn’t be solved according to any optimization algorithm (as in standard record linkage problems) because they represent actual mutual connections related to the land ownership or the farm operation conducted by several different relatives of the same family, on the same land area, at least on the basis of the available information.

Moreover, the category “farm demography” was introduced to measure the risk of linkage errors. In fact, strictly speaking the “farm demography” should not represent over-coverage, because continuity rules are respected in order to assure that the same unit has been identified. However, for these farms the linkage status is less positively defined, further investigations on different variables with respect to those utilized for the linkage were needed, in order to assess the continuity rules hold in despite of the strong changes in the demographic variables (names, organization, land ownership, land extension). So, according to the linkage point of view, the “farm demography” gives a measure of criticisms in identifying farms connected to the use of the administrative sources.

The previous phenomena can be summarized in the following tables, where figures on their impact are reported.

Table 1: *Percentage of under-coverage factors with respect to the total amount of under-coverage*

Cause of under-coverage	Relative Percentage
1. non response or kitchen garden	19.25
2. in pre-census list	5.52
3. in administrative archives	41.65
4. not present in any lists	33.58

Table 2: *Percentage of over-coverage and linkage errors with respect to the total amount of covered farms*

Over-coverage and linkage errors	Relative percentage on the total amount of covered farms
a. farm demography	5.51
b. farm with multiple links	1.91

Table 1 shows that the hardest component of under-coverage (farms not present in any lists) is just one third of the total amount. Most of the not-covered farms (41%) were remain in the administrative sources used to build the pre-census list, meaning that if the procedures adopted in forming the preliminary list is improved enough, the total census under-coverage will be halved. Conversely, the percentage of farms remained in the pre-census list is small (about 5%), while actual farms but differently assigned in the census list is a most considerable percentage (about 20%) with respect to the overall under-coverage. Finally, table 2 shows that the risk of linkage errors, represented by the "farm demography" that explain the difficulties in linking units connected to the same farms from the several administrative sources containing so different kinds of entities, seems bigger than the risk of over-coverage, explained by the "farm with multiple links".

The Table 2 provides measures of over-coverage and linkage errors manly related to the use of administrative data in preparing census list. These errors should be introduced in the selected estimator for the evaluation of the total amount of the interest population in order to reduce its bias. Nevertheless, as far as the 2011 Italian Agricultural PES is concerned, no adjustments were applied and these measurements were provided mainly to stress their importance in a future scenario where the traditional census would be substituted by a farm register built exploiting the administrative sources. In fact, it is important to underline the PES was not designed in order to measure and correct the over-coverage, but only to evaluate the under-coverage of the census list. Anyway, in the next paragraph, an exercise is proposed in order to evaluate the impact of linkage and over-coverage errors on the standard DSE results.

3.1 Adjusting for over-coverage and linkage errors: an exercise

In order to evaluate the effect of over-coverage, the census counts can be deflated by the estimated number of over-enumerated farms, obtained by means of the over-coverage risk represented by "farm with multiple links" reported in table 2. The approach is similar to those applied in UK and Israeli, with simplifications due to the reasonable assumption of absence of local over-coverage (farms are likely less and less moveable than people). In formula,

$$\hat{N}^{O}_{DSE} = \frac{(N_{1+} - \hat{O}) \times \hat{N}_{+1}}{\hat{N}_{11}} \qquad (2)$$

where the DSE estimator of the population total is corrected by the over-coverage error and the number of over-enumerated farms O, the PES totals and the units enumerated both by census and PES are sample estimates.

On the other hand, the adjustment for linkage errors can be obtained following the Ding and Fienberg (1994) proposal. In this context, the probability of missing a true link (i.e. the false non-matches errors, when records that really represent the same unit are erroneously left unmatched) can be considered negligible and approximated by zero (α=1, according to the Ding and Fienberg notation). Otherwise, the probability of false matches (when records referred to different entities are linked) can be evaluated by the risk of linkage errors represented by the "farm demography" (β=0.0551 in the Ding and Fienberg notation). The resulting "linkage error adjusted" DSE total estimator is:

$$\hat{N}_{DSE}^{L} = \frac{(N_{1+} + \hat{N}_{+1} - \hat{N}_{11})}{\hat{p}_{1+}^{L} + \hat{p}_{+1}^{L} - (1-\beta)\hat{p}_{1+}^{L}\hat{p}_{+1}^{L} - \beta\hat{p}_{1+}^{L}} \quad (3)$$

Moreover, the over-coverage and the linkage errors can be taken both into account, deflating the census totals of the estimated over-enumerated units and re-calculating the $\hat{p}_{1+}^{L}$ and $\hat{p}_{+1}^{L}$ as well. In this way, the following linkage and over-coverage unbiased estimator will be obtained:

$$\hat{N}_{DSE}^{L-O} = \frac{(N_{1+} - \hat{O} + \hat{N}_{+1} - \hat{N}_{11})}{\hat{p}_{1+}^{L-O} + \hat{p}_{+1}^{L-O} - (1-\beta)\hat{p}_{1+}^{L-O}\hat{p}_{+1}^{L-O} - \beta\hat{p}_{1+}^{L-O}} \quad (4).$$

In table 3, the resulting under-coverage ratios corresponding to these different estimators are reported, as well as the percentage relative difference with respect to the standard DSE estimate.

Table 3: *The coverage ratio estimates and percentage relative difference with respect to the standard DSE estimate*

	Under-coverage ratio estimates	Percentage Relative Difference
$\hat{\tau}_{DSE}$	11.70	--
$\hat{\tau}_{DSE}^{O}$	9.98	14.73
$\hat{\tau}_{DSE}^{L}$	11.44	2.21
$\hat{\tau}_{DSE}^{L-O}$	9.60	17.93

The table shows clearly that the adjustments for over-coverage and linkage errors work both in the same direction, decreasing the under-coverage rate. Moreover, even if the linkage errors risk seems bigger than the risk of over-coverage (table 2), their impact on the DSE adjustment is exchanged, the over-coverage adjustment being more effective than the linkage one. Finally, it seems important to remark that in this adjusting estimation exercise the measures of over-coverage and linkage errors were derived both from the PES, that was designed uniquely for evaluating the under-coverage. Due to the relevance of over-coverage issues when dealing with administrative sources, it could be preferable to achieve more reliable measures of this kind of error by means of explicit and specific methodologies, as a dedicated survey (like in US) or detailed analyses on a designed sample for quality assessment.

4. Concluding remarks and future works

This paper focalizes attention on quality issues in using administrative data, mainly stressing under-coverage, over-coverage and imperfect matching errors. Examples are reported, from the Post-Enumeration Survey of the 2010 Italian Agricultural Census. In this context the target is to estimate the unknown total amount of farm. The case is complicated by difficulties in recognizing the farm entity in the several administrative sources exploited for assisting the census, with consequent linkage problems in the resulting pre-census list. Other issues are related to changes and modification in the farm entities, the farm demography, also reflecting in linkage errors when comparing data sources. In the framework of capture-recapture models, generally adopted to evaluate the unknown total amount of a population, these facts represent removals of basic assumptions, i.e. the closeness of the population, the absence of over-coverage and the perfect matching hypotheses. Standard estimators should be adjusted in order to take into account the potential biases introduced when these assumptions do not hold, as already done in case of removal or relaxing the hypotheses of independence of captures and homogeneity of capture probabilities.

The analyses proposed in this paper try to recognize the main components of coverage errors so to identify possible solutions. Generally speaking, when administrative data are exploited for statistical purpose, strategies for minimising over-coverage are adopted, as well as for reducing matching errors. However, even if over-coverage is reduced there will likely be some unknown residual amount which the estimation methodology has to take account for. Moreover, minimising over-coverage risks increasing under-coverage and the robustness of the dual system estimation approach to departures from its assumptions tends to decline as under-coverage increases and this could risk unanticipated errors. It seems possible that the effect of matching errors and over-coverage could be in the same direction, leading to over-estimation of the population, due to the fact that even relatively small errors could lead to non-negligible biases. So further investigation in the estimation methodology is needed in order to adequately take account of these kinds of errors.

USE OF ADMINISTRATIVE DATA FOR AGRICULTURAL STATISTICS

Session Organizer
N. Keita | FAO | Rome | Italy

ABSTRACT

A large proportion of the data being currently produced in developing countries comes from administrative sources, mainly as a by-product of activities of extension workers and other administrative processes and this situation is likely to stay for a long time because of resource and capacity limitations in many of these countries to conduct proper sample surveys. Also because of the growing need for very low geographical level data and for early warning and pre-harvest crop forecasting data to inform governments on the prospective food situation which is mainly derived from crop monitoring and other auxiliary information produced by field staff. Furthermore, data on livestock, fishery, forestry, land and water is usually derived from administrative reports prepared by subject matter specialists. In developed countries, budget restrictions, respondent burden and availability of new tools and methods are prompting many countries and institutions to undertake research in new ways of producing agricultural statistics with a more important role of administrativesources. However, several studies have underlined the limitations of data from administrative sources in terms of their low quality for a number of technical reasons. This session will present and discuss findings from research undertaken on the improvement and use improvement and of administrative data for a cost effective agricultural statistics system both in developing country and developed country context. Papers can focus on successful research or implementation of methods and tools for use of administrative data in agricultural statistics in a country.

ABSTRACT

The Government has three main missions: to ensure the internal and external safety of the society, to create necessary prerequisites for sustainable development of every member of the society and to ensure the minimal needs of those members of the society, who can't yet/no more to cover their needs by themselves. Authorities who carry out the realization of state mission are government bodies that have administrative power (ministries, administrations, etc.), local self-government bodies and government bodies that render public services (non-administrative). Tools for administrative influence (for administrative competences) are registration and calculation of rights and liabilities, activity endorsement, permissions, prohibitions and prevention, encouragement and destruction, regulation and control. There are other tools for administrative influence such as checking, correction, inspection, monitoring, discussions of disputes and solutions, enforcement of penalties and restrictions, privileges, reimbursements, and gratuitous assistance, etc. The main principles of forming the administrative registers are definitions of concepts and criteria, classifications (status, type of activity, production, and administrative territorial and other units), coding (common identification codes), individual addressable information (developed as a result of using administrative tools). The administrative registers are individual addressable databases that are used by state and local self-government bodies, and are the basis and effect for administrative influence. The administrative registers are used by bodies that create administrative registers (realization of their individual addressable administrative influence authority), other bodies that possess administrative authority (by identifying it with individual data from other administrative registers), statistical bodies (for providing public statistical services), scientific and educational institutions and individual researchers (for providing scientific and research and educational services).

The peculiarity of use of administrative registers by official statistics is that official statistics, as a provider of statistical information, is entitled to use and modify the information received from administrative registers in order to ensure their compliance and comparability with statistical definitions and classifications. The data that is received in this way cannot be transferred to the primary information holder (administrative register) or transferred to the third party for the purpose of using them for administrative purposes.
Given the fact that for agriculture as a type of economic activity there are specific factors such as measurements regulated by the administrative legislation like the land, machinery, other fixed assets (from the viewpoint of property registration on land, machinery, other fixed assets and relations on their taxation), subsidies to economic units (from the viewpoint of the relevant administrative registrations and monitoring), numbering and movement of the livestock, including diseases control, etc., so the use of administrative registers, as a source of E-based information is actual and urgent.
Use of administrative registers is also stipulated by the fact that agricultural technologies by their character require more detailed regulation and control by administrative bodies, therefore, and more disaggregated registrations that are crucial for complete statistical indicators with the higher degree of aggregation.

Keywords: Administrative bodies, administrative records, definitions, classifications.

1. Introduction

In Armenia, under the centralized planning of the economy, the official statistics was used as consolidated and fragmented information for authorities. Official statistics mainly played the role of administrative information systems for government agencies at all the levels. Such practice took place in the transition period until 1999, when the Eurostat developed and presented the scheme of a model law on statistics based on the UN Fundamental Principles of Official Statistics. Based on that model law the National Statistical Service of the Republic of Armenia (NSSRA) has developed the new law "On State Statistics" that has been adopted by the Armenian Parliament and came into force on 10th May 2000.

2. Formation of administrative registers in transition period

According to the above-mentioned law, the change of the functions of statistics from a "state accountant" to a role of an information supplier for the whole society, economy and authorities is a process that should proceed in parallel in the framework of official statistics and administrative information systems.
However, in conditions of liberal economy an old inertia, which took place in the administrative cycles, hampered the process of formation of administrative registers. The official statistics supplier's legal refusal to draw up administrative information has certainly accelerated the process of formation of administrative information systems in the country. Laws on social cards, population register, securities market and others have been adopted. Amendments have been made to laws regulating the powers of administrative bodies on formation and maintenance of administrative registers both by activity and certain functions. In particular, by functions of state registration (property rights register, entrepreneurship rights, shareholders and others).

Powers for establishing administrative registers have been assigned to the general state agencies. However, this process is not always smooth, even with the methodological support of the NSSRA. The main reason for the complications of the process of formation of national registers is the lack of registers at the level of communities and regions.
In Armenia, with a population of 3 million there are 915 communities, of which 866 are rural, most of which are very small. Because of lack of resources the majority of communities (local self-government bodies) are not able to organize and establish administrative registers. Based on the new edition of the Law "On local self-government" the process to delegate new and necessary powers to communities has started, which has created a basis for their consolidation and implementation of the full administrative registration system. In particular, since 2004, the authority to collect the property tax has been delegated to urban communities, and, since 2005, the process has been extended to rural communities. In 2005, the country's population register has been established and started from the involving of communities.

3. Challenges of formation of administrative registers at the community level in transition countries

Taking into account the above mentioned developments, the NSSRA has developed and tested a model "passports of communities and regions", which are the necessary minimum sets of basic indicators describing the administrative information system of these territorial units. The piloting process has revealed a number of unsolved problems, connected with:

- technical equipment,
- professional training,
- methodological support,
- organizational links with regional and nation-wide registers,
- identification problems on perception other administrative and statistical registers, etc.

According to the description and analysis of the current situation there are the following tasks in transition countries:

- a clear definition of statistical and administrative purposes and character of links between them,
- providing guarantees for non-involvement of official statistics in the conflict of administrative and similar interests,
- a clear legal distinction between statistical and administrative information,
- formation of a complete system of administrative information in the country,
- providing easy use of administrative information for statistical purposes,
- promotion of expanding the scope of the administrative information on the basis of modern information and communication technologies,
- developing methodologies and improving the quality of administrative information,
- developing and improving statistical methodology for the use of administrative records for statistical purposes.

4. General factors of formation of administrative registers in transition countries

There are the following factors that could help to solve the above-mentioned tasks:

- general accounting and statistical culture of the country,
- complexity of the payment and accounting system of the country,
- completeness of reforms in the country's management system,
- level and scale of the use of international standards and classifications in the payment and accounting system of the country,
- universality, accessibility and comparability of the methodology used at national and international levels,
- degree of complexity (simplification) of procedures and tools of state registration, licensing, permits, etc.
- level of self-regulation of local self-government bodies.

In conclusion, it should be emphasized that for countries in transition a starting point to solve the above mentioned problems, from the NSS RA` point of view, is an intensification of stimulating formation of administrative registers at the community level. This process has not just statistical and administrative value, but also political one. Strengthening the accounting capacity of communities will enhance their role as a source of administrative information, thus reducing the possibility of the temptation to use statistical data for administrative purposes that at the same time will improve the quality and integrity of the state administrative registers.
In general, this process will affect on the ability of the interactive character of administrative information, thus highlighting the problem of perception of information flows in both administrative and statistical systems. All this, in a long run will promote to improve the quality of information and to achieve a high level confidence in any information systems, and to form an information society.

5. The Government mission as a basis to form administrative registers

The Government has three main missions: to ensure the internal and external safety of the society, to create necessary prerequisites for sustainable development of every member of the society and to ensure the minimal needs of those members of the society, who can't yet/no more to cover their needs by themselves.
Authorities who carry out the realization of state mission are government bodies that have administrative powers (ministries, administrations, etc.), local self-government bodies and government bodies that render public services (non-administrative).
Tools for administrative influence (for administrative competences) are registration and calculation of rights and liabilities, activity endorsement, permissions, prohibitions and prevention, encouragement and destruction, regulation and control. There are other tools for administrative influence such as checking, correction, inspection, monitoring, discussions of disputes and solutions, enforcement of penalties and restrictions, privileges, reimbursements, and gratuitous assistance, etc.
The main principles of forming administrative registers are definitions of concepts and criteria, classifications (status, type of activity, production, and administrative territorial and other units), coding (common identification codes), individual addressable information (developed as a result of using administrative tools).

6. Main characteristics of administrative registers

The administrative registers are individual addressable databases that are used by state and local self-government bodies, and are the basis and effect for administrative influence.
The administrative registers are used by bodies that create administrative registers (realization of their individual addressable administrative influence authority), other bodies that possess administrative authority (by identifying it with individual data from other administrative registers), statistical bodies (for providing public statistical services), scientific and educational institutions and individual researchers (for providing scientific and research and educational services).

7. Peculiarity of using administrative registers for agricultural statistics

The peculiarity of using administrative registers by official statistics is that official statistics, as a provider of statistical information, is entitled to use and modify information received from administrative registers in order to ensure their compliance and comparability with statistical definitions and classifications. The data that is received in this way cannot be transferred to the primary information holder (administrative register) or transferred to the third party for the purpose of using them for administrative purposes.
Given the fact that for agriculture as a type of economic activity there are specific factors such as measurements regulated by the administrative legislation like the land, machinery, other fixed assets (from the viewpoint of property registration on land, machinery, other fixed assets and relations on their taxation), subsidies to economic units (from the viewpoint of the relevant administrative registrations and monitoring), numbering and movement of the livestock, including diseases control, etc., so the use of administrative registers, as a source of E-based information is actual and urgent.
Use of administrative registers is also stipulated by the fact that agricultural technologies by their character require more detailed regulation and control by administrative bodies, therefore, and more disaggregated registrations that are crucial for complete statistical indicators with the higher degree of aggregation.
According to the RA Law "On State Statistics" and based on the results of agricultural census conducted for the first time in Armenia in 2014 and usage of relevant administrative registers, the NSSRA will establish a statistical farm register for statistical purposes that could be used as a frame for sample surveys, as well as to complete survey data, and could be linked with state administrative systems, particularly land balance, livestock and machinery registers.
The NSS RA actively cooperates and has close partnership relations with administrative data providers to assure the data quality. According to the RA Law "On State Statistics" the NSS RA effectively coordinates administrative statistics. The NSS RA has concluded the Agreements with owners of administrative data on the access to and use of administrative data for statistical purposes. The NSS RA provides methodological support, including training materials to ministries and other public authorities to properly manage their administrative registers.

8. Conclusion

In countries in the course of management reforms, the capacities of administrative registers in the field of administrative records should be strengthened, including technical capacity and training, as well as interrelations among them and with the NSOs should be enhanced to use common identification codes, definitions and classifications.

ABSTRACT

Agricultural production data have been mainly compiled by Turkish Statistical Institute (TurkStat) through regional offices of Ministry of Food, Agriculture and Livestock (MFAL) in district detail. Many administrative sources are used in data collection for crop and animal production statistics by the agricultural engineers, veterinarians, and technicians in the province and district offices of MFAL. Current study presents information about the administrative data, and the statistical data network used for data compilation, the scope of the administrative data, and the data analyze methods used in producing agricultural statistics compiled by TurkStat.

Keywords: Administrative data, Agricultural production, Statistics, Turkish Statistical Institute

1. Introduction

It is needed to produce reliable and timely agricultural production statistics in order to monitor the developments of agricultural production sector, and to develop agricultural policies. In Turkish Statistical Institute (TurkStat), there are two kinds of data source used in agricultural production statistics (i) administrative data (e.g. yearly crop and animal production statistics) and (ii) vey data (e.g. monthly poultry statistics, milk and milk products statistics).

'Administrative data' is defined as the set of units and data derived from an administrative source (OECD, 2002). And, it is collected for administrative purposes by administrative sources, and not primarily intended for research or statistical purposes (Smith et al., 2004, ADLS, 2016). The administrative data has intensely used, and has ensured important advantages in producing agricultural statistics in Turkey.

Many data on animal production, crop production, production under protective cover area, organic farming, pesticides use, and fertilizer use are based on administrative records and agricultural technician's regional observations through Province and District Offices of the Ministry of Food, Agriculture and Livestock (MFAL) in Turkey.

[1] The opinions and contents of the article remains the responsibility of the author, not of the Turkish Statistical Institute.

Current study presents information about the administrative data, and the statistical data network (SDN) used for data compilation, the scope of the administrative data, and the data analyze methods used in producing agricultural statistics.

2. Scope and Method

Agricultural production data have been mainly compiled by TurkStat through regional offices of MFAL in district detail. Many administrative sources are used in data collection for crop and animal production statistics by the agricultural engineers, veterinarians, and technicians in the province and district offices of MFAL. These sources are Farm Registration System (FRS), Turkish Veterinary Information System (TURKVET), National Milk Recording System, National Red Meat Recording System, Agricultural Information System, Land Parcel Identification System, Greenhouse Registration System, Organic Farming Information System, Agricultural Fertilizer Register System, Agricultural Pesticides Register System, Ornamental Plants Register System, Sea Products Information System, Apiculture Registration System, Sheep and Goat Registration System, National Sheep and Goat Information System, Pedigree and Pre-pedigree Registration System.

FRS and TURKVET are the most comprehensive administrative sources in MFAL. FRS is an agricultural database, which the farms are registered by MFAL. The farmers should present requested documents to register to the system. The government promotes the farmers to register to the system (e.g. subsidies, grain purchases etc.)

TURKVET is a database based on the ear tags of animals. The system is formed by MFAL regional offices, and ensures to monitor the animals from birth to death.

Animal production statistics compiled by TurkStat consist of data on number of bovine animals, sheep and goats, poultry, meat, egg, milk, wool, hair and mohair production, apiculture, and sericulture. These data except for sericulture have been compiled via SDN system through regional offices of MFAL in district detail. Data on sericulture is compiled from Bursa Silk Cocoon Association of Agriculture Sales Cooperatives.

The data on crop production (sown area, harvested area, production, yield, number of fruit trees, fallow land), production under protective cover area have been compiled via SDN system through regional offices of MFAL in district detail same as in animal production. Moreover, organic farming and fertilizer use data have been compiled from MFAL through Organic Farming Information System and Fertilizer Sales data, respectively. Sugar beets production data has been compiled from Turkish Sugar Authority, tobacco production data has been compiled from Tobacco and Alcohol Market Regulatory Authority, and poppy (capsule and seed) data has been compiled from Turkish Grain Board (TurkStat, 2015).

Agricultural production statistics by theme compiled by TurkStat and administrative data used are presented in Table 1.

Table 1. *Agricultural production statistics by theme compiled by TurkStat, and administrative data used*

Agricultural production statistics by theme	**Data source**	**Administrative data used**
Agricultural Land and Forest Area	Ministry of Food, Agriculture and Livestock (MFAL)	• Farm Registration System • Agricultural Information System • Land Parcel Identification System
Production and Area of Crop Products	MFAL, Turkish Sugar Authority, Tobacco and Alcohol Market Regulatory Authority	• Farm Registration System
Crop Products Balance Sheets	Various	• Farm Registration System • Turkish Feed Manufacturers' Association Registers • Agricultural Cooperatives' Registers
Production for Land Under Protective Cover	MFAL	• Greenhouse Registration System
Organic Agriculture Statistics	MFAL	• Organic Farming Information System
Ornamental Plants	MFAL	• Farm Registration System • Ornamental Plants Register System
Agricultural Fertilizer Statistics	MFAL	• Agricultural Fertilizer Register System
Agricultural Pesticide Statistics	MFAL	• Agricultural Pesticides Register System
Number of Animals by Type	MFAL	• Turkish Veterinary Information System (TURKVET) • National Sheep and Goat Information System • Pedigree and Pre-pedigree Registration System.
Monthly Production of Milk and Milk Products	Survey	-
Number of Hen Eggs	Survey	-
Number of Animals Slaughtered and Production Quantity of Red & Poultry Meat	Survey	-
Animal Products (other)	MFAL	• Turkish Veterinary Information System (TURKVET) • National Milk Recording System • National Red Meat Recording System • Apiculture Registration System
Apiculture		• Apiculture Registration System
Sericulture	Bursa Silk Cocoon Association of Agriculture Sales Cooperatives	• Bursa Silk Cocoon Association of Agriculture Sales Cooperatives' Registers
Sea Products	Survey	• Sea Products Information System
Inland Water Products	MFAL	• Sea Products Information System
Aquaculture	MFAL	• Sea Products Information System

SDN is a data entry system, where the data are entered by the agricultural engineers, veterinarians, and technicians in the province and district offices of MFAL via electronic media. The MFAL technical personals use above-mentioned administrative records of MFAL in data entry.

In analysis of data in SDN, firstly the data provided by MFAL regional offices have been controlled by MFAL Central Office. And then TurkStat analyzed the data by using change ratios, consistency analysis, confidence intervals, and outlier detection. Then, TurkStat forms the list of suspected data, and re-sends to the MFAL in order to control suspected data (Fig. 1). After the data analyze process, the statistics have been published via Press Releases and statistical tables through web media.

3. Conclusion

When the high number of farms in Turkey, about 2,2 million (MFAL, 2014), is considered, administrative data has an important role in agricultural production statistics. The use of administrative data ensures following advantages in producing statistics: simplicity, speed and frequency of updating; lower costs; wider coverage, completeness and disaggregation; and low-response burden (ADB, 2010). Administrative data has widely used in agricultural production statistics in Turkish Agricultural Statistics System because of these advantages. However, there are some disadvantages of using administrative data. Smith et al. (2004) summarized the disadvantages of administrative data as follows;

- Information collected is restricted to data required for administrative purposes
- Lack of researcher control over content
- Proxy indicators sometimes have to be used
- May lack contextual/background information
- Changes to administrative procedures could change definitions and make comparison over time problematic
- Missing or erroneous data
- Quality issues with variables less important to the administrator e.g. address details may well not be updated
- Metadata issues (may be lacking or of poor quality)
- Data protection issues
- Access for researchers is dependent on support of data providers
- Underdeveloped theory and methods

There are some of above-mentioned disadvantages in administrative data used in Turkish Agricultural Statistics System. Particularly, missing use of classification and of national address codes in the administrative registers, and lack of coverage in the administrative register systems. Development of these issues in administrative data is important to increase the quality of agricultural statistics. For the development of agricultural registers in Turkey, some additional works have been started since 2014 in the scope of establishing Agricultural Production Register System (APRS). In APRS, which uses quantified agricultural land parcel information, the main variables (agricultural production, land use, animal production, agricultural equipment etc.) of agricultural holdings have been obtained for the production year, and it is planned to revise the system annually (MFAL, 2016).

ABSTRACT

Swedish official statistics in the agricultural area has since 1995 been based upon the extensive use of administrative data. However, in most cases it is not advisable to produce statistics direct from administrative registers. This paper reviews the methodologies and techniques used in order to ensure sufficient statistical quality when using administrative sources together with the Farm Structure Survey for the creation of the statistical farm register. The Farm register (FR) is used as a sampling frame for all agricultural statistics based on holdings.

In the paper we will show how the frame can be updated regarding the holdings constituting the frame as well as regarding the characteristics for example area of different crops, rented land and number of animals needed to stratify samples. The results show that integrating administrative registers with surveys is a cost-effective way of updating the frame while reducing the burden on respondents. Various aspects of the quality dimensions “accuracy”, “comparability” and “coherence” are the key issues for development in order to improve the quality when integrating registers and surveys. However if extensive, systematic work is integrating registers and surveys, the quality in these dimensions can be high. It is shown that there is at least as much need for work with improving quality, methodological studies and quality assurance for statistics based on administrative registers as for statistics based on sample surveys. When using administrative registers, the integration phase where data from several sources are integrated into a new statistical register is central for improving quality.

Keywords: register-based statistics, administrative registers,

1. Background and aim

At least from 1965 and onwards agricultural statistics in Sweden has been dependent on an updated Farm register (FR). The FR consists of all agricultural holdings in Sweden as well as variables needed for creating a typology consisting of type of farm, size of farm and region. The variables include different kinds of animals and crops, rented land and some general information about type of holding and the holder. The typology is used to stratify effectively and thus minimise the sample in almost all agricultural sample surveys. Up until 1996 the FR was updated by a yearly census where farmers were asked about all crops and animals.

When Sweden joined the EU in 1995 administrative registers of all farms applying for EU-subsidies where made available for statistical purposes. Subsequently several studies were made to see how the registers best could be used for agricultural statistics. Selander et al. (1998) and Wallgren & Wallgren (1999) for example compared IACS (the register for area-based subsidies) from 1996 with the objects in the FR from 1995. The results showed that 88 per cent of the objects matched, 4.9 per cent of the objects had multiple links between the registers and 6.9 per cent could not be found in IACS. Of the objects in the IACS register on the other hand, 2.9 per cent could not be found in the FR. As a result of the studies work the following years were focused on integrating the registers and FR. Several questionnaires were sent to subgroups of farmers asking them about keys in IACS.

In recent years Dias et al. (2016) has shown, with the example of Portugal, how alternative methodologies to a traditional population-census could be evaluated. They conclude that since there are advantages and disadvantages to all methods, it is important to make a systematic evaluation so that the trade-offs between options could be taken into account in the decision making process. It is stressed that registers might not have all the content needed; instead the registers may need to be combined with traditional surveys. The findings in the studies of Wallgren & Wallgren (1999) also showed that it is not possible to produce the FR directly from administrative registers. However they showed that administrative registers could be used for updating the objects in the FR as well as give information on some variables, for example crops.

As a result, starting in the year 2000 the FR was no longer updated with an annual full census, instead it was updated with an integrated use of registers and surveys in the years for which EU require the member states to conduct a Farm structure survey (FSS) according to regulation (EC) 1166/2008. In the years in-between, the FR is updated mainly from registers, together with information from a sample survey on animals. In recent years additional registers have been used, for example administrative registers on cattle, sheep, poultry and pigs.

When using an administrative register there is at least as much need for methodological studies and quality assurance as for statistics based on statistical surveys. However, the quality deficiencies and the approaches to investigate and resolve them differ. Several studies, for example Wahlgren & Wahlgren (2014), Laitila et al. (2011), Daas et al. (2009, 2010) and Agafitei et al. (2015) have discussed quality frameworks for using administrative registers for statistical purposes. This includes the quality of the register itself, the possibilities of integrating administrative registers into statistical registers and how to document the quality of the statistics produced. There is also a discussion about which part of the process to focus on. Holmberg (2015) summarises that there is an ongoing theoretical development on how to assess the quality of administrative data, but that more work is needed for example regarding linkage errors and cowerage errors.

The framework by Daas et al. (2010) is recommended by EU (2016) for assessing the quality of administrative registers. In 2016 the framework was used for evaluating registers for FSS 2016 (SJV, 2016)

1.1 Aim of the paper

This paper will describe how the FR in Sweden is updated using administrative registers in combination with some census data. The quality achieved by using the administrative registers in combination with a statistical survey will be compared to what quality could be achieved by updating FR using only a census and using only administrative registers. The framework recommended by Eurostat (2016) presented by Daas et al. (2010) will be used to highlight the quality in the administrative registers.

The quality will be described according to the quality criterias stipulated in regulation (EC) No 223/2009 on European statistics. Furthermore aspects of cost-effectiveness, privacy and response burden will be addressed.

2. Updating the Farm register (FR)

Figure 1 shows that the overall method for creating the FR is to make a maximal sampling frame (2) with combining the objects in the FR from the latest FSS year (1a) by all new possible objects that can be found in registers (1b). Next a questionnaire is sent out to the maximal sampling frame (3), and a current FR is made (5) by combining the information in the maximal sampling frame with information from the questionnaire (4). In the end the variables needed for the typology are added.

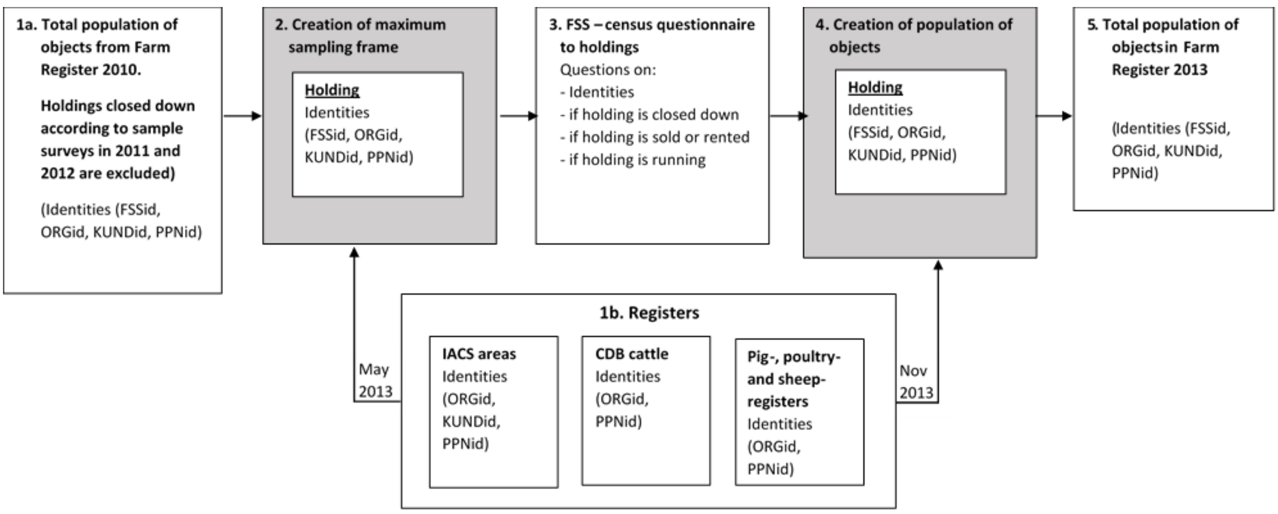

Figure 1: *Creation of the Farm register 2013.*

The target population of the farm register is the same as the target population of FSS. The variables of animals and crops in FR are also defined in the same way as the variables for animals and crops in FSS. I.e. producing the FR means doing a large part of the work needed for FSS.

2.1 Creating the maximal sampling frame

In the beginning of 2013 the total population was taken from the 2010 Farm Register. The indicators related to the source as described in the hyper-dimensions of (Daas et al., 2010) are used to describe the quality of the registers. The Swedish Board of Agriculture is the supplier of the data sources for all registers except the Business register (BR), where the supplier is Statistics Sweden. The Board is also the responsible NSO for agricultural statistics, so privacy and security rules are in place. Historically the registers have always been delivered in time. All persons and organisations in the registers as well as in the FR have a unique organisational number (ORGid). The ORGid is therefore always a linkable auxiliary key between registers.

The IACS register is highly relevant. It consists of all holdings applying for area based subsidies in May each year. In IACS about 60 codes for crops are included. It has unique keys (KUNDid) and the linkability is high. It has clear definitions and the information is well checked. However there is an under-coverage since about 10 per cent of the holdings do not apply for or are eligible for area based subsidies. Following the definition in FR a holding might contain several KUNDid. IACS could be used both for updating the register and for a large proportion of the variables.

The registers for poultry, pigs and sheep as well as the cattle database are aimed at tracing animals in case of an outbreak of a contagious animal's disease. Each production-place with these animals have a unique key (PPNid). The production-place is related to a person or legal entity with an organisational number (ORGid). One holding can relate to several production-places. The information in the registers differs. The poultry-and pig- registers mainly holds information on the number of animals that could be held at the production-place.

In the sheep-register additional information on the number of sheep in December are added by a questionnaire. There is a unit non-response of about 24 per cent. This register also has an over-coverage of about 20 per cent. It can be assumed that the over-coverage of the poultry- and pig-registers is the same. The under-coverage is small since the PPNid needs to be reported when animals are slaughtered. These registers could be used to update the objects in the maximal sampling frame but the quality is not sufficient for the variable values.

In the cattle-database each head of cattle has an identifier that is related to a production place (PPNid). There is, however, no distinction in the register between dairy-cows and cows for meat-production. Information from a second auxiliary register of milk deliveries is used to obtain the required information. It is assumed that if the holding delivers milk in the month of the reference day, the cows on the holding are all dairy cows. This approach will result in a small over-estimation of dairy cows and subsequently an underestimation of cows for meat-production. However a sample survey conducted in 2002 showed that the error was less than 1 per cent. The cattle database is therefore used both for updating the objects and for the variables needed for cattle.

The use of registers means that the postal questionnaire sent to the farmers did not have to include questions on crops and cattle since this information is available from registers. Only questions on the number of horses, poultry, pigs-, and sheep were included. Since there could be multiple to multiple objects in the different registers, the order of merging is decided by specific rules. Each holding in FSS has a set of related keys (for example Orgid and KUNDid). The keys are ordered by their quality. If there are multiple possibilities of linking, the key ordered the highest i.e. with the best quality is used first.

The linkages made in the spring 2013 showed that 64 036 objects could be linked to the registers while 11 689 holdings in the FR 2010 could not be found in registers. 3 004 of them had not been found in registers 2010 either and 8 685 are holdings that existed in registers 2010 but not 2013. Information from sample surveys done in 2011 and 2012 indicate that 800 holdings had closed down during the period. 868 additional holdings were found in the cattle register, IACS or the pig-, poultry-, and sheep registers. 934 horticultural enterprises in the business register were added to find horticultural holdings that might fit into the frame. In the end the maximal sampling frame amounted to 77 527 holdings. By creating the sampling frame this way there will be an over-coverage in the frame. The under-coverage is assumed to be small as long as the holdings were present in 2010.

When the questionnaire was created it included questions regarding what keys (ORGid, KUNDid, PPNid) that were related to the holding and whether it was sold, rented out, closed down or still running. If the holding was sold or rented out it was asked who was now running the farm. It is assumed that most of the 8 685 holdings that could no longer be found in the registers are no longer farmers, but some of them are likely to be the same as the 868 holdings that were found in registers but not in the register from 2010. This together with the linkage process could mean that the same holding might get more than one questionnaire. Whether this has occurred is therefore a question in the questionnaire. The questionnaire also includes questions on animals and rented land, variables that could not be found in the registers. The variables grazing land and arable land are included as a reference to the area of rented land.

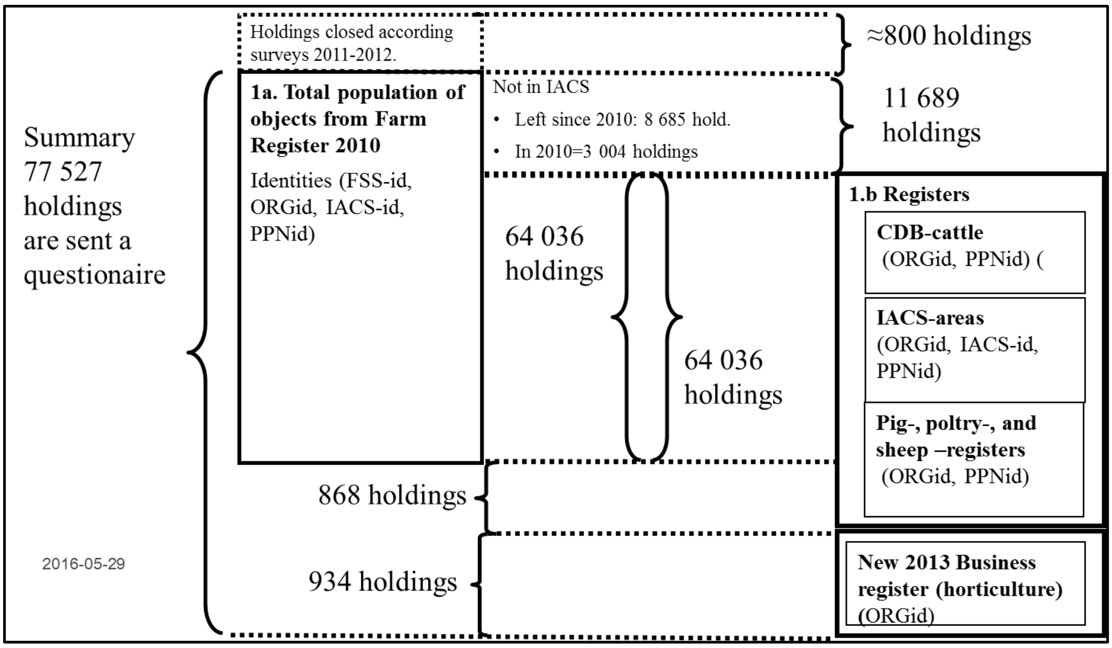

Figure 2. *Creation of the maximal sampling frame.*

2.2 Results from 2013

In November when the answers from the questionnaire were processed, updated data was gathered from the registers and related to the reference time. The information from the questionnaire and the registers was matched and the population of objects for 2013 was created. In the questionnaire the set of keys and the quality of the keys related to the holding were updated. The linkage was then made using the same principles as when creating the sampling frame. The linkage resulted in 67 126 holdings in the FR for 2013.

613 duplicates were found. The duplicates were mostly holdings in FR 2010 that were not found in registers included in the group “left since 2010”. The duplicates were due to linkage errors.

The holdings in the group “left since 2010” were mainly growing crops. Out of the 8 684 holdings 3 125 had been closed down and 3 626 had been taken over by another holder. I.e. only 16 per cent were still farmers so there is a large over-coverage in this group. Out of the 3 004 holdings in the group “In 2010” 989 holdings had closed down and 541 had sold the farm to someone else. I.e. 58 per cent were still running the holding. It could be concluded that those holdings that for several years are running their business without applying for subsidies continue to do so.

The results regarding the horticultural register showed that 30 per cent were still running their holdings. 574 holdings had closed down and 77 had sold it to someone else. For the holdings in this group it is more common to close down the business than letting someone else continue it. Out of the holdings in the pig-, poultry-, and sheep groups about half were still running their holdings and out of the large group that matched with IACS 98 per cent were still running their holding.

When the population was created, the variables were connected to the objects using the established links of keys. The information on areas and crops given in IACS as well as information about cattle given in the cattle register are considered to have high quality since the information is subject to extensive controls. For example, the holding is requested to give information about the total area of arable land in hectares as well as the total area of rented arable land in hectares. If the total area of arable land differs from the summarised areas of arable land used for different crops in IACS, the IACS figure will be used. As a result, the answers in the questionnaire were only used to calculate the share of rented arable land at the holding. The divergent answers could also be a sign that the creation of objects had not been fully successful. Consequently the information was used to improve the creation of objects.

3. Comparing quality between registers, census and multiple source

Every 10:th year a full census needs to be made meeting the target-population of FSS according to regulation (EC) 1166/2008. The census includes the variables in the FR. The alternatives which are interesting to compare are different methods for updating the FR in the two times during the 10 year period when the FSS is stipulated to be made as a sample survey. The three alternatives compared are a:

1. combination of census and registers i.e. the current method described in section 2,
2. register based approach, using registers in combination with the FSS-sample survey,
3. full census based method using a census and not any of the registers available.

3.1 Cost-effectiveness, privacy and response burden

Privacy and the principle that information given for statistical purposes should not be used for administrative purposes are fundamental when producing statistics (Eurostat 2016). On the other hand, administrative registers may be used for producing statistics. In Sweden, the Official Statistics Act (2001:99) addresses data disclosure and the Secrecy Act (1980:100) addresses the confidentiality of individual information. In the case of the FR, individual data from administrative registers are protected by the Secrecy Act (1980:100) when used for statistical purposes, regardless of whether the data would be public or not from the body responsible for the administrative register.

Using administrative registers is also a way of reducing the burden on respondents. At our user-meetings the Union of Swedish Farmers states that it is favourable to share information between governmental bodies in order to make it possible for farmers to only provide the same information once. The hours spent filling out the present set of questionnaires are calculated to 5 800 hours. If no administrative registers where used the questionnaire would also need to have information on all animals and all crops and the total number of hours spent could be calculated to 9 600 hours. If only administrative registers were used the time would be 0. However compared both to the current method used and the full census the quality of the register would be lower. The samples for surveys in the years 2014-2020 would need to be larger. We have calculated those extra hours to 9 500 hours. This includes larger samples for the sample surveys of crops, rented land, fertilisers and the census 2020. Over the 10 year period the difference between register-based statistics and the current method regarding response-burden is low.

The total cost for the current method used in 2013 was 750 000 euro. The cost for a full census through postal questionnaires could be estimated to 1 100 000 euro and for producing the statistics solely from registers to 450 000 euro. However there would be an additional cost for the larger samples in the years 2014-2020. Producing statistics from administrative registers is cost-effective in relation to postal questionnaires. From a cost-effectiveness point of view it can be seen that a large proportion of the cost is due to handling paper questionnaires. In 2013 only 20 per cent answered using the web service. I.e. the most obvious way of saving money would be to persuade farmers to answer through the web.

3.2. Quality criteria

Relevance refers to the degree to which statistics meet current and potential needs of the users. The updated FR is harmonised with the target population and some of the variables in FSS. I.e. the needs from EU-legislations are met. The FR also can be used to disseminate statistics for small regions or groups as well as combining data in new ways without restrictions. It could be assumed that a full census would meet the same quality criteria. If the FR were updated only by registers it would still fulfil the needs from EU-legislation regarding FSS. However since animals would be sampled it could only be used for producing statistics on NUTS3 sometimes NUTS2 level.

Accuracy refers to the closeness of estimates to the unknown true values. For register-based surveys, key issues are integration errors as well as how well the definition of objects and variables in the registers correspond with the required definitions in the statistics. The problems of matching different sources should not be underestimated. There is a risk for over-coverage in the FR. Parts of the same holding or the same areas could be counted several times. It is possible that a landowner, who is no longer cultivating his land and who belongs to the 8 685 holdings that could not be found in the register, answers the questionnaire on the basis of the land that he owns without cultivation. At the same time, the tenant of the same land who has applied for subsidies also states that he uses the land. Using only a census would lead to an under-coverage of the FR since the holdings not applying for subsides might be lost and new holdings more difficult to find. Using only registers for creating objects might also lead to an under-coverage since holdings not in the subsidy systems would be excluded.

For *timeliness* i.e. the period between the availability of the information and the event or phenomenon it describes there are no differences between approaches. Wallgren & Wallgren (2014) stress that timeliness is often a problem when using administrative registers. However in the case of IACS and the cattle-database this is not a problem. IACS data are available in May the reference year and the cattle-database is updated constantly.

Punctuality which means if release dates are kept, *accessibility and clarity* that has to do with the user's possibilities to access and compare data and *coherence* i.e. if the information is put together and presented in a logical way present no differences between alternatives.

Concerning *comparability*, or the possibility to compare results over time, problems might occur. Statistics based on administrative registers are dependent on changes that the statistical bodies may not be able to predict. For example, the change in the CAP in 2005 meant that the holders applying for subsidies in 2005 would be eligible for subsidies in subsequent years. The changes in the CAP affected the statistics in several ways, for example the number of holdings increased. Two explanations to this increase could be found. Firstly it was thought that small farms that had not been eligible for subsidies now applied for subsidies and were consequently incorporated into the population of holdings. The change in administrative rules thus improved the quality of the FR, correcting a previous under-coverage. Secondly, it could be assumed that some landowners applied for subsidies although the land in practice was cultivated by a neighbouring holder, leading therefore to over-coverage in comparison with the definitions in the FR. This problem would be the same for the register based approach but would not occur for the alternative based on full census.

The quality in terms of comparing results from registers and surveys are high because of the wide-ranging work done to merge different registers. In this sense the quality would be lower in the two other alternatives.

1. Conclusion

To conclude the use of registers is cost-effective and reduces the response burden for the holdings. Regarding the quality criteria of relevance, there are advantages to integrating registers with surveys and censuses when collecting data for the FSS. On one hand, in solely register-based surveys, the register may not cover the requested variables. On the other hand, in solely statistical surveys, the questionnaire would be expensive and cause a high response burden. Regarding the dimension of timeliness, the registers used for the FSS are updated and available earlier than results from a survey or census would be. When comparing the accuracy of the results, there are several aspects to consider. However, integrating registers and surveys as well as only using a statistical survey is considered to give accurate results. The coherence and comparability is assumed to be the highest when registers and surveys are integrated because of the wide-ranging work done to merge different registers. The availability is good in all three alternatives.

The paper shows that different aspects of accuracy are the key issues to consider in order to improve the quality when integrating registers and surveys in the FSS.

ABSTRACT

Agricultural surveys traditionally consist of censuses and sample surveys. The *sample surveys* commonly use stratified cluster sampling or stratified multiple-stage cluster sampling designs to select sampling units as farms or households from an area frame. The Farm Census is often based on a frame that is based on the agricultural households in the Population and Housing Census.

Many countries have started to use administrative registers with microdata to produce social, economic and agricultural statistics. The countries in northern Europe started the transition from a traditional, area frame-based statistical system into a completely register-based system in the 1960s. Since 1997 Eurostat has been in favor of the member countries' increasing use of administrative registers for statistical purposes.

In a register-based system, all sample surveys are based on frames that have been created with statistical registers. In addition, for a *census* such as the Farm Census, the Farm Register is used as a frame and questionnaires are sent to all farms to gain additional information that is not already in the register. A third kind of survey is based entirely on available microdata in the system of statistical registers. The traditional Population and Housing Census is replaced by a number of such *register surveys* that are based on statistical registers created by the national statistical institute. The statistical registers can be used to create an integrated register system, where microdata can be combined and used efficiently. Consistency and coherence are important quality dimensions that can be measured and improved through the systems approach.

Expert judgements or *eye estimates* are often used in Agricultural Routine Data Systems to produce agricultural statistics in developing countries. Unfortunately, this kind of data is often called *administrative data* as in FAO (2015e). The methods used for expert judgements have nothing in common with the methods used for censuses, sample surveys or register surveys. Administrative data originates from administration of separate units as persons or enterprises – expert judgements are not used in this way and should not be called administrative data. In contrast to administrative data, data collected in Agricultural Routine Data Systems do not represent something new in agricultural statistics.

The *Global Strategy to Improve Agricultural and Rural Statistics* by the World Bank, FAO and the UN (2011), was launched to modernize and improve agricultural statistics in developing countries. One important goal is that agricultural statistics should become an integrated part of the national statistical system. Another part of the strategy is for administrative data to play a more important role in the production of agricultural statistics than today. FAO has therefore published a number of working papers on *Improving the Methodology for Using Administrative Data in an Agricultural Statistics System* (FAO 2015a–e).

This paper discusses the long-term strategy for developing agricultural statistics to achieve integration with the national system and the more efficient use of administrative data. The ultimate goal is to create a statistical Farm Register that can be regularly updated with administrative sources. Note that administrative registers are also being used for non-agricultural statistics. Parallel to the work with improving agricultural statistics, national statistical systems are becoming increasingly register-based. When the Population and Household Census is replaced with statistical registers, the preconditions for a Farm Census will be completely different – the Population Census can no longer be used as a frame for agricultural surveys.

Keywords: Integrated statistical systems, Farm register, Coverage errors, Multiple frame approach

1. Agriculture and the rural population in a register-based system

This section describes how statistics on agriculture and the rural population are produced in a country where statistics production is based on registers. Statistics on agriculture are based on the Farm Register, but the Farm Register is only one of many registers used for statistics production. The Population Register and Business Register and the registers that have replaced the population and housing census constitute an integrated system.

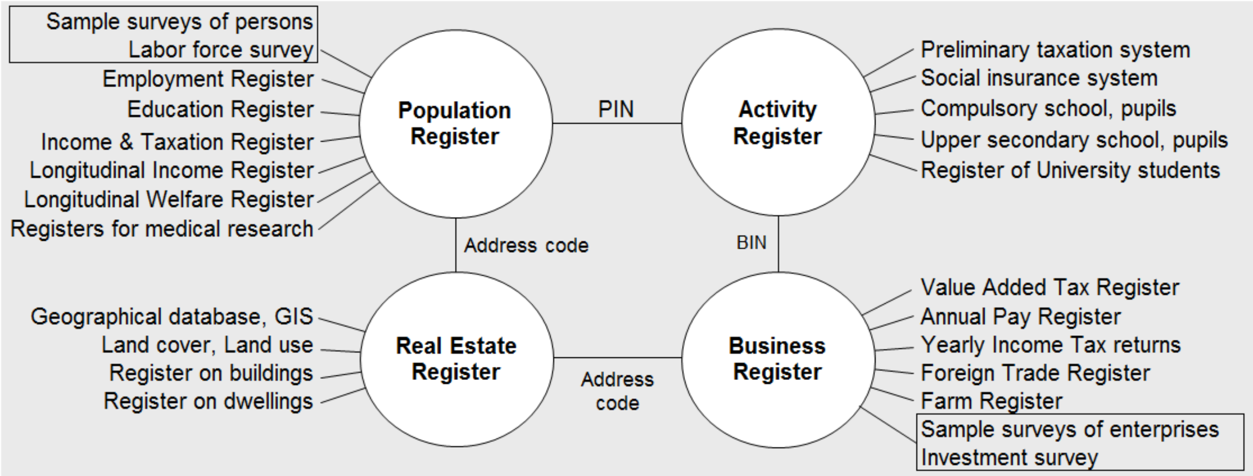
1.1 The key features of a register-based system

In a traditional system based on area frames, the *location* of a statistical unit is the factor that determines if a unit is sampled and interviewed or not. A sampled person's name or identity is not important for the production of statistics. Consequently, information regarding the identities of units is not used in the production process. Countries with register-based production systems use *identity numbers* in all surveys: all censuses, sample surveys and register surveys. The Population Register, the Business Register and the Farm Register are used to create frames, and the statistical units are identified by unique numbers that are used in the production process. In sample surveys and censuses, the identities are used to contact the respondents by mail or telephone. In register surveys, microdata from different registers is combined to create the required data set for the specific survey. These combinations are created by record linkage using the identity numbers as matching keys.

In a national statistical system with a coordinated register system, all microdata in the system can be integrated. In a coordinated system, the populations in the different registers are consistent regarding coverage, and variables in different registers do not have contradicting values. This is what we mean by *an integrated statistical system*. Of course, perfect consistency is difficult to obtain. However, if coverage problems and variable inconsistencies are tolerable, we can say that the system is an integrated system. Integration of microdata will become possible without disturbing problems regarding lack of consistency between populations and variables.

Chart 1 illustrates a register-based production system. The basis is the register system consisting of four base registers (circles) defining the *populations* in the system and a number of statistical registers with important statistical *variables*. The lines in the chart illustrate the important *links* between units in different registers. We have added two sample surveys – the Labor Force Survey and the Investment Survey. These two sample surveys are only examples; all sample surveys can be linked to the register system.

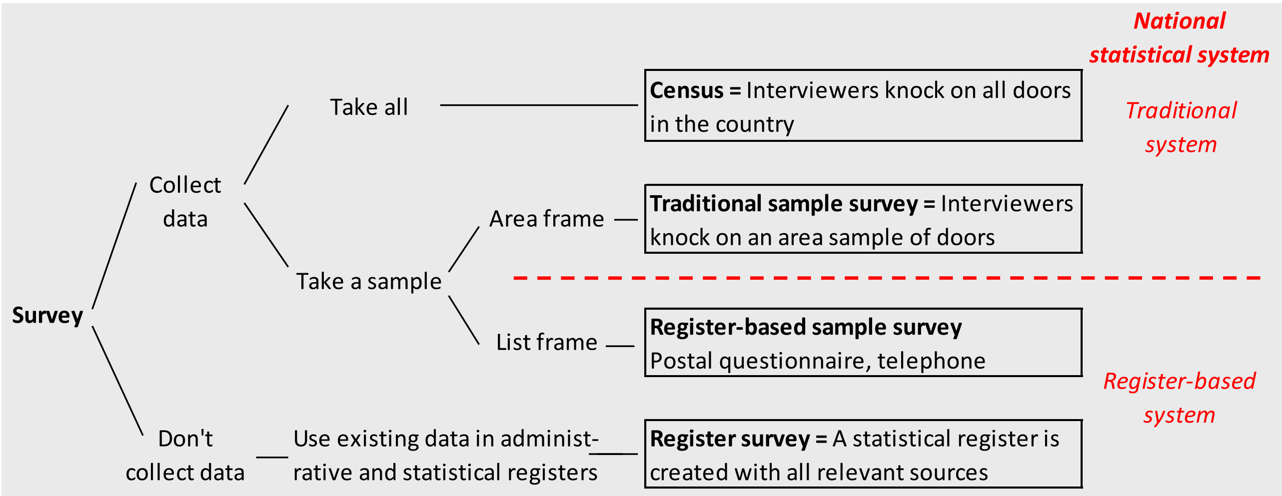
Chart 1. A register-based production system – the register system and sample surveys



PIN = Identity numbers of persons BIN = Identity numbers of enterprises

Chart 2 illustrates the different survey methods used in traditional and register-based production systems. In a register-based system the censuses are replaced with statistical registers, and sample surveys are not based on area frames. This explains why a register-based system is much more cost efficient than a traditional system.

Chart 2. Survey methods in traditional and register-based statistical production systems



1.2 The Farm Register in a register-based system

The population of the Farm Register is determined using one or more administrative registers. The Integrated Administrative and Control System (IACS) is a yearly source in countries that are members of the EU. Instead of conducting a census every tenth year with a census population that will soon be outdated, the IACS system generates a new register population every year.

The Farm Register and the Business Register should be consistent. All holdings in the Farm Register should be linked with enterprises in the Business Register. The holdings are local kind of activity units (LKAU) in the Business Register. The enterprises in the Business Register that are linked to the holdings should be active within NACE 1. There should be no other enterprises with NACE 1 as one of its economic activities in the Business Register.

1.3 Opportunities and problems with a register-based system

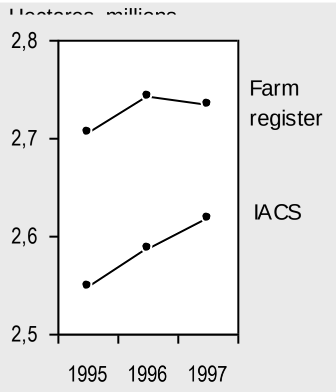
All registers in the system can be used to describe agriculture and the rural population, and there is no extra cost or response burden related to this way of gaining information. If the Farm and Business registers are consistent in the way described in Section 1.2, all administrative data linked with enterprises in the Business Register can be used to describe the agricultural sector.

All registers in Chart 1 contain information regarding agricultural enterprises and/or persons working for agricultural enterprises as self-employed or employed. The households related to these persons can be described as well as the households living in rural areas. With the GIS-system that is linked to the Real Estate Register, the rural regions can be defined freely without using administrative borders.

In Wallgren and Wallgren (2010) we discuss methodological issues and quality problems related to the Farm Register in a register-based statistical system. In a decentralized national system, agricultural statistics and economic statistics can be produced by different statistical institutes. If these institutes do not cooperate, the Farm and Business registers will be inconsistent and this will create problems for the National Accounts, for instance.

Selander et al. (1998) discuss the problem of undercoverage in the IACS register. If this undercoverage is not handled, the consequences can be misleading statistics. This is illustrated in the example in Chart 3, taken from Wallgren and Wallgren (2014). Even if coverage is rather high, variations in coverage will destroy time series patterns.

Chart 3. Undercoverage in an administrative register, the IACS-register



Farmed area of arable land, millions of hectares			
	IACS	Farm Register	Coverage
1995	2.548	2.707	94.1%
1996	2.587	2.743	94.3%
1997	2.618	2.734	95.8%

Change in per cent between years		
	IACS	Farm Register
95/96	1.5%	1.3%
96/97	1.2%	–0.3%

Selander et al. suggest that the population of holdings is divided into three parts, and coverage errors should be reduced by combining register data for the first part with statistical questionnaires for the other parts. This is actually a kind of multiple frame approach:

1. IACS 1 is the part of IACS that consists of the holdings that have reported the entire area of arable land divided among different crops.
2. IACS 2 is the part of IACS where there is no complete crop data in IACS, though there is information for register keeping.
3. The holdings that are outside the IACS system. This third part consists of the holdings that have not applied for subsidies. This part of the population can be monitored by using administrative data from registers with business data.

In Sweden in 1995, IACS 1 comprised some 69,000 holdings, IACS 2 comprised some 6,000 and the non-IACS population some 20,000. The lines of demarcation between the different parts of the population may be changed as a result of a change in agricultural policy.

Some general conclusions can be made based on this IACS example.

- A register-based system is dependent of the administrative systems that generate the administrative data. The coverage problems related with these administrative systems must always be analyzed and monitored over time. Changes in the administrative systems can produce changes regarding coverage.
- The example also illustrates that a multiple frame approach should be used to reduce coverage errors. Undercoverage can be reduced by combining many administrative registers (‘frames’). This is an option in countries with many administrative registers available to the statistical institute.
- Coverage errors can be reduced by combining registers with list-based sample surveys or area samples. In the IACS example, list based samples or censuses covering the second and third part of the population will reduce undercoverage errors. In developing countries, combining registers with area sampling may be necessary to reduce the coverage errors related to the registers.

In Wallgren (2016b) we use the dual frame approach to discuss two problems:

- First, residential addresses are often not updated in administrative population registers in many countries. This means that it is difficult to use administrative population data for regional statistics. In countries with strong urbanization, this will lead to overcoverage of rural register populations and undercoverage of urban register populations.
- In addition, a difficult but important problem is the informal sectors that exist in many countries. Family farms in many countries can belong to this informal sector. Only the formal sector will be found in the administrative sources and these administrative registers must be combined with area samples that cover both the formal and informal sectors.

These two problems are common in developing countries. The problems must be solved so that these countries can modernize their traditional census-based statistical systems into register-based systems. The final solutions of these problems will require many years of applied methodological work.

As a rule, we assume that an area sample has no coverage errors. For the case when we work with flow data, such as production etc., the area sample must also cover all time. In the Swedish Labor Force Survey, we ask *“what did you do last week?”*. To cover all time with the LFS, a new sample is interviewed every week during the calendar year. Thus, we must cover all weeks during the year, quarter or month to be able to assume that we have no coverage errors in the area sample. In contrast, administrative registers cover all time; births and deaths are registered continuously and, for instance, taxation systems measure income night and day during the entire year.

Our aim with this paper is to describe the long-term strategy that should be used when developing countries start to use administrative registers for statistical purposes. When we discuss how administrative registers can be used for agricultural statistics, we must at the same time understand that non-agricultural statistics are becoming increasingly register-based. This will change the preconditions for agricultural and rural statistics. Therefore, the transition processes that will change both agricultural and non-agricultural statistics should be considered together. Agricultural statistics must be an integrated part of the national system and should not be discussed and developed separately.

2. What strategy and methods should developing countries adopt?

This section illustrates that starting to use administrative registers for statistics production implies many new 'non-statistical' activities that are necessary for success. We discuss here the modernization of the national statistical system from a traditional census-based system with no statistical registers into a register-based system. This will be a general discussion describing how administrative registers can be used to create an integrated system of statistical registers. The discussion is based on our experiences from visits to a number of countries in Latin America and the Caribbean during 2011–2016.

If the system for agricultural statistics is to be fully integrated with the system for social and economic statistics, the Farm Register should be an integrated part of the register system. The statistical system should describe statistics on crops and livestock as well as rural regions and households that are dependent on agricultural activities.

2.1 Microdata with identities

All administrative registers contain *identities*. The registered transactions include the identity of the administrative unit responsible for the transaction and/or the identity of the unit that is administrated. These identities are the most important variables in a register-based statistical system. With the identities we can check quality issues as for example coverage and we can combine records for the same unit from different sources. The identities link the different parts of the system together and it becomes possible to create an integrated system and produce consistent statistics.

We also need access to *microdata* to enable work with administrative registers in a methodologically efficient way. In many countries the national statistical institute, NSI, receives only aggregate administrative data from the ministries due to a desire to protect the confidentiality of citizens and enterprises. However, quality assurance and quality improvements will then become difficult and in many cases impossible; and it will not be possible to combine data from different sources so that relations between variables can be studied.

The conclusion is that the statisticians at the NSI must gain access to administrative microdata with identities of good quality. The goal is to have identity numbers so that deterministic record linkage can be used in all statistics production. In addition, those who work with agricultural statistics should have access to microdata with identities. These identities can link together different sources with agricultural data and link agricultural registers with registers in the general system.

2.2 Survey design includes work with improving administrative systems

Many countries in Latin America have reformed their national registration systems so that almost all newborn receive their identity numbers soon after the birth. The situation is worse in other countries: there can be one old system of identity numbers, a new system for adults, one system for children and another system for persons born abroad. In addition, some persons may not have registered and consequently have no identity numbers.

Administrative systems that do not generate data of good administrative quality cannot be used for statistical purposes. When the administrative system is improved, both administration and statistics production will be improved – this is a win-win situation. The national registration system with identity numbers, registration of births, deaths and migration is the most important administrative system for statistics production. If this system is not robust, there will be no identities that can be used to identify farmers, family farms and households; and register-based rural statistics will not be possible.

In many of the countries we visited, the NSIs are actively working to improve the national registration system and the cadaster. All births and deaths should be registered and migration within the country must be registered to make regional statistics possible. Emigration must also be measured; otherwise, there will be overcoverage in the population register. These improvements require political support and sometimes new legislation. This is high-level survey design – the preconditions for all statistical surveys in the country are improved.

We have seen an example where an old, very bad system was replaced by a new system for criminal statistics. In the old system microdata with identity numbers were created by many persons working for two ministries, the police and the correctional authorities. The information could be recorded through hand-writing or with different IT-systems, and different authorities used different codes for classification. Registering information in the old system was difficult and retrieving information was almost impossible. The new system developed by the NSI is based on one form and will standardize and simplify reporting. Retrieving information is now easy. The administration of crime reporting, victims and criminals has been improved and microdata for the production of crime statistics is now available.

2.3 Protection of confidentiality

When a country changes the national statistical system from a traditional into a register-based system, new methods must be developed to protect confidentiality. Identities can be handled and should be handled in such a way that confidentiality is protected *at least as well* in the new register-based system as in the traditional system.

One unit at the NSI, consisting of a small group of persons, should be responsible for receiving all microdata that is stored in an input database with very restricted access. At this unit, names and addresses are removed and official identity numbers are replaced by anonymous numbers. After this work has been completed, the anonymized data is stored in the output database and those who need access to data for statistics production can use it for their purposes. Record linkage is carried out with the anonymous numbers if information in different statistical registers must be combined.

Providing microdata with identities to the NSI will be something new for ministries and other authorities. In many cases old attitudes must be changed. If the ministries understand how the NSI works to protect confidentiality, it will be easier for the NSI to gain access to the data.

2.4 Centralization, cooperation and legislation

Centralization is not as important in a traditional statistical system as it is in a register-based system. In the production system in Chart 1, we want the register populations to be consistent. The populations in different registers must be compared when checking for consistency. When the registers are created, other registers must be used in a systematic way. This work is simplified if all registers are stored together at the same statistical institute. A natural and important role for the NSI will be to create and maintain the system of statistical registers.

Thus, the transition from a traditional system into a register-based system will actualize a more centralized national system. We recommend that the NSI be responsible for all registers that replace the population and housing census and all registers that are used for the National Accounts.

Politicians, ministries, other administrative authorities and the NSI must work together to develop register-based statistics. This cooperation is necessary to improve the administrative systems. Cooperation between the NSI and the authorities that deliver administrative registers will be a permanent task in a register-based system. Old legislation must be replaced with new laws that define that the NSI should have access to microdata and that protect confidentiality.

Regional register-based statistics require that that all persons’ residences are georeferenced and that all job activities are georeferenced. In all Nordic countries it is mandatory that a person's place of residence (dwelling) is registered and that all employers report at which local unit (establishment) each employee works. These two laws were passed by each Nordic parliament to make the register-based population and housing census possible.

2.5 Quality assessment

Problems related to field work, sampling errors and nonresponse are our main concerns when working with sample surveys. In register surveys we have no fieldwork, no sampling errors and we do not ask any questions and we do not have any nonresponse. This probably explains why many people feel bewildered when they start working with administrative registers – how shall we now work with quality assessment?

The understanding of field work and how it determines quality issues in a sample survey corresponds to the understanding of the administrative system that has generated the administrative register. The staff must develop this new competence by studying the administrative system, by having discussions with persons at the administrative authority and by spending time analyzing microdata from the source.

Instead of computing sampling errors, we should analyze coverage problems and other inconsistencies. We do this by comparing coverage at the micro level in different sources describing similar populations. If we combine two registers with record linkage, the mismatch gives us a measure of the differences in coverage (if we have good identity numbers, mismatch is caused by coverage differences). If we combine sources with similar variables, we can also study inconsistencies between variables in different sources. When we find inconsistencies regarding coverage and/or variables, the next step is to try to understand why we have these differences. This is difficult but necessary. Finally, we should correct the errors we have found and reduce the inconsistencies.

There is one important difference between sample surveys and register surveys. In sample surveys we cannot see the errors, we know that we have sampling errors and nonresponse errors but can only give an interval for the probable sampling error. In register surveys, however, many errors can be seen if microdata is analyzed. Here are two examples:

- We found that 16% of the persons between 20–24 years had different residences in the University Register and the Population Register. This is an example of inconsistent variable values. The Population Register can be corrected and improved with this information from the University Register.
- We found that the turnover of *Manufacture of pharmaceutical preparations* was underestimated by 17% due to undercoverage in the SBS, the Structural Business Statistics Survey. This is an example of inconsistent populations. The SBS can be corrected with the information we used.

Each administrative register should be evaluated for statistical purposes prior to use. However, administrative registers are often evaluated one by one and this may lead to wrong conclusions. This is because an administrative register can be used in many ways – for one use the register may be good, for another use the register may be bad. In addition, registers can be combined. Each register may appear to be bad when analyzed separately, but the register based on the combination can still be good. Systematic check of input data quality is discussed in Wallgren and Wallgren (2014, p 273ff). The main purpose is to find out *how* an administrative register should be used. Every new source should be considered as a methodological challenge.

3. Creating a system for agricultural statistics based on registers

FAO (2015e) describes the situation regarding agricultural statistics in some African countries. Three survey methods are used today:

- An agricultural *census* of agricultural holdings is interviewed perhaps every tenth year. This gives detailed statistics for small areas but the information is not timely.
- An *area sample* of agricultural holdings is interviewed. This gives timely information but not for small areas.
- A specific form of statistical survey where statistical data is collected regarding *eye estimates*[1] made by farmers and/or *expert judgements* made by regional officers. This gives timely information for small areas, but the content is not as detailed as in the census.

According to Ssekiboobo (2015), *administrative registers "are rarely used in developing countries because of quality and coverage issues."* This means that register surveys are not used in African countries today, but if we want to modernize national statistical systems as many countries in Latin America do, then administrative registers must become available and be used for statistics production. If the present administrative systems are not sufficiently good, then the first step in the modernization process is to improve the registration systems as discussed in Section 2.2.

---

[1] This kind of survey is called *administrative data*, both by the FAO (2015a-e) and by Ssekiboobo (2015). It is a kind of statistical survey that only can be used for agricultural statistics – everyone can look at fields and can judge if the crop looks good or bad. These judgements can be collected and used for statistics based on eye estimates. For other kinds of statistics, it is impossible to make eye estimates – e.g. labor market statistics require the established kinds of sample surveys or register surveys.

It is confusing to call these *eye estimate surveys* for administrative data. We must be careful with our statistical terms – when we work with developing national statistical systems from traditional systems into register-based we must use the term *administrative register* in the correct manner. We ask our colleagues working with agricultural statistics: *Please, do not to destroy this term!* In Wallgren and Wallgren (2014, Chapter 2, particularly on page 28) we discuss the nature of administrative data.

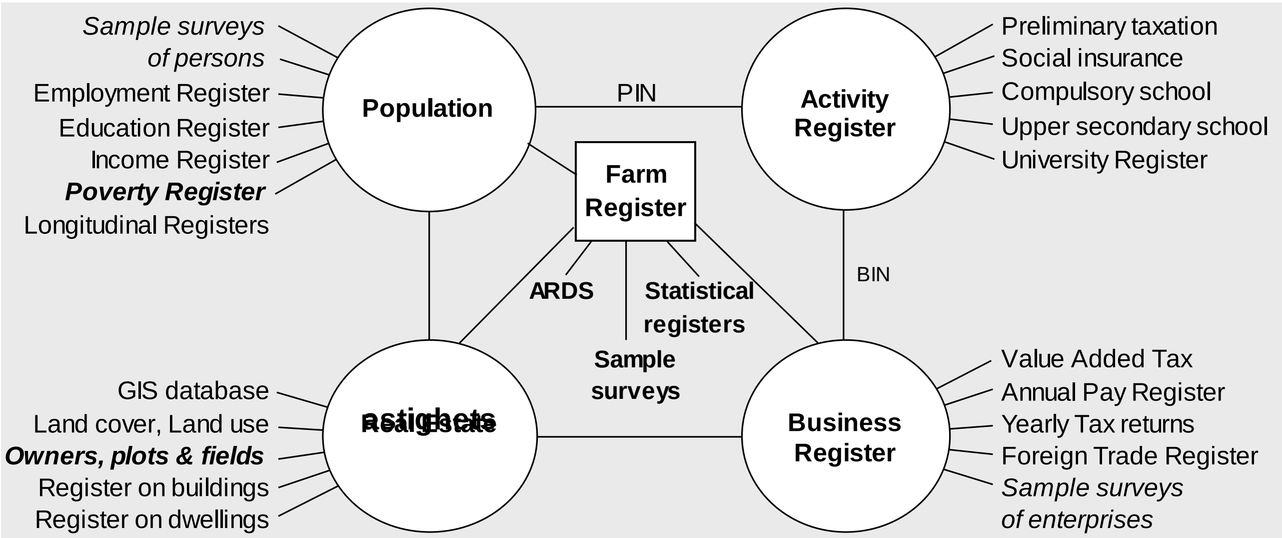
3.1 The Global Strategy and the register system

The Global Strategy by the World Bank (2011) states that agricultural statistics should be an integrated part of the national statistical system. This is an important aspect that is not discussed in FAO (2015a-e). For us, the term *integrated system* is a statistical term with a specific meaning: *Populations and variables should be consistent and estimates should be coherent.* Chart 1 (and also Chart 4) illustrates the production system with base registers, other statistical registers and sample surveys. The following quotations come from the Global Strategy (our italics):

> The integration and underlying methodology … considers the quality dimensions, which include relevance and *completeness,* accuracy, timeliness, accessibility, *coherence, and comparability.*
>
> The process of improving agricultural statistics will begin with the integration of agriculture into the national statistical system. This integration will be accomplished by the development of a master sample frame for agriculture to ensure relevance and completeness; its use *in implementing a coordinated data collection program to produce timely and accurate data that are coherent and comparable*;
>
> One of the shortcomings of current statistical systems in both industrialized and developing countries is that data are collected by sector, using different sampling frames and surveys. The division of data by sector leaves no opportunity to measure the impact of an action in one sector on another. In some cases, different organizations produce statistics for the same items, with different results, which confuse the data users.
>
> Surveys are often conducted on an ad-hoc basis … *It is therefore difficult to integrate data from various surveys for in-depth analysis with cross tabulation of variables.*
>
> *Integrated statistical systems can resolve many of these problems by avoiding duplications of effort, preventing the release of conflicting statistics, and ensuring the best use of resources. Concepts, definitions, and classifications become standardized, allowing more systematic data collection across sources.*

The master sampling frame in the Global Strategy corresponds to the Farm Register in Chart 4. All sample surveys of holdings are based on the Farm Register and sources with crop areas, etc. are linked to the Farm Register. Thus, all data collection regarding agricultural variables is coordinated when the Farm Register is used in this way. As the Farm Register is linked to the Population and Business Registers, agricultural statistics can become an integrated and consistent part of the national system. Micro integration is possible, which makes *"in-depth analysis with cross tabulation of variables"* possible according to the quotation from the Global Strategy.

Chart 4. A register-based production system – the agricultural parts highlighted



The conclusion is: If you want an integrated statistical system that includes agricultural statistics, then the statistical method to achieve this goal is to create a system[2] of consistent registers according to the model in Chart 4.

[2] The eye estimate surveys denoted with ARDS (Agricultural Routine Data System) in Chart 4, can be included in this system if these surveys use data from agricultural holdings and contain identities of the holdings or holders.

3.2 Building the system step by step

The transition from a traditional statistical system based on censuses into a register-based system will take many years. The pioneer country was Denmark that managed to make this transition during 1968–1981. Austria managed to change into a completely register-based system during 2001–2011. The transition in Sweden was slower. The necessary legislative changes took many years, and the changes of the national registration of persons required much work with standardizing of addresses and the creation of a dwelling register. The Swedish transition took place between 1967 and 2011. This section provides an outline of the transition into a system for agricultural statistics that uses administrative registers.

The first step

In an integrated system, *identity numbers* play a very important role. The first step should therefore be to create a national registration system with good identity numbers. Newborns should be registered and receive their national registration number in connection with the birth. These personal identity numbers (PIN) should be used in all administrative systems. The identity numbers of holders can be used to identify holders or holdings in agricultural censuses and sample surveys and in administrative systems regarding agriculture.

The second step

The statistical Population Register is the most important part of a register-based statistical system. It is also important for agricultural statistics to have access to a Population Register with rural and agricultural households. The second step should therefore be to develop a *statistical Population Register*, which can be based on the administrative population register and supplemented by other sources to improve coverage and the quality of residential addresses. These addresses must have sufficient quality; otherwise, regional statistics will be impossible. Wallgren and Wallgren (2015) describes some of our experiences from Latin America.

The third step

The role of the base registers is to define statistical units and populations in the statistical system. The third step should therefore be to develop the Real Estate Register or Cadaster, the Business Register and the Farm Register. The Activity Register is also essential – all job activities are needed for the *Employment Register*, and all study activities are necessary for the *Education Register*. These two registers are important parts of the register-based population and housing census.

For register-based agricultural statistics, we need a Farm Register with all holdings and administrative registers with information regarding holdings. Within the European Union, three administrative sources can be used: the IACS-register, the Cattle Register and the Business register. In developing countries, a register can exist with big and/or commercial farms, but there is no register with small family farms. An inventory of sources with microdata regarding farms or farmers should be carried out. Cooperation between ministries can be important – other ministries than the Ministry of Agriculture may have data that includes farming households.

We can give one example from Latin America: The Ministry of Interior created a register to administrate support to poor households. The register covers between 60% – 95% of the population, with the highest coverage in poor rural regions. Here we suggest *integrated data collection* so that the Ministry of Interior will include questions when creating their register to identify agricultural households. This information can then be used by the Ministry of Agriculture and as a source for a Farm Register. Today, the Farm Census is often based on a frame based on the agricultural households in the Population and Housing Census. In the future, this integrated data collection can replace this way of using the Population and Housing Census.

Agricultural statistics as an integrated part of the national system

When a country has established a system with national identity numbers for persons (PIN) and if there is a population register with information on where people live and together with whom, then the preconditions for statistics production have been greatly improved. It will now be possible to create statistical registers and produce register-based statistics on persons.

All administrative systems concerning persons and households should use identity numbers PIN. Then data from these systems can be used for statistics production. Also all surveys as population censuses, all area frame based sample surveys of households, all register-based (list based) sample surveys of persons and all register surveys[3] with data on persons should include the identity numbers PIN. Then these surveys can be developed into an integrated statistical system that produces coherent statistics.

If we want to make agricultural statistics an integrated part of the national system, there must be a national system with registers that we can link to the agricultural registers. We assume therefore that the statistical Population Register exists and that family farms can be linked to this register with the identity numbers PIN of the holders. Commercial farms can be linked to the Business Register with business identity numbers BIN. If there exists a Real Estate Register, then the holders and holdings can be linked to the fields and plots they own via the identity numbers PIN and BIN. A Farm Register should be developed that can be linked to the registers in the national system. This is the necessary precondition that must be fulfilled is we want that agricultural statistics based on registers should be integrated with the national statistical system.

3.3 Agricultural surveys in an integrated system

In Chart 5 we give a short description of different sources with identities and agricultural data and how they can be used to create an integrated system of agricultural surveys. All relevant sources should be used to create a statistical Farm Register with as good coverage as possible. The Farm Register should also include basic classification variables as address, size and kind of farm.

Chart 5. Sources used to create a Farm Register and agricultural statistical registers

Source		Identity number	Survey
1.	Population census with identity numbers PIN and a variable that indicates holders	PIN	Statistical Farm Register
2.	Register to administrate support to poor households with identity numbers PIN and a variable that indicates holders	PIN	Statistical Farm Register
3.	Agricultural Routine Data System, field staff is used to improve and update the Farm Register	PIN, BIN	Statistical Farm Register
4.	Administrative Farm Register with commercial farms	BIN	Statistical Farm Register
5.	Agricultural Routine Data System, field staff is used to report holding identities together with holding level data	PIN, BIN	Statistical Registers with crop areas, production etc.
6.	Administrative registers with different content: Tax data for holders and holdings Land ownership Agricultural production and inputs Data from manufacturers and distributors Data from farm associations	PIN, BIN	Different statistical registers Can also be used to improve the Statistical Farm Register

[3] A *register survey* is a survey where data from existing statistical registers and administrative registers are combined to create a new statistical register for specific statistical purposes.

Population census

If a country does a traditional population and housing census (perhaps for the last time), this census should be used not only to improve the Population Register but also to improve the Farm Register. Identity numbers, PIN, of all persons should be included in the census and also questions that identify holders and holding households. This information together with the residential address can be used to establish a first version of the family farm part of the Farm Register.

Register to administrate support to poor households

In Latin American countries, many ministries create their own registers with population data to administrate their different political programs. In one country we found six different registers with population data for different purposes. If some of these ministries include questions to find holders and holding households, then this kind data can be used to create the family farm part of a Farm Register.

Agricultural Routine Data System

FAO (2015e) describes the Agricultural Routine Data Systems, ARDS, that are common in many developing countries. There are many problems with these systems: the staff is not always motivated, there is lack of training and the reports are not standardized etc. However, the ARDS is an old and well established kind of statistical system that has field staff all over the rural parts of the country. We think that the ARDS gives opportunities that can be used in a register-based statistical system. But to become an integrated part of the new statistical system, the ARDS should include identities of the holders and collect microdata from holdings. Today the ARDS staff aggregates data from holders into village data. These aggregated data are then transferred to wards and regions etc. We suggest that gradually the ARDS changes from collecting the aggregated data that is used today into collection of microdata with identities of holders. This microdata can then be used to create registers with agricultural data.

The field staff working with the ARDS can also report changes in the stock of holdings. In this way the quality of the Farm register will be maintained. The knowledge that the field staff has regarding the farm population should be used to improve and update the Farm Register.

Administrative Farm Register with commercial farms

A register with commercial farms should be one of the sources that should be used to create the statistical Farm Register. There are as a rule also administrative sources with tax data and other economic information that are important for agricultural statistics. These sources can be combined with business identity numbers BIN for enterprises. One BIN identity can however be linked with more than one holding.

Administrative registers with different content

When the statistical Farm Register has been established, available administrative registers can be used to create new statistical registers with agricultural and rural information. The populations should be created with the Farm Register and the administrative registers will be used as sources of the variables in these new registers.

When the administrative system that generates the administrative data is old and bad, the data will have poor quality. The NSI should in such cases take the initiative so that the bad system is replaced with a modernized system. This requires cooperation with administrative authorities as we explained in section 2.2.

4. Conclusions

Administrative data and agricultural statistics – what strategy and methods should we adopt? The following two quotations come from Wallgren and Wallgren (2015) and are based on our experiences from Latin America.

> "Administrative systems in the public sector generate vast amounts of data that is stored in administrative registers. These registers is a resource that can be used for statistics production. This resource is growing in volume and as the administrative systems gradually improve, the quality of the administrative data that is generated by these systems will become increasingly better."
>
> "If administrative registers are used for statistics production, costs can be saved and quality can be improved. Censuses can be replaced by register surveys, and new kinds of regional and longitudinal statistics can be developed. The national system can be changed into an integrated statistical system with consistent and coherent statistical registers and sample surveys. During the transition period, it may be necessary to combine the register-based statistics with estimates from area samples."

According to the Global Strategy (World Bank 2011), agricultural and rural statistics in developing countries must be improved and become an integrated part of the national statistical system. When a country starts to use administrative registers for statistics production, more and more statistical registers are developed. With identity numbers, all registers and surveys can be linked and become parts of an integrated system that can be used to produce coherent statistics.

In this paper, we have tried to give an overview of the strategy and methods that should be used in this transition process. Many countries in Latin America are working in this direction and we think that within five years some of these countries will have improved their national systems considerably.

THEMATIC SET

F34

INTEGRATING AGRICULTURAL AND HOUSEHOLD SURVEYS

Session Organizer
C. Carletto | The World Bank | Rome | Italy
S. Hofman | USDA National Agricultural Statistics Service | Washington, DC | USA

ABSTRACT

One of the central tenets of the Global Strategy to Improve Agricultural and Rural Statistics is the recognition of the need for greater integration of different agricultural data sources. Of particular interest are the analytical advantages of an integrated survey system and the ways in which household and farm surveys can be linked through various methods and techniques. As countries, particularly in the developing world, are faced with increasing pressure to collect more and better information at lower costs, this linkage between household and farm surveys becomes more important. Enhanced integration can be seen as a double win both in cost-efficiency as well as analytical potential. The session will explore different ways in which survey integration can be pursued, including by (1) using common master sampling frames and/or spatial sampling units and by designing "smart" samples enabling a closer correspondence between household and farm units, (2) encouraging thematic overlapping, allowing for better "cross-walking" between surveys through scalable imputation techniques, and (3) supporting geo-referencing of the different data sources. Submission of empirical applications of innovative methods of particular relevance to agricultural farming systems and statistical capabilities of developing countries are encouraged.

ABSTRACT

Rural development specialists working with agricultural statistics confront the tension between collecting data for the purposes of measuring farm sector performance versus that of assessing farm household well-being. While it is recognized that the activities of the farm enterprise and farm household generate a broad spectrum of market relationships in their local economies – linkages found in capital markets, commodity production, household consumption, and alternative income-generating activities on and off the farm, most agricultural data collection systems focus primarily on commodity production and just the basics of farm household structure (Bollman, 1998). The survey instrument that embraces the dual mission of collecting data on the farming enterprise and on farm households can allow specialists to study a broader complement of farm-rural economy linkages (Johnson, et al, 2008). Such a survey generates a more comprehensive quantitative assessment of the farm household as a multifaceted enterprise and its linkages to the rural economy (Vogel, 2012).

In this case study, we exploit microdata on farm household activities drawn from U.S. and Canadian national agricultural surveys to shed light on the impact of farmers who simultaneously operate off-farm businesses on their local communities– a farm/rural interface often overlooked by agricultural economists and rural development specialists alike. These entrepreneurial farmers provide additional employment and growth opportunities separate from commodity production for

their rural economies. Hence, instead of depending on the local communities' resilience for their household well-being, they contribute to it.

We use the Agricultural Resource Management Survey jointly administered by the Economic Research and the National Agricultural Statistic Services of the U.S. Department of Agriculture and the Farm Financial Survey administered by Statistics Canada. Given the sufficiently detailed data on these farmer-operated off-farm businesses, we are able to use the input/output modeling toolkit to recover estimates of nonfarm value added, sales, and employment generated by them. With respect to the rural economy, we find that the share of a rural county's employed nonfarm labor force linked to these off-farm businesses increases the further they are located from the urban core. Thus, the business acumen of these farm portfolio entrepreneurs is an even more valued intangible asset for communities in more remote rural areas.

For developing economies with large farming populations, data on the full complement of farm household enterprise activities can provide opportunities of regional development specialists to analyze the potential breadth of farm-generated development pivots.

Keywords:, off-farm businesses, farm microdata, entrepreneurship, rural resilience.

1. Introduction

In the current global economy, some elements in the development processes in agriculture remain intertwined with those of the rural economy, while other relationships have attenuated. in part to the increasing scale and concentration of farm operations and in part to the economic diversification of many rural economies, the farm links to the local economic base have weakened while the majority of farm households in many countries have at least one household member in non-farm employment. Farmers who simultaneously operate off-farm businesses provide additional employment and growth opportunities for their rural economies.

The activities of the farm *family enterprise* – farm production, farm household consumption plus all other household income-earning activities generate distinct market relationships, but most agricultural data collection systems focus primarily on family *farm enterprise* and just the basics of farm household structure (Bollman, 1998, Johnson et al., 2008). The survey instrument that collects data on these market relationships generates a more comprehensive quantitative assessment of the farm household as a multifaceted enterprise and its linkages to the rural economy (Vogel, 2012).

This case study shows how using farm sector microdata for rural development purposes is able to uncover additional contributions made by a small segment of U.S. and Canadian farm families to their communities' well-being. By simultaneously operating both farm and off-farm businesses, these farm families appear to use their comparative advantage in being able to organize resources across multiple enterprises when new business opportunities arise. A large body of case study research classifies these multifunctional farm families as "portfolio entrepreneurs" (Carter and Ram, 2001; Seuneke, et al., 2013).

In the local economy, off-farm business income serves a dual purpose. First, from the farm household's perspective, off-farm business income represents an additional, potentially lucrative source of household income. In section 2,
Survey (ARMS) jointly administered by the Economic Research and the National Agricultural Statistic Services of the U.S. Department of Agriculture and the Farm Financial Survey (FFS) administered by Statistics Canada to examine the incidence and distribution of these farm portfolio entrepreneurs (FPEs).[1] Second, from the perspective of the local economy, off-farm business income represents profit income derived from these FPEs marshaling local resources in producing nonfarm goods and services, without which they may have been imported or not available at all. In

section 3, we use elements of the social accounting matrix modeling toolkit to estimate of their contributions to local output, nonfarm value added income, and employment.

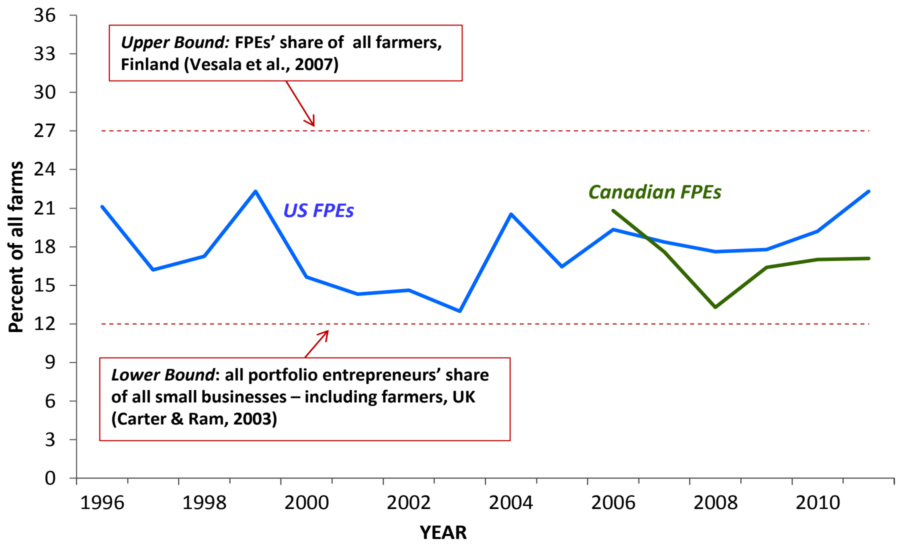
2. View from the Farm Gate: Characteristics of U.S. and Canadian FPEs

Why do farm households become portfolio entrepreneurs? For small farms generally, the ability to make a living solely from farming has declined over time as economies of size increasingly limit the profit potential of smaller operations. These multifunctional farm households rely on portable skills, multiple job-holding, and multiple enterprises as the basis for maintaining their household incomes. Farm households with excess resources at their disposal may operate a second enterprise if adjacent land or other key inputs become too costly or unavailable, or if nonfarm opportunities appear to be more profitable than intensive development of existing farm resources. For large commercial family farms with multiple operators, operating an off-farm business can provide an income and career path for extended family members, insuring that they remain part of the broader family farm business (Vogel, 2013).

Statistics on the incidences of farm and nonfarm portfolio entrepreneurship are uneven, ranging from 12 percent of all small businesses in England to 27 percent of Finnish farm households (Carter and Ram, 2003; Mikko Vesala, et al., 2007). Although ARMS collects data on off-farm business income annually, the data necessary for estimating farmer-operated off-farm business contributions to their local economy exist only for the years 2006-2012. For these years, FPEs reported the industrial sectors to which their businesses belonged, profit income, and how many workers their businesses employed. For the Canadian case, data on off-farm business income from the FFS was collected every two years prior to 1995 and continuously only for 2006-2011.

U.S. and Canadian FPEs represent a relatively small, enduring segment of all farm households, averaging 17.9 for the U.S. and 17.1 for the Canadian case (Figure 1). Vogel (2012) found that most of these farm families operated nonfarm businesses out of necessity, a small segment as part of family-enterprise growth and wealth generation strategies, and an even smaller portion as part of a transitional pathway into and out of farming. Compared to other types of small business entrepreneurs, farm and nonfarm portfolio entrepreneurs are more likely to rank their ability to organize resources and spot new opportunities as a greatest strength, more likely motivated by wealth creation, and to have invested more capital from both internal and external sources in their businesses (Westhead, et al., 2005).[2]

Figure 1. Incidence of Canadian and US farm portfolio entrepreneurship, 1996-2011



Source: USDA, ERS, ARMS, 1996-2011; Statistics Canada, FFS, 2006-2011.

In 2007, 395,583 U.S. farm households earned US $21.6 billion US off-farm business income and 39,243 Canadian farmers similarly earned CA $2.1 billion (Table 1).[3] The incidences of portfolio entrepreneurship by farm sales class among all U.S. and Canadian farm households also lie in the established range in Figure 1, suggesting that the human capital skills unique to farm portfolio entrepreneurship are universal and not directly linked to farm size.[4]

The distribution of farms across farm sales classes is different in the U.S. and in Canada – in 2007, the USDA ARMS survey reported that 58% of U.S. farms had sales under $10,000 whereas the Canadian 2006 Census of Agriculture showed that only 22% of Canadian farms had sales under $10,000. Thus, with a similar incidence of portfolio entrepreneurship in each sales class (Table 1), we find a much larger share of FPEs operating small farms in the U.S., compared to Canada. In 2007, 82 percent of U.S. FPEs were small farms with gross sales of less than $50,000, whereas only 48 percent of Canadian FPEs were classified as such. Medium-sized farms with sales between $50,000 and $249,999, and large farms with $250,000 or more in sales accounted for 52 percent of Canadian FPEs versus 21 percent of U.S. FPEs.

Table 1. Number of U.S. and Canadian FPEs and their off-farm business income, 2007

	*Farm Sales Class**			
	Less than $50,000	$50,000 up to $249,999	$250,000 or more	All
United States				
Number of farm portfolio entrepreneurs	325,617	41,864	28,102	395,583
Percent	82.3	10.6	7.1	100.0
Percent of all farms	19.5	14.8	13.7	18.4
Off-Farm business income (US $ millions)	17,028.0	3,053.3	1,538.0	21,618.9
Percent	78.8	14.1	7.1	100.0
Canada				
Number of farm portfolio entrepreneurs	19,008	12,450	7,785	39,243
Percent	48.5	31.7	19.8	100.0
Percent of all farms	16.0	17.4	20.0	17.1
Canada (CA $ millions)	1,091.0	600.7	427.8	2,119.9
Percent	51.5	28.3	20.2	100.0

*Farm sales classes were demarcated in U.S. dollars for U.S. FPE's and Canadian dollars for Canadian FPE's (2007 exchange rate: 1 USD = 1.07 CAD).

What underlying factor accounts for the disproportionately higher share of small farms among U.S. PFEs relative to Canada? Is it important to sustaining rural livelihoods? For the rural development specialist, a natural candidate is the role of population density. Figure 2 depicts average population densities for nonmetropolitan (rural) counties by the size of their urban populations in the 48 contiguous U.S. states (excluding Alaska and Hawaii) and in the Canadian provinces (excluding the Northern Territories). Nonmetropolitan counties with urban populations of 20,000-249,999 inhabitants are classified as 'urbanized', as 'less urbanized' for those with urban populations of 2,500-19,999 inhabitants, and 'totally rural' for those counties with less than 2,500 urban inhabitants. Within each of the three county types, population densities in US rural counties are 2 to 4 times higher than Canadian counties. In the Canadian counties, the centers of urban activities – be they small cities, towns, or villages – serve a much broader rural expanse than for corresponding U.S. counties. Regardless of the size of the urban center, higher population densities in rural counties may constrain farm-size expansion, but they can offer more opportunities for farm households to earn income in the nonfarm economy and more business opportunities for the entrepreneurial farm family.

Figure 2. Population Densities of Nonmetropolitan Counties by Type*

3. View from the local economy: economywide contributions of off-farm businesses

From a 'rural wealth creation' perspective, the long run sustainability of a rural community's well-being depends on promoting the economic activities that simultaneously augment its stocks of intangible resources. That is, fostering social and business networks, the capacity to innovate, and institutional malleability – social capital, intellectual capital, and cultural capital – can become important pivots in a rural community development strategy (Pender, et al., 2012). Case studies find that FPEs contribute to their communities' stocks of social and entrepreneurial capital. Our use of farm microdata complements these findings by quantifying the measureable economic impacts of their off-farm businesses.

The 2007 ARMS data allow us to distinguish between two types of FPEs based on whether or not they employ part-time or full-time workers. Off-farm businesses with no employees classified as sole proprietorships are referred to as "survival entrepreneurs" who may face few off-farm employment opportunities or possess limited financial or physical resources for farm enterprise growth. Off-farm businesses with employees are referred to as "growth entrepreneurs" contributing to a community's dynamic process of wealth generation (Markley and Low, 2012).

3.1. Industry Data and Methodology

To estimate the value of sales, labor income, and employment that, in theory, must exist to support the levels of U.S. and Canadian off-farm businesses incomes reported in Table 1, we assume that these businesses exhibit on average the same industrial characteristics as those operated by these countries' establishments not associated with a census-farm. This assumption lets us use the structural relationships embedded in the Canadian and U.S. benchmark input/output tables.[5]

For our simulations, we aggregated the 2007 ARMS data on off-farm businesses into 5 industrial classifications: (i) agricultural services, forestry and fishing, (ii) construction and manufacturing, (iii) utilities, wholesale trade, and transport, (iv) services, and (v) 'unclassified' or 'necessity' proprietorships. The Farm Financial Survey does not collect data on the type of industry to which Canadian off-farm businesses belong. As indicated below in Table 2, we assume that the distribution of Canadian off-farm businesses by sector is the same as in the U.S. We then use the input/output data regarding profit income, labor productivities and input usage for all firms in these sectors to estimate the contribution of Canadian off-farm businesses in each sector. Therefore, the differences between the two countries is generated by the differences within sectors as we assume a common weighting of the data across sectors to generate the national estimates of the contribution of off-farm businesses (Vogel and Bollman, 2012).

We used the fixed relationships between profit income and output embedded in a social accounting matrix (SAM) multiplier model to estimate the contributions to output, value-added income, and employment generated by off-farm businesses. Traditionally, after extracting the matrix of direct expenditure coefficients (**B**) from the data SAM, an exogenous shock to a particular group of industrial sectors or households ($\mathbf{\Delta x}$) multiplied by a matrix of SAM multipliers (**M**) yields economywide effects on sectoral outputs, factor incomes, and household incomes ($\mathbf{\Delta y}$),

(1) $$\mathbf{\Delta y} = (\mathbf{I} - \mathbf{B})^{-1} \cdot \mathbf{\Delta x} = \mathbf{M} \cdot \mathbf{\Delta x} .$$

Given that our farm microdata were collected on current-period enterprise activities, we assume that these off-farm businesses operate in the current period equilibrium. They did not generate any "new" derived demands for intermediate goods and labor services that would have been captured by the SAM multiplier **M**. Instead, we are only allowed to estimate the direct impacts of these off-farm businesses. Dividing the sectoral-level off-farm business incomes ($\boldsymbol{\pi}$) by their direct profit-income coefficients ($\mathbf{B}_{\pi}$) obtained from the 2002 U.S and the 2006 Canadian benchmark input-output tables yields estimates of sector-level output or sales for these off-farm enterprises (**x**),

(2) $$\mathbf{x} = \boldsymbol{\pi} / \mathbf{B}_{\pi} .$$

Given the estimates of total sales (**x**) for U.S. and Canadian off-farm businesses, we use the ratios of sectoral income and employment obtained from their respective input-output tables to estimate these business's contributions to their local economy's value-added income, labor income, and employment for the Canadian case. For the U.S. case, we report the 2007 ARMS employment estimates. As a robustness check, we found that the employment estimates for the U.S. case derived from equation (2) were within 6 percent of the 2007 ARMS employment estimates. Table 2 reports the contributions made by FPEs to their nonfarm economies.

3.2. Results

The summary measure of FPEs' contributions to their communities' well-being is value-added income, defined as the sum of labor and capital income plus indirect business taxes generated by their off-farm businesses. In addition to the value-added income generated by the farm operation, in 2007 off-farm businesses in the U.S. generated an estimated $111.6 billion in sales of goods and services, which resulted in an additional contribution of $54.6 billion to their communities' gross county products (Table 2). Similarly, Canadian farmers operating off-farm businesses generated $12.1 billion in sales, which resulted in $5.5 billion in additional value-added income accruing to their communities. The nonfarm businesses of FPEs paid out $19.7 billion in wages and salaries to 853,100 part-time and full-time employees in the U.S. and almost $2.9 billion in labor income to 68,200 employees in Canada.

For both countries, service sector businesses appear to generate the largest economic footprint in their local communities, accounting for about 55 percent of total value-added and labor income and the largest shares of employment linked to these businesses (Table 2). This outcome reflects the overall pattern of service sector enterprises driving the industrial composition of the two countries' rural and national economies.

Table 2. Contribution of FPEs to the off-farm economy

Item	All industrial sectors	*Industrial sector:* Agriculture, forestry, and fishing	Construction and manufac-turing	Infrastructure (utilities, wholesale trade, and transport)	Services	Unclassified proprietorships (with no employees)
United States		*Percent of total distributed across all categories*				
Off-farm business income (US $ milliions)	21,619	7.9	18.2	7.3	53.5	13.0
Sales (US $ milliions)	111,615	6.0	28.7	8.6	44.1	12.6
Value added Income (US $ milliions)	54,649	5.1	21.5	10.5	56.9	6.1
Labor Income (US $ milliions)	19,723	3.2	28.5	10.8	57.4	–
Jobs (number)	853,129	12.5	21.4	17.7	48.4	–
Canada		*Percent of total distributed across all categories*				
Off-farm business income (Can $ millions)	2,120	7.9	18.2	7.3	53.5	13.0
Sales (Can $ millions)	12,123	7.7	30.1	6.4	44.3	11.5
Value added Income (Can $ millions)	5,501	5.3	21.4	8.1	54.9	10.2
Labor Income (Can $ millions)	2,860	4.8	25.4	8.6	61.2	–
Jobs (Number)	68,194	9.8	19.4	7.2	63.6	–

This table's key finding points to the disproportionate contribution growth-oriented FPEs make to rural sustainability. These FPEs operating employer establishments generated 87 percent of all firm sales in the US and 88 percent in Canada, and contributed almost 94 percent of all value-added income from off-farm businesses in the US and 90 percent in Canada (Table 2). Yet, small in number, they make up in the U.S. case only 38 percent of all FPEs, and may represent key fixed-place human capital assets for local communities facing changing agricultural and rural economies (Vogel, 2012).

How important are U.S. and Canadian jobs directly tied to FPE off-farm businesses to the rural economy? In both countries, the share of local employment linked to these nonfarm businesses is higher in rural counties that are further from an urban core. In 2007 for both countries, jobs directly linked to off-farm businesses operated by farm households accounted for 0.2 percent of the employed labor force in metro counties and 1 percent in the urbanized nonmetro counties (Figure 3). In the U.S., the share of the total county labor force directly linked to FPEs' off-farm enterprises increased to almost 3 percent in less urbanized nonmetro counties to 4.3 percent in the completely rural counties. For the U.S. case, we observe when traversing the urban/rural continuum a 20-fold increase in the nonfarm employment directly linked to their farmer-run nonfarm employer establishments. In Canada, the shares of the total county labor force directly linked to these off-farm businesses increased to 1.6 percent in the less urbanizes counties to 2.3 percent in the completely rural counties. Similarly, for the Canadian case, we observe a 13-fold increase in the nonfarm employment linked to these farmer-run firms.

These findings suggest two additional stylized facts on the importance of farm portfolio entrepreneurship for rural communities. First, FPEs in the more remote rural areas play an increasingly important role in developing business opportunities. For these rural areas, attracting outside entrepreneurial resources is difficult. Hence, the place-based FPE's portfolio of intangible and tangible resources becomes a more highly valued development pivot, particularly in densely populated remote rural areas with large numbers of small farms. Second, the increase in the share of the total labor force tied to Canadian farmer-operated off-farm businesses is half that for the U.S. in the less urbanized nonmetro and totally rural counties. For the U.S., the county-level incidence of FPEs among all farmers is halved when the county's population density falls below 5 inhabitants per square mile (Vogel, 2012). For these Canadian counties, their population densities fall below this threshold, such that markets are too thin to support the same incidence of farm portfolio entrepreneurship observed in the more populous counties.

Figure 3. Percent of total county labor force employed directly by farm household operated off-farm businesses by type of county*

4. Conclusion

FPEs represent a small, but enduring segment of farm households in the U.S. and Canada, but agricultural economists or community development specialists have not recognized their importance to the rural economy. We found that for both the U.S. and Canada the share of local employment linked to these off-farm businesses is higher for rural counties that are more distant from an urban core. In these rural areas with limited resources, local communities increasingly rely on the FPEs as place-based contributors to its economic resilience. We found that the smaller shares of nonfarm employment supported by FPEs in Canadian rural counties relative to the U.S. were accounted for low population densities resulting further in thin markets and limited nonfarm entrepreneurial opportunities.

Rural development specialists working with agricultural statistics confront the tension between collecting data for the purposes of measuring farm sector performance versus that of assessing farm household well-being. In both the U.S and Canada, rural policy and rural programming largely emanate from the ministries of agriculture at both the national and state/province levels. Our study identifies and measures the contribution of FPEs to their local economies. In each country, the addition of a few more key questions to the ongoing farm surveys and censuses can improve our understanding of this and other rural development opportunities (Bollman, 1998). For countries in which separate household-level data on their rural economies is difficult or costly to collect, amended agricultural data collection systems allow the agricultural policymakers and researchers concerned with agricultural sustainability and the rural development policymakers and researchers concerned with rural community sustainability to explore the extent of the overlap between the two.

[1] Our data comes from U.S. and Canadian farm surveys in which one business enterprise is a census-farm. In this paper a 'farm' refers to a 'census-farm'.
[2] Scholars of small business entrepreneurship classify as 'novice' entrepreneurs those farmers whose sole business is the farm operation, or 'serial' entrepreneurs if having operated another farm or nonfarm business prior to running their current farm operation.
[3] We used 2007 data to establish a pre-Great Recession benchmark. Figueroa-Armijos, et al. (2012) found that the Great Recession induced a decline in 'growth' entrepreneurship in U.S. rural areas and an increase in 'necessity' entrepreneurship due to employment losses and business enterprise failures.
[4] This research was based on an earlier ERS farm typology that has subsequently been revised (Hoppe and MacDonald, 2013).
[5] For a detailed discussion on the methodology, data development, calibration, and robustness tests, see Vogel and Bollman (2012).

COMPARATIVE ANALYSIS OF CROSS SECTIONAL AND PANEL DATA COLLECTION FOR AGRICULTURAL STATISTICS IN MALAWI: DOES AN INTEGRATED VEHICLE PROVIDE AN EFFECTIVE FRAMEWORK?

ABSTRACT

This paper conducts a comparative analysis between cross sectional and panel component data collection methods for agricultural statistics in Malawi. The paper uses meta-analysis and / or revelatory case study approach to characterize a stand over cross sectional and panel data collection in Malawi. In this paper, we adopt a conclusion statement made by Deaton, Solon and Ashenfelter (1986) that, while there are genuine difficulties, there are good arguments for collecting panel data. Collecting panel data in Malawi is a sensible enterprise where both the dynamics and annual level statistics are generated. Despite advantages of a panel component in Malawi, they are very expensive as compared to cross section survey. We recommend a panel that is integrated in cross sectional data collection as is the case in the current Integrated

Household Survey design. This will not only improve and address data demands but also become cost effective for agricultural statistics stakeholders as would have been realized through a fully-fledged panel.

Keywords: Malawi, Cross Sectional, Panel Data Collection, Agricultural Statistics.

1. Study Context and Problem Statement

Agricultural development is an essential engine of growth in Malawi (GoM, 2012). It is also indicated as effective mechanism for combating food poverty. It often results in greater benefits accruing to the poorest segments of the population (National Statistical Office (NSO), 2014; Ravallion and Chen, 2007). It contributes about 40% to the Gross Domestic Product (NSO, 2016). Approximately 90% of households in Malawi depend on agricultural for their welfare security (NSO, 2015).

Success made in agriculture can only be tracked and attributed if consistent data is made available over time and in space. Prevailing data collections have produced conflicting agricultural statistics. Climatic change and weather related effects have led to high demand of agricultural statistics. World Bank (2010) argues that rapidly changing nature of agriculture in less developed countries especially in the errors of climatic change and the emergence of new issues make the available data and methods obsolete. Conversely, agricultural statistics are becoming expensive to collect, compile and analyze. Limited public finance and dwindling donor support of data collection exercises in agricultural sector is another obstacle that NSOcontinue to encounter. In other words, statisticians have to innovate new ways of achieving statistical demands in the agricultural sector in order to provide timely, relevant and consistentagricultural data (Binswanger, 2008). Innovations should at a minimumdisaggregate agricultural data into hard to reach population such as women, rural/urban and many others (International Development Committee, 2013).

Existence of serious weaknesses in agricultural statistics also persist throughout sub-Saharan Africa of which Malawi is not an exception (Carletto et al, 2010). Compliance to statistical standards in most of thesecountries remain low (FAO, 2008). Knowledge about agriculture and its impact on welfare and equity is limited by the lack of available, high quality, and consistent data on rural and gender disaggregated households. Althoughstudies have attempted to understand intra household dynamics, data is lacking to validate cases in terms of intra-household decision-making within agricultural activities (Koirala, Mishra and Sitienei, 2015).

On other hand, agricultural programming would be effectively realized and implemented if policy makers exploit data evidence based decisions. Of which data for informed decisions have to meet quality, timely, relevant and coordinated scopes (Binswanger, 2008). The Malawi National Statistical Office as a government department has this mandate and to exploit best practices that are innovative to ably capture agricultural data in a very cost effective manner and that meet quality dimensions aforementioned. One way would be to must partner with international organizations such as the World Bank, International Food Policy Institute (IFPRI and other institutions to have quality data in the agricultural sector. These institutions would provide an automated technical assistance that most government owned statistical offices lack.

In Malawi, NSO has embarked on this agenda through integrating household surveys with a huge agricultural component where most indicators are tracked. A data quality assurance framework has been developed and declares the needs of adopting a 10 year integrated household survey programme that streamline data collection activities (NSO, 2015).This would achieved both cost effectiveness and efficiency. Similarly, NSO has also reduced the time between panels to facilitate quick and comparable dynamic data of households' welfare in the country. Nonetheless, a rush decision to adopt a survey programme without a verified research would yield more costs than benefits. In this paper, we attempt to provide empirical responses conducting a comparative analysis of cross section, panel and integrated data collections in terms of their value for money, effectiveness and feasibility?

2. Rationale

Agricultural and rural development policies have gained in importance since independence (Moreddu, 2011). In Malawi, more complex information has been demanded to evaluate them (Matchaya, 2014). These new types of information that are at once more local, complex, multidisciplinary and integrated (Moreddu, 2011). Rural development and rural statistical indicators require information that goes beyond the agricultural sector, that is available at a disaggregated level, and which is comparable across area such as agricultural versus non-farm activities, males versus female plot managers (FAO, 2015). This requires significant resources sometimes to the detriment of basic agricultural information.The huge outcry of most Central Statistical Offices to become autonomy is not an issue of professional independence but of financial independence. This means existing data collection approaches may be finance demanding. In other words, a properly design data collection vehicle is critical for most National Statistical Offices for their continued existence and role in the economy.

3. Research Methodology

In this paper, we first adopt a meta-analysis (desk research) of cross section and panel data collection. In other words, we adopted a revelatory case study approach following Fitzgerald and Fitzgibbon (2014). We basically review publishable articles of the living standards measurement study team of the World Bank and World Class Universities that have provided a thorough discourse on data collection approaches.Survey reports that have been reviewed include Integrated Household Survey and Agricultural Production Estimate Surveys. Second, we have tried to interact with technocrats in agricultural statistics so that we derive experiential based understanding of cross section and panel data collection methods. We have lastly tried to relate such data collection approaches to Malawi.

4. Value for Money

Agricultural surveys,such as Agricultural Production Estimate Survey, Cost of Production and other, are determined based on national priorities within the limitations of cost and other constraints (World Bank, 2010).They capture quarterly information on a variety of topics, such as crop areas, yields, production, livestock, pesticides, etc. Carletto et al (2010) points out that such surveys usually collect information on structural characteristics; economic characteristics; labor force characteristics and share of income that goes to household. In the case of Malawi, an agricultural production estimate survey is, a traditional cross sectional survey, conducted quarterly to capture the whole agricultural value chain that is from land preparation, planting and harvesting (MoA, 2016). Nonetheless, it provides data on production, area and yield quantities.

On the other hand, an Integrated Household Survey (Malawi IHS) or Integrated Surveys on Agriculture is more complex than traditional cross-sectional data. This is both analytically and in terms of actual data collection (NSO, 2012). It combines both a cross section and panel data collections. Panel survey sample component areregularly refreshed to maintain the national representativeness of the data (NSO, 2016). It collects a wide variety of indicators as compared to a traditional agricultural production estimate survey.

In other words, an integrated household survey fits well in the needs of the country. On average a panel embedded survey in Malawi collects almost all FAO minimum core indicators in agricultural sector. Agriculture questionnaires collects information on a core set of indicators that have been identified through a consultative process with several experts. Additionally, an Integrated Household Survey programmesupports the National Statistical Office (NSO) to generate nationally representative, household panel data with a strong focus on agriculture and rural development through technical assistance, hands on trainings and others.

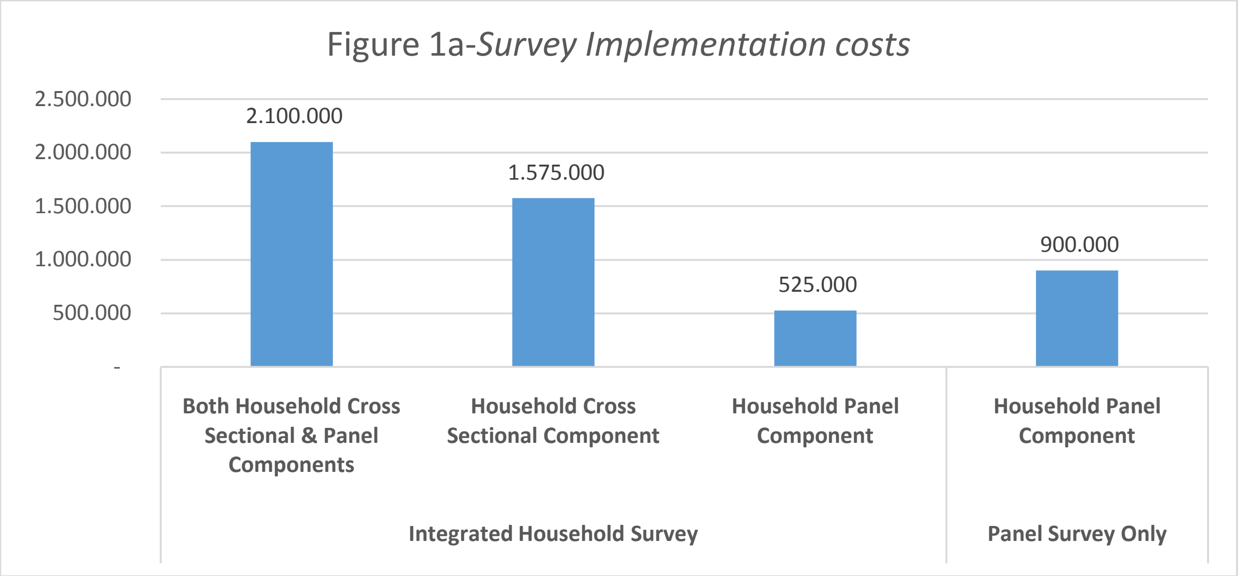
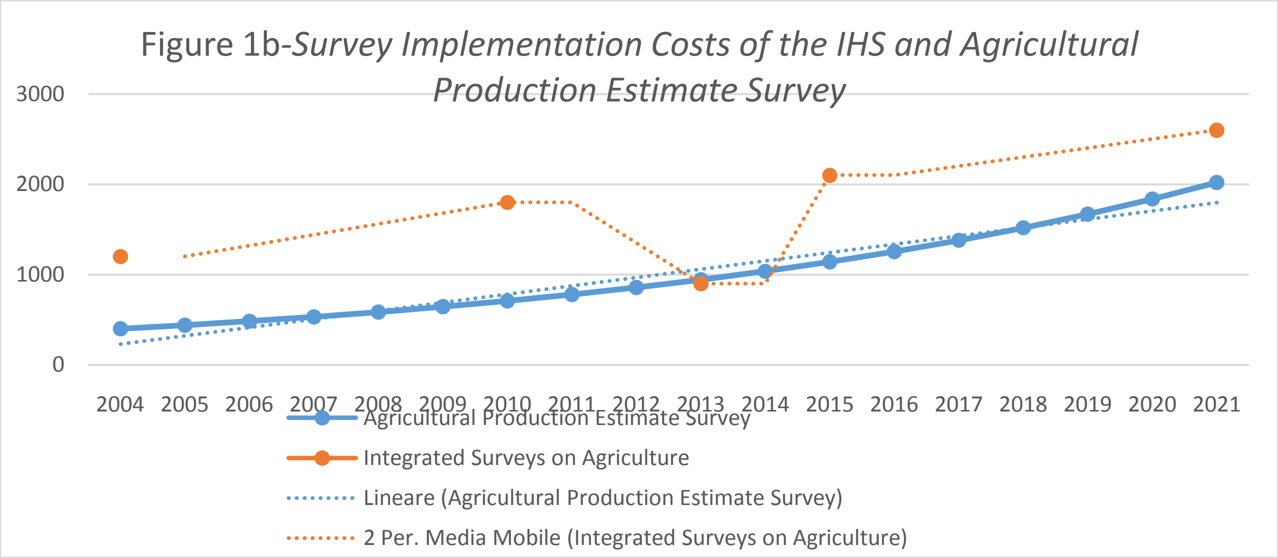
Sources: Ministry of Agriculture (2016); NSO (2014); FAO (2011); FAO (2008)

The Integrated Household Survey is expensive as roughly compared with the Agricultural Production Estimate Survey (APES) (see Fig 1a& 1b). A stand-alone household panel survey component costs more than an APESS. However, if we adopt an integrated household survey approach, the cost of a panel in an integrated household survey is just one quarter of the total cost of the survey.

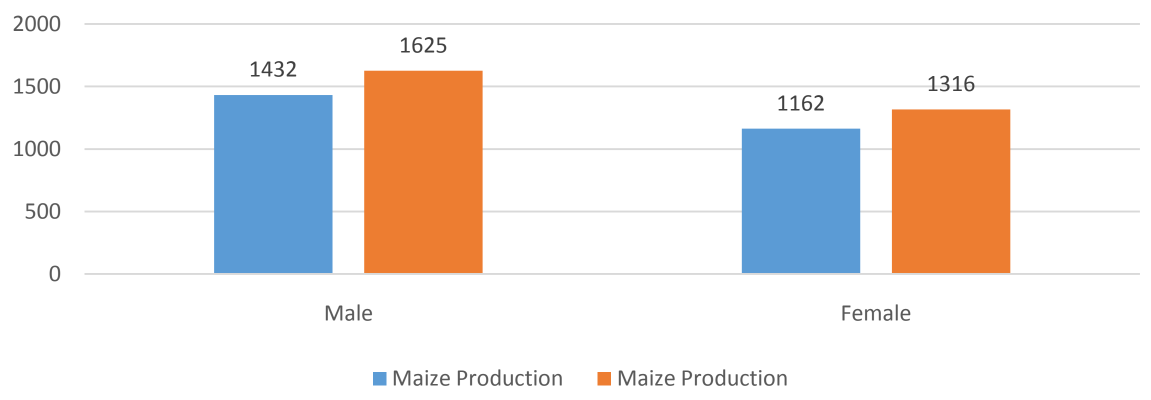


In terms of value for money, an integrated household surveys collects data on all types of household characteristics, not just households with agricultural holdings (Carletto et al, 2010). This allows for comparison between the different economic sectors and other important disaggregation.



Importantly, an Agricultural Production Estimate Survey supports annual decision with regards to areas under cultivation, production and yield. However, this does not permit the analysis of the relationship between the holding characteristics and the characteristics of the household and its members (MoA, 2016; NSO, 2014).

Figure 2-*Maize crop production by gender*



Agriculture is critical if countries are to achieve the poverty targets set forth by Development Goals within the agreed timeframe (World Bank, 2007). In Malawi, the majority of people suffering from food poverty are rural dwellers and other vulnerable groups,including women, who rely heavily on farm activities (GoM, 2015)). Thus, efforts to fight poverty must focus on rural areas and agriculture, and must be gender-sensitive (Carletto et al, 2010).

Table 2: *Agricultural characteristics by gender of household heads*

	Female Heads	*Male Heads*

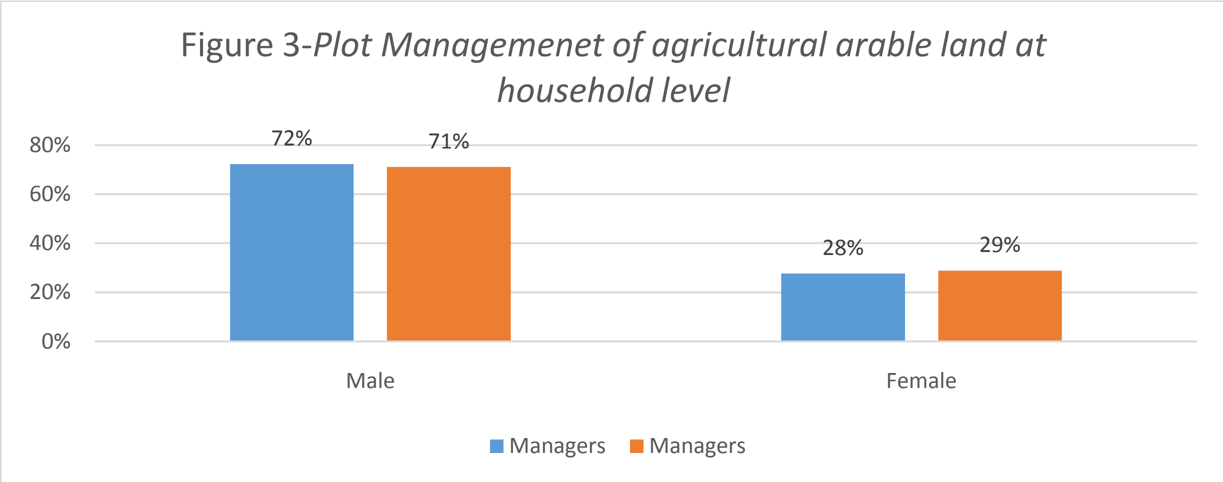
land value in Mk	48154	53200
land rent in Mk	3369	3700
seed in kg	14	20

Source: Koirola, Mishra and Sitienei (2015)

An Integrated Household Survey approach is implicitly therefore designed to meet this global development goals' call as it collects individual-level data by gender on control of household resources, decision-making and participation in agriculture and off-farm activities (see Figure 2 & 3). This provides researchers with a platform to conduct gender-specific analysis related to agriculture and off farm activities. From an

Integrated Household Survey approach we can assess the changes in household management between genders.



5. Advantages

First, research based on cross-sectional data helps to describe snapshots, and with repeated cross-sectional data, to measure broad trends at the macro level. However, they do not assist in understanding the dynamic aspects of the population change at the individual level (Wijesekere, 2009). This limitation portrays lack of capacity to discuss structural change and non-existence of data that could describe across individual and household characteristics. In 2013, a household panel in Malawi provided dynamics over various variables that could be correlated at individual and /or gender level (NSO, 2014).

Second, as the panel surveys have both cross-sectional and time-series elements; each wave is similar to a cross-sectional survey and when data for more than one wave have been collected then it will become a time series. Thus, panel surveys allow cross-sectional analysis of a particular issue of policy relevance as well as providing time-series analysis to assess trends, at the individual level, as opposed to aggregate-level analysis that is possible with cross-sectional data. More importantly, panel surveys provide opportunity to examine transitions between states–flow data to analyze change.

Third, like panel surveys, repeated cross-sectional surveys can collect information on the target population at different points in time, but without the assurance that the subsequent surveys will include the same population covered in the previous rounds. The advantage of panel surveys, therefore, is that they cover the same persons at different points in time, including split families or households, and add new members 'born into' the sample when they become in-scope according to the criteria used for sample management. This means a panel would still achieve dynamisms in human society (Wijesekere, 2009).

Panel data can further provide valuable information for policy-makers on an issue of policy significance that cross-sectional data cannot provide. At times panel data provide information that is quite different to that derived from cross-sectional analysis. In Malawi, for example, there are large differences in the estimates of the number of farm households between the Ministry of Agriculture (3.4 million farm households) and the National Statistics Office (2.47 million rural households), which in turn affects the accuracy and effectiveness of planning for the subsidized input program (School of Oriental and African Studies, 2008).

It is well known that cross-sectional data cannot resolve the issue of ambiguity in correlation and, more importantly, cannot confidently demonstrate the direction of causality (Davies, 1994:28). As panel surveys interview the same individual over different points in time, and panel data have a time order of measurement, they are suitable for assessing causality between variables (Hsiao, 2014). Panel data have the capacity to identify stability and change at the individual level. The causal association can be determined when the cause precedes the effect (or outcome of interest). Panel data have the advantage of convincingly identifying this. A detailed discussion of advantages of panel data collection can be found through work of Hsiao, 2014.

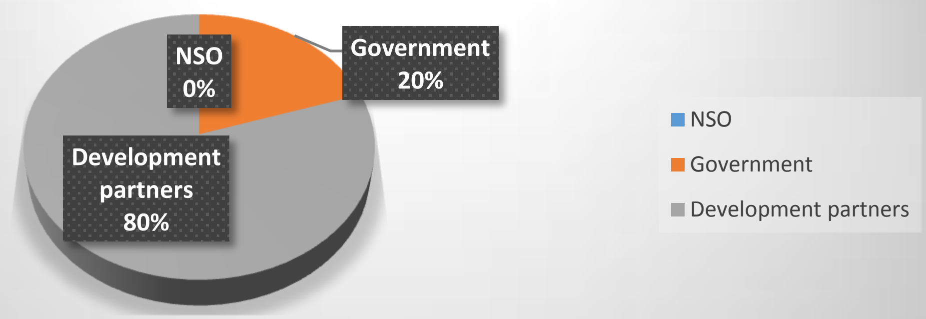
The current statistical system provides a fresh cross section of data each year for a new set of (randomly selected) agricultural holders. This format is very good, however, it does not enable policymakers to empirically assess the effectiveness of agricultural interventions over time or investigate medium- to long-term agricultural dynamics. For this, they need a subsample of agricultural holders to be surveyed repeatedly over a number of years(IFPRI, 2011).

Generally, an Integrated Household Survey improves the quality of household survey data; increases the capacity of statistical institutes to perform household surveys; improves the ability of statistical institutes to analyze household survey data for policy needs and provides policy makers with data that can be used to understand the determinants of observed social and economic outcomes (NSO, 2015).

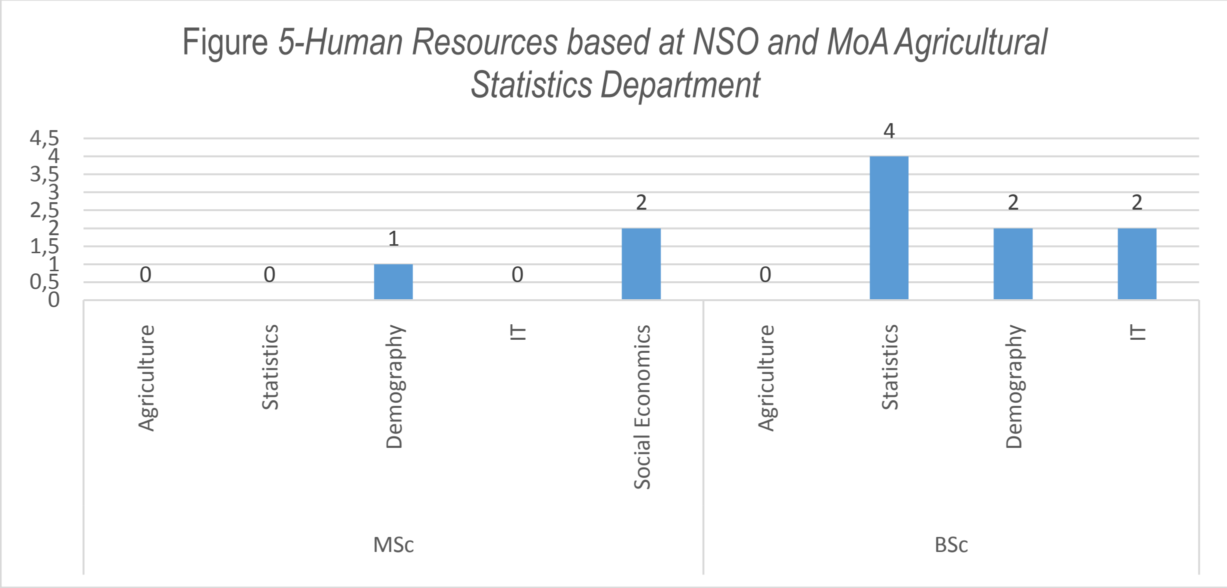
6. Limitations

Panel data collection demands financial and human capacity. Malawi, for which agriculture is a critical source of livelihoods, lacks the financial resources to generate survey data related to agriculture and off-farm activities (see Figure 4). It is noted that most agricultural survey collections are financially supported by development partners. This creates a threat for continued panel data collection in Malawi. For example, in 2015, an Integrated Household Survey failed to take off because of frozen development partner support. Even with sufficient financial resources, the NSO still lacks agricultural driven human resources to collect and analyze such data in a cost-effective and sustainable manner (see Figure 5).

Figure 4-*Financial Contribution towards implementation of household surveys*



Agricultural data are often collected in institutional isolation, with little coordination across sectors and little analytical value-added beyond the sector. For example, the Ministry of Agriculture collects agricultural data using a production estimate survey while the NSO collects agricultural data using an HIS or National Agricultural Census or Welfare Monitoring Survey. Carletto et al (2010) reports that there is disparity between number of households and yield reported by the MoA and the NSO due to institutional isolated survey designs and implementation. Lastly, there is also lack of analytical capacity that has created a vicious cycle of poor analysis undermining the demand for high-quality data. For example, Figure 5 shows that there is only one personnel with a Masters in Economics and one staff with Masters in Demography. These personals do not have agricultural background.



Author: Calculations

While panel data have numerous advantages over cross-sectional data they too are subject to limitations. The major limitation is the cost. Depending on the methods used to choose the samples, the cost of the first wave of a panel survey is expected to be not much different from that of the cross-sectional survey. Conducting subsequent waves in a Panel survey is expensive because it involves tracking all the original sample members who are in-scope for subsequent surveys.

Panel surveys are considered not as good as cross-sectional surveys at giving cross-sectional estimates if the subsequent waves of panel surveys are not representative of the population or subject to a high level of coverage errors, which are likely to accumulate over time (Deaton et al, 1986). Additionally, the response rates of subsequent waves could also be lower than those observed in cross-sectional surveys, partly because of dropouts from later waves and difficulty in tracing sample members.Obtaining exactly the right balance between overlaps and new households requires more detail on preferences than most investigators could be expected to provide for a multi-purpose survey, but the point remains that a rotating design of some sort will generally be better than either a pure panel or independent cross-sections.

7. Conclusion and Recommendations

The paper adopt a conclusion statement made by Deaton, Solon and Ashenfelter (1986) that, while there are genuine difficulties, there are good arguments for collecting panel data. Collecting panel data inMalawi is a sensible enterprise through generating both the dynamics and annual level statistics. However, they are very expensive. It would therefore be important for the panel component to be integrated into cross section household surveyvehicleas in the current Integrated Household Survey design so that there is reduction in costs of implementing a fully-fledged panel.

Demographic and social characteristics of the agricultural producer's households

Susana Pérez*
INEGI, General Direction of Economic and Agricultural Censuses
Aguascalientes, México
susana.perez@inegi.org.mx

DOI: 10.1481/icasVII.2016.f34c

ABSTRACT

The Food and Agriculture Organization of the United Nations (FAO), in its "World Programme for the Census of Agriculture 2010" and "Global Strategy to Improve Agricultural and Rural Statistics", recommends capturing the demographic and social characteristics of the household members of a producer that performs agricultural operations, regardless of whether it is the household´s predominant activity or only a secondary source of income.

Knowing the characteristics of the population that lives directly on agricultural or livestock activity, allows a better study of the conditions under which rural producers perform their duties, and provides more elements to perform various analyzes of its economic and social environment, thus contributing to the design of public policies and support programs.

In Mexico, projects that generate social-demographic statistics provide the country with a wealth of information on the characteristics of the population and, although these statistics account in particular localities with fewer people, they do not provide specific data on households located in rural areas, in which the persons responsible of the management and decision making of the agricultural and forestry production units live.

Therefore, taking advantage of the performance of the National Agricultural Survey 2014 conducted by the National Institute of Statistics and Geography (INEGI), a complementary chapter was included in the questionnaire, which guaranteed the collection of the producer´s data and of the people living in the dwelling. This yielded information on aspects such as kinship, age, gender, economic dependence, indigenous self-description, indigenous language, education and participation in farming or other economic activity.
This paper is aimed at presenting various shades of the agricultural producer´s household, such

as:

- Economic and social characteristics of the small, medium and large agricultural producers
- Characteristics of the production units run by women farmers
- Characteristics of the production units run by indigenous farmers
- Economic and social characteristics of the persons performing family agriculture
- Production units' social characteristics according to producer's schooling
- Characteristics of both households whose economic dependence comes entirely from farming as those households where agricultural production is a marginal activity.
    - Characteristics of rural households in the different regions of the country.

Keywords: sociodemographic, farming, livestock, support programs.

Introduction

The 2014 National Agricultural Survey

In this context, the National Institute of Statistics and Geography (INEGI), conducted the 2014 National Agricultural Survey (2014 ENA), which was conceived as a survey for exploiting data on the main species produced in the agricultural sector in Mexico.
2014 ENA is the second from a series of surveys that INEGI has raised as part of an agricultural information system that provides structural information and in both structure and the circumstances surrounding the sector to meet the data requirements of the primary sector, thus contributing to decision-making and to the definition of programs for the producers and country benefit.
Selected products for 2014 ENA are those that generate higher added value in the agricultural and forestry sector in Mexico and that are considered in the laws and programs that regulate objectives, priorities and policies for economic growth, and particularly for the Agricultural sector.
Thus, the final list for the survey includes 34 priority products:

> Agricultural products: white corn, yellow corn, forage maize, sugar cane, wheat grain, avocado, grain sorghum, beans, chili, alfalfa, tomatoes, potato, melon, watermelon, coffee, orange, grape, banana, lemon, mango, onion, pumpkin, zucchini, green tomato, cotton, apple, cocoa, rice, barley and soybeans.
>
> Livestock products: cattle, milk, pork, poultry and eggs.

As well as nine more products that are significant in some regions of the country:

> Agave in Jalisco; forage oats in Chihuahua, Mexico City, Durango, State of Mexico and Zacatecas; coconut in Colima and Guerrero; strawberry in Michoacan; guava in Aguascalientes, Michoacan and Zacatecas; nopal vegetables in Mexico City; pine in Chihuahua, Durango and Michoacan; forage sorghum in Coahuila, Nuevo Leon and Sonora; and blackberry in Michoacan.

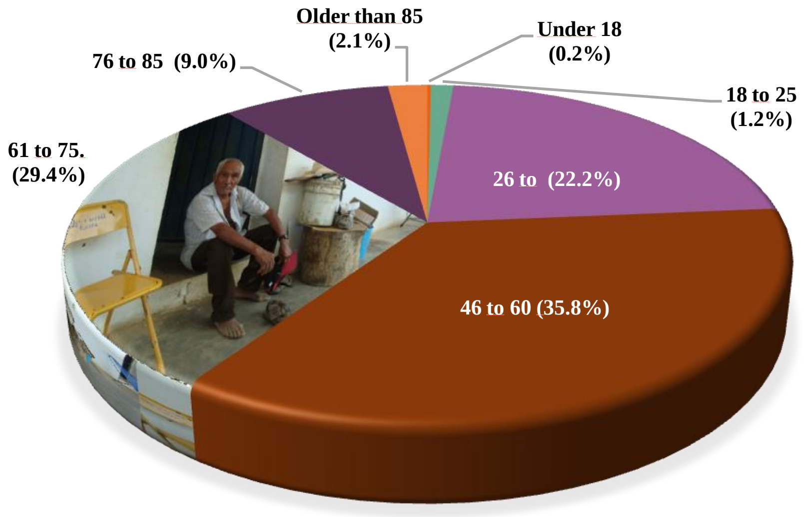
2014 ENA, estimated 3.8 million production units that cultivated or exploited from the above products. Final data are supported by the design of a probabilistic sample, except for four products (poultry, eggs, pine and blackberry), where a deterministic design was applied.

This survey provides information on the supply of food products; needs and employment opportunities in the field; the participation of women in farming and livestock activities; the destination of crops; technological innovations for production; degree dependence on fertilizers and other inputs; the needs of natural resources; water and irrigation systems benefits; seeds availability; use and deterioration degree of vehicles, tractors and machinery; financing; insurance; the main problems producers' deal with; and social and demographic characteristics of people living from agricultural production; among other topics.
Overall, the results of this survey provide a wide range of possibilities to know about quantitative and qualitative information from agricultural and forestry production units; specifically, the results of the 2014 ENA provide insight into typologies from the producer and the members of his household, such as kinship, age, sex, education, economic dependence, indigenous self-identification, indigenous language and participation in farming or other economic activity, as shown in the following sections.

Age and education of farm producers

Obtained data reflect one of the biggest current problems in the Mexican countryside, which is the producers' age: 76.3% are 46 or older, and from that percent, 40.5% specifically reported to be older than 60 years old; i.e. agricultural activities are not being undertaken by new generations, and that includes producers' children.

2014 National Agricultural Survey
Producer's age (%)



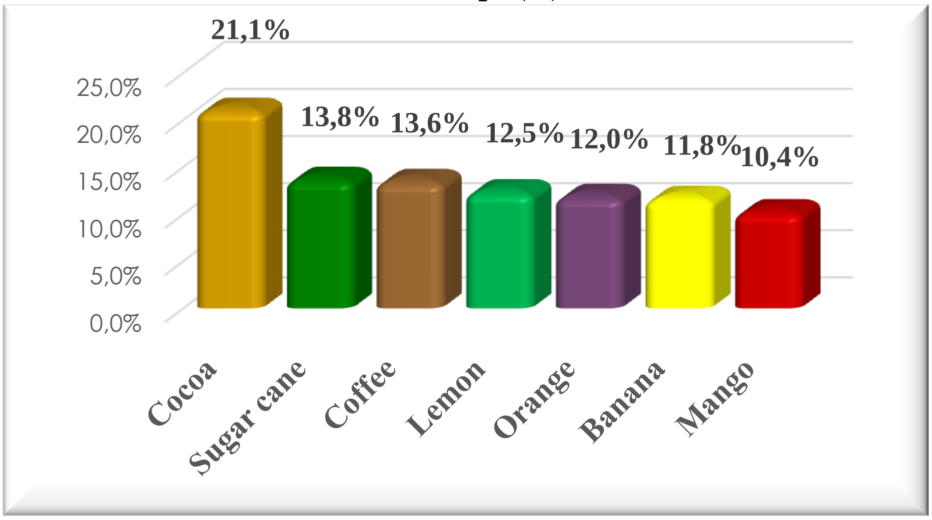
Concerning education level of the producer's and people living in farm households, most producers have an elementary education level (57.6%) and only 9% reported a high school education level or higher; in comparison, the percent of inhabitants of the country, not in the agricultural sector, shows a tendency to have higher education levels, since 17.7% achieved a high school education level or higher. By comparing these data with those of the total population, it can be determined that, in general, the education level of rural producers and their families is below the average of the total population, where

26.8% studied high school or has a bachelor's degree (according to the 2010 Population and Housing Census in Mexico).

Production units managed by women and participation of women

From surveyed production units, 11.3% are under women's responsibility. In the case of crops, according to production volume, participation of female producers stands out in obtaining cocoa, sugar cane, coffee, lemon, orange, banana and mango.

2014 National Agricultural Survey
Production units whose owner is a woman
Production volume according to total national production
Main crops (%)

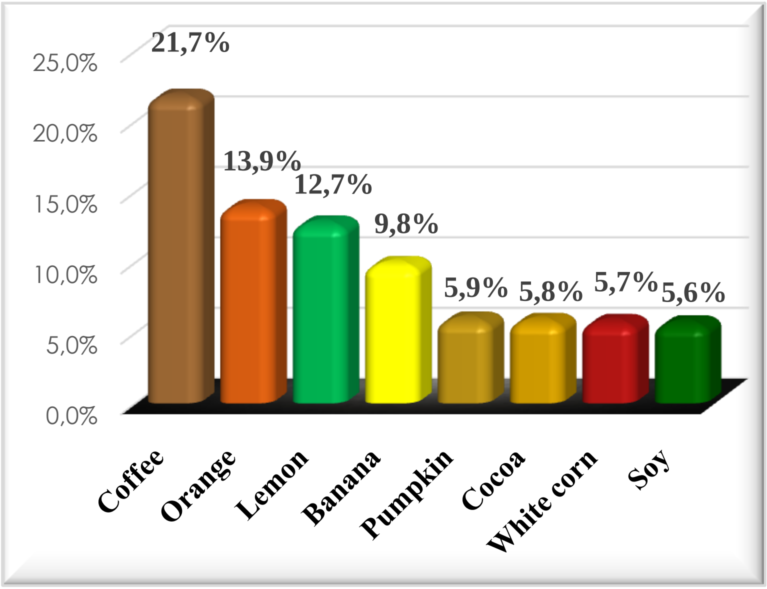


The participation in labor force in agricultural activities was of 17 women per every 100 male workers; female participation is higher in the farming activities (18.1%) than in cattle activities (15.8%).
It can be established that the participation of women in agricultural activities is significantly lower than the participation in not agricultural activities, where, in average, there are 44 women for every 100 persons employed (according to data from 2014 National Economic Censuses in Mexico).

Production units of indigenous self-identification

One of the concepts that was collected in 2014 ENA is the term *indigenous self-identification,* i.e. if the farmer considers himself indigenous because of his ethnicity or for preserving the customs and traditions of his ancestors.
The result indicates that 18% of the surveyed producers were self-identified as indigenuos, of which 81.8% stated speaking a native language.
Consequently, 18% of agricultural production surveyed units, are led by an indigenous producer, but that only represents 8.5% of production volume. The main crops they produce are coffee, orange, lemon, banana, squash, cocoa, white corn and soybeans.

2014 National Agricultural Survey
Production units whose owner identifies himself as indigenous
Production volume according to total national production
Main crops (%)



4.6% of bovine stock and 3.8% of pig stock nationwide, correspond to the production units whose holder identifies himself as indigenous.

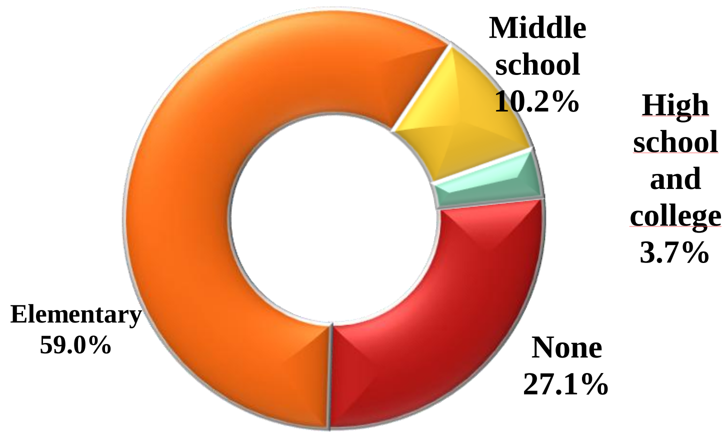
Regarding the destination of the production, 53.8% is destined to self-consumption (47.9% to cattle, 4.9% to the family and 1.0% to sowing seed), 43% goes to sales and 3.2% corresponds to losses for wastage.

2014 National Agricultural Survey
Production units whose owner identifies himself as indigenous
Production volume by destination (%)

	Destination of production	Indigenous production units	Total production units
	Sale	43.0%	73.4%
	Household consumption	4.9%	1.6%
Self consumption (53.8%)	Cattle consumption	47.9%	20.5%
	Seed for sowing	1.0%	0.9%
	Losses for wastage	3.2%	3.6%

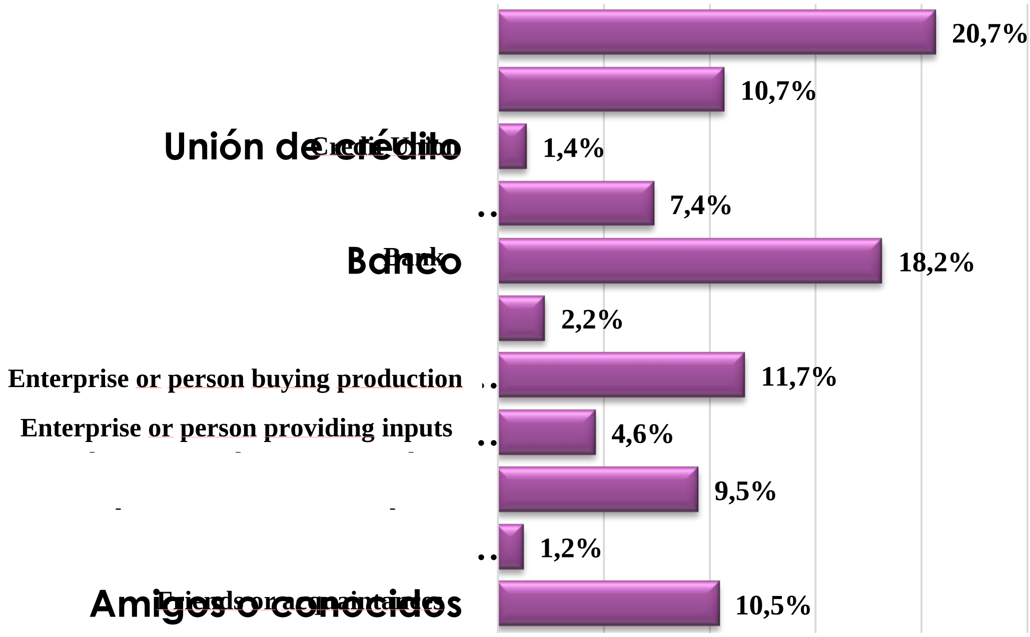
In production units led by indigenous, one of each five employed persons are women and four are men. As for schooling, 27.1% have no educational level, 59% have some elementary grade, 10.2% some middle school grade and only 3.7% reported to have studied high school, or college.

2014 National Agricultural Survey
Production units whose owner identifies himself as indigenous
Education and indigenous language speakers (%)



4.8% of the production units whose holder identifies himself as indigenous, obtained some type of financing for his agricultural activities with savings banks and banks as their main suppliers.

2014 National Agricultural Survey
Production units whose owner identifies himself as indigenous
Sources of credit or loaning
4.8% of indigenous production units obtained credit
(Percentage is 10.4% at national level)



Family Agriculture

A subject in which international agencies have special interest is "Family agriculture", in order to define public policies aimed at supporting these types of units (according to the Center of Studies for Sustainable Rural Development and Food Sovereignty of the Chamber of Deputies, family agriculture is defined as *agriculture that is performed predominantly with the work of the producer and his family*).
For 2014 ENA results, the units that reported only family labor without receiving a wage or salary were considered as family agriculture production units (all units that reported having hired any type of personnel for agricultural work were excluded).
Under this definition, 32.6% of the agricultural production units in Mexico perform family agriculture, which represents 9.9% of the production volume.
As for the products generated by these units, the cultivation of cocoa, beans, white corn, orange and coffee stand out. Also, 15.5% of bovine stock and 8.8% of pig stock are located therein.
As in production units under responsibility of indigenous, most of the production is destined to saleS (53.9%), while self-consumption represents 38.6%, (where cattle consumption predominates with 47.9%) . The wastage in this case represents 7.4%.

Another interesting aspect is the type of buyers, where intermediaries stand out (34.9% of total production), followed by the final consumer (17.2%) and packing and processing industries (5.4%). And to a lower extent, the sales to commodity markets, malls and supermarkets, among others.

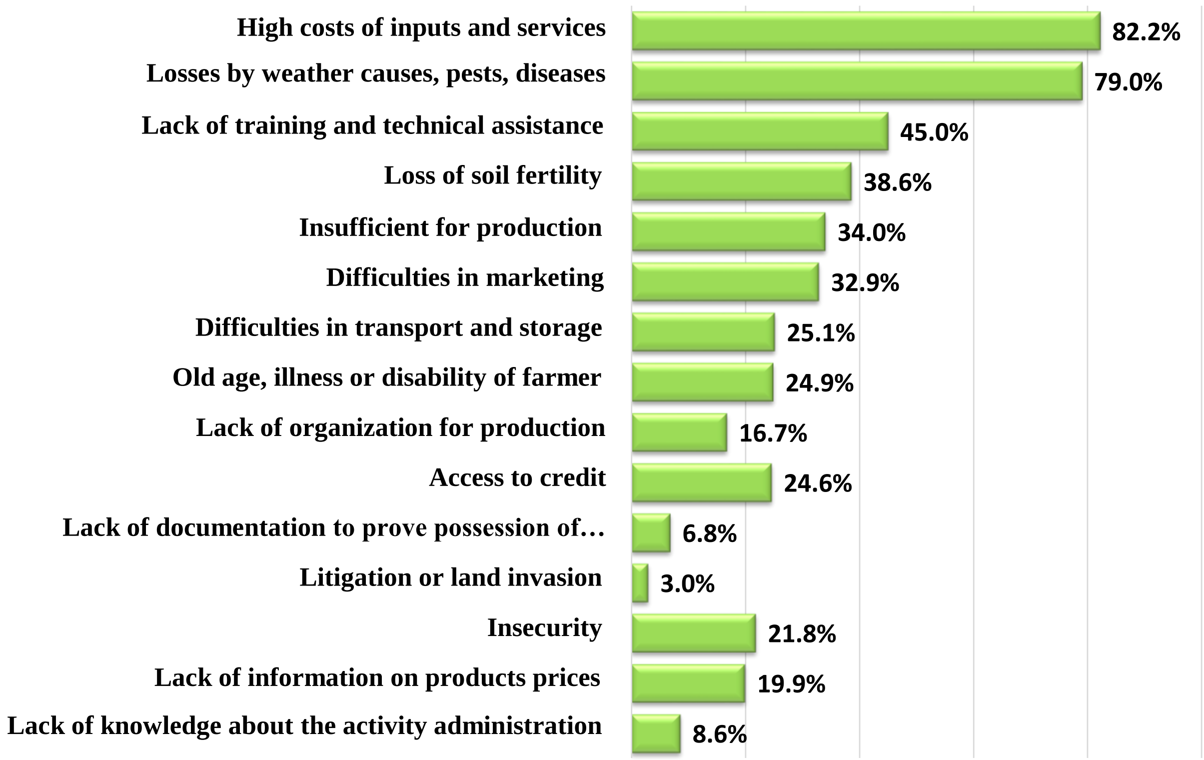
2014 National Agricultural Survey
Production units that perform family agriculture
According to sales of agricultural production (%)

Addressee of sold production	**Production units that perform family farming**	**Total production units**

Directly to consumer	17.2%	24.5%
Intermediary (broker)	34.9%	45.0%
Commodity markets	1.4%	2.6%
Malls or supermarkets	0.5%	0.8%
Packing or processing industries	5.4	5.0%
Other country	0.0%	0.1%
Other buyer	2.5%	2.6%

On another issue, 6.2% of the production units that perform family agriculture obtained some type of credit, mainly from savings banks.
It is worth noting that family agriculture production units reported that their main problems to carry out their agricultural and livestock activities are the high cost of inputs and services (82.2% of the units), losses due to weather causes, pests and diseases (79%) and lack of training and technical assistance (45%).

2014 National Agricultural Survey
Family agriculture production units
Problems presented during the development of the activities of agricultural production units (%)



Conclusion

ENA 2014 was created as survey that considers several matters of interest from institutions that regulate, assess and determine support programs for forestry and agriculture producers. Its results a wide range of possibilities, which allows us to know among other topics: particularities of women, farmers, important features of family agriculture and the conditions of production for indigenous producers. ENA 2014 provides significant indicators for public policy to be focused on supporting disadvantaged groups, by implementing practices that meet their needs.

THE AGRICULTURAL INTEGRATED SURVEY (AGRIS): RATIONALE, METHODOLOGY, IMPLEMENTATION

François Fonteneau
AGRIS Programme Manager
Food and Agriculture Organization of the United Nations (FAO), Statistics Division
Via delle Terme di Caracalla, Rome, Italy
Francois.Fonteneau@fao.org
DOI: 10.1481/icasVII.2016.f34d

ABSTRACT

The Agricultural Integrated Survey (AGRIS) is a farm-based modular multi-year survey program. The AGRIS methodology is being finalized by FAO in the context of the Global Strategy to improve Agricultural and Rural Statistics. AGRIS complements other relevant initiatives such as the World Bank LSMS-ISA and aims to scale-up these global efforts. AGRIS implementation is just starting with partner countries.

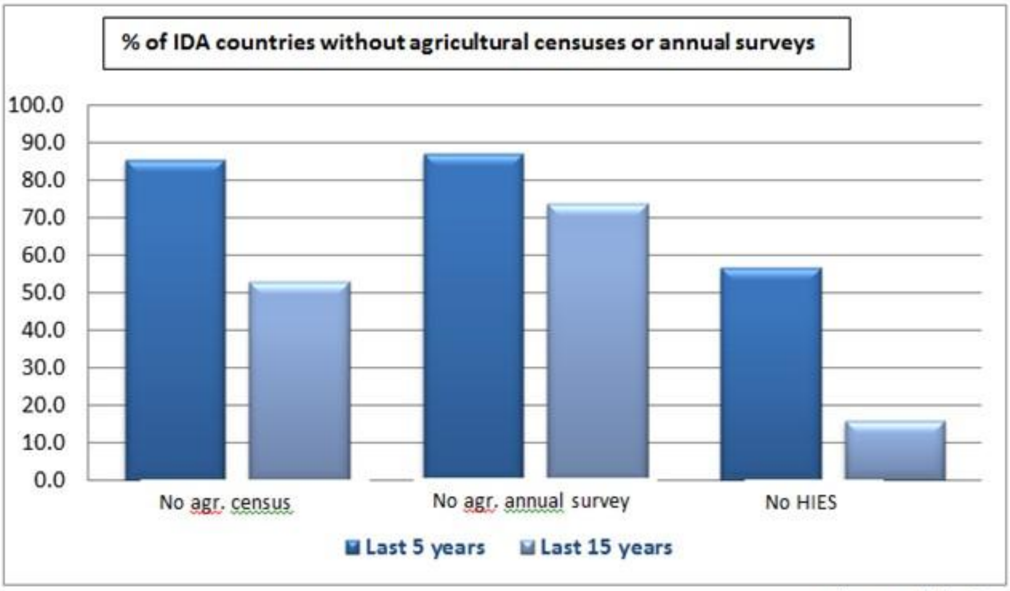
AGRIS is designed as a cost-effective way for national statistical agencies to accelerate the production of quality disaggregated data on the technical, economic, environmental and social dimensions of agricultural holdings. The data generated is meant to inform policy design and implementation, as well as improve market efficiency and support research. AGRIS constitutes an invaluable data source and provides the framework for designing, monitoring and evaluating any agricultural and rural policy or investment. AGRIS is designed to be particularly relevant for developing countries. Together with the agricultural census which it complements, a versatile agricultural market information system, and an appropriate use of remote sensing and administrative data, AGRIS is a cornerstone for the establishment of a comprehensive rural information system.

National agencies that are willing to design and implement a customized AGRIS will find in the AGRIS Toolkit the necessary resources in terms of (1) technical methodology, (2) specialized survey tools and instruments that use the latest knowledge and technology and cover the full range of survey steps, and (3) budget and institutional framework guidelines. Currently, FAO and its partners are scaling up a network of expertise, especially at regional level, to provide the necessary training, technical assistance and funding opportunities.

Keywords: agricultural integrated surveys, farm level data collection, modular approach, SDG, FAO guidelines

1. Rationale

3.1 The need for more, better, cheaper and faster statistical data in the agricultural and rural sector generally is widely recognized. While some progress on accessing existing information has been made in recent years, thanks to the traction of the open data movements, critical gaps on data production still remain in many countries. These gaps are largely explained by an absence of quality data collection, whether censuses or surveys. Some countries have yet to successfully leverage the technical and institutional innovations available for the industrialization of statistical production. Indeed, the majority of IDA countries1 have not conducted any agricultural annual surveys or censuses over the last 15 years, as shown in the table below:



(source: Author)

Figure 1: *The lack of agricultural surveys and censuses in IDA countries*

3.2 The Global Strategy to Improve Agricultural and Rural Statistics was endorsed in 2009 by the United Nations Statistical Commission, to address these concerns relating to poor data availability or quality, and the lack of capacity in developing countries. The Global Strategy is a coordinated effort to provide a conceptual and institutional framework for the production of data, to establish a Minimum Set of Core Data (MSCD) required to meet the current and emerging demands of national development policies, to develop cost-effective methodologies for data production and use, and to establish the necessary governance structures and capacities.

[1] http://www.worldbank.org/ida/borrowing-countries.html

3.3 As one of the main features of cost-effective methods, the Agricultural Integrated Survey (AGRIS) is designed to help national agencies accelerate the production of quality disaggregated data on the technical, economic, environmental and social dimensions of agricultural holdings[2]. AGRIS builds on the previous work of the Global Strategy and presents a unique opportunity to channel these methodological innovations, and to have a real impact on data systems on the ground.

3.4 The data generated by AGRIS is meant to inform policy design and implementation, improve market efficiency and support research. AGRIS constitutes an invaluable data source and provides the framework for designing, monitoring and evaluating any agricultural and rural policy or investment. The proposed generic set of AGRIS questionnaires will generate 65% of the MSCD data requirements. It will also provide basic data for monitoring the relevant SDGs. AGRIS provides essential and direct information for the following 6 SDG indicators: 2.3.1 / 2.3.2 / 2.4.1 / 5.4.1 / 5.a.1.a / 5.a.1.b. Additionally, AGRIS provides essential but indirect information for the following 16 SDG indicators: 1.1.1 / 1.2.1 / 1.2.2 / 1.3.1 / 1.4.1 / 1.4.2 /2.5.1 / 2.5.2 / 5.b.1 / 7.1.1 / 8.5.1 / 8.5.2 / 8.7.1 / 8.8.1 / 9.1.1 / 17.8.1. Finally, AGRIS is expected to generate the flow of quality data required to monitor regional policy frameworks, such as the African Union Comprehensive Africa Agriculture Development Programme (CAADP).

3.5 AGRIS, being a 10-year integrated survey program, lays the foundations for the creation of an efficient agricultural statistical system. Together with the agricultural census which it complements, a versatile agricultural market information system, and an appropriate use of remote sensing and administrative data, AGRIS is a cornerstone for the establishment of a comprehensive rural information system.

3.6 Without AGRIS, existing data gaps can only be filled by ad-hoc suboptimal mechanisms with high transaction costs. This would further increase the burden on people, agricultural holdings and data systems, and would not guarantee the data quality required by users. Ultimately, this would prevent any monitoring of these policy frameworks and would constitute an obstacle to the accountability and transparency required by functioning markets.

2. Methodology

2.1 The AGRIS methodology is being developed by FAO in the context of the Global Strategy. Some activities involve partner agencies, for example the World Bank and ILO. Research and testing is also conducted with national agencies on an ad-hoc basis.

[2] "An agricultural holding is an economic unit of agricultural production under single management comprising all livestock kept and all land used wholly or partly for agricultural production purposes, without regard to title, legal form, or size. Single management may be exercised by an individual or household, jointly by two or more individuals or households, by a clan or tribe, or by a juridical person such as a corporation, cooperative or government agency. The holding's land may consist of one or more parcels, located in one or more separate areas or in one or more territorial or administrative divisions, providing the parcels share the same production means, such as labour, farm buildings, machinery or draught animals." From FAO, WCA 2020.

Overall data collection strategy

2.2 AGRIS is synchronized with the Agricultural Census and operates over a 10-year cycle. AGRIS proposes to decrease the burden of conducting censuses by scheduling the collection of thematic data (e.g. non-structural data) over this time frame. This will contribute to a more regular flow of data, which would be more in line with the limited capacities currently in place for the production and use of statistics.

2.3 AGRIS consists of a collection of questions that can be classified in one of two main categories: a core section and a rotating section. The core section (also referred to as the ‘core’ or ‘core module’) focuses on a range of different themes that remain largely the same in each survey round. The rotating section (‘rotating modules’) is devoted to specific themes, the implementation frequency of which will vary among countries with different agricultural systems and data demand priorities.

2.4 The following table summarizes a possible modules flow for the four recommended modules: ‘economy’, ‘labour force’, ‘machinery and equipment’, and ‘production methods and environment’. The financial and human resources input required to sustain and implement such a set-up is relatively stable over the 10 year cycle, making it a viable set-up for a data producing agency. The targeted annualized budget for an IDA country for such a set-up is within the USD1m – 1.5m range. The flexible, modular nature of AGRIS makes it easy to modify this proposed setting and thus enhance its national relevance and its cost-effectiveness. Additional rotating modules may also be added to respond to additional specific data needs.

	Years	0	1	2	3	4	5	6	7	8	9	10
Agricultural Census		●

AGRIS Rot. Module 1	Economy				●		●		●		●	
AGRIS Rot. Module 2	Labour force			●				●				●
AGRIS Rot. Module 3	Machinery and equipment					●				●		
AGRIS Rot. Module 4	Production methods and environment				●			●				●

Figure 2: *Proposed AGRIS modules flow*

2.5 In order to provide timely information for market efficiency and decision making, data collection should be conducted several times during the year. This is particularly true for the Core Module in countries with several crop periods. Rotating Modules, in particular the Economy and Labour Force modules, could also require several waves of data collection in their years of implementation. Sub-sampling plans could be used to accommodate budget constraints, while producing more frequent data with different levels of statistical significance.

2.6 Survey-to-survey imputation methods can be a cost-effective way to fill some of the data gaps in the AGRIS scheme above, or between AGRIS and other relevant surveys (such as stand-alone labour force surveys). The key challenges for survey-to-survey imputation are that the two types of surveys (or modules) must be designed in a similar way (including questions asked), and the model parameters must not change over time.

Data collection mode

2.7 In the context of developing countries, improving data quality, and in particular accuracy and timeliness, remains a top priority. Face-to-face interviews carried out by professionals enumerators remain the best means of quality data collection. When required, data collection could include the use of self-reported log-books (or SMS log-books), for example in the case of multiple harvest seasons or livestock data (Core Module), or cost of production (Rotating Module 1). The use of CAPI technologies is recommended, to improve data quality and timeliness. Add-on devices to the mobile CAPI-enabled platforms could be used to perform a number of direct measurements – whether geocoding and plot area measurements (GPS), or measurements relating to the environment (leaf cover indices, soil and water characteristics, etc.). Mixed-mode data collection will be piloted to ascertain the benefits of surveying a panel of household holdings by phone and a panel of non-household holdings by means of web questionnaires. The systematic use of the GPS coordinates of the location of holdings and plots is recommended, to accelerate the ground-truthing of complementary remote sensing information systems.

Sampling

2.8 The AGRIS sample techniques and sample size will be decided by the implementing national agencies, based on the sample frames available, the capacities to design and implement complex sampling techniques and corresponding field work, the budget available and the ultimate data accuracy and disaggregation required.

2.9 Specific and detailed sampling guidelines and tools are provided in the AGRIS Toolbox (see paragraph 27 below). These tools are based on the advanced research conducted by the Global Strategy on Multiple Frame Sampling and on the Integrated Survey Framework.

2.10 Different theoretical and practical issues relating to frames exist, and, in many countries, still limit surveying options and eventually reduce data quality and usability. These issues range from generic issues, such as frame coverage (for list frames in particular) to more specific issues, such as the poor accuracy of livestock statistics based on area frames. Guidance upon these matters will be provided in the AGRIS Toolkit.

2.11 The AGRIS sampling strategy is versatile, to be able to meet the different national situations. In a nutshell, the strategy is articulated around the following elements:

- Stratified multistage random sample for farms from the household sector, based on a list frame when relevant or on an area frame (points or segments)
- Stratified simple random sample for farms of the non-household sector
- Panel sampling to enable longitudinal analyses
- Subsampling for rotating modules

2.12 Seasonality is a key dimension in agriculture. Right timing of data collection is of critical importance. The appropriate use of sub-samples and panels will allow AGRIS to capture some of the seasonality factors. Methodological options to administer data collection only once or several times a year are provided - both for the core and the rotating modules.

Topics covered and data items

2.13 AGRIS covers different technical, economic, environmental and social dimensions of agricultural holdings through its core module and its 4 rotating modules: ‘economy’, ‘labour force’, ‘machinery and equipment’, and ‘production methods and environment’. The following tables list the proposed data items for each module. The AGRIS Toolkit further details these data items and proposes corresponding generic questionnaires.

2.14 AGRIS collects sex-disaggregated data on key topics, through both the core and the rotating modules. This entails a more refined identification of male and female headed households, and will help to assess women's contribution to agriculture through labour and their access to and control of productive assets, resources and services.

2.15 Different series of generic questionnaires will be proposed for the AGRIS core module, to capture the variety of farming systems worldwide. The core module will collect data on the following topics:

<u>CORE MODULE</u>

1. Ide ification and general characteristics of the holding
2. emographics and social characteristics *[HS-AH only]*
Demographics Social protection : safety nets Social protection : transfers / gifts
3. olding housing infrastructure and key assets *[HS-AH only]*
4. ccess to markets and information
Access to agricultural markets Access to information
5. Pro ction Methods and Environment
6. abour
Labour input on the holding Work force availability
7. conomy
Access to finance
8. gricultural Productions
Crops: temporary crops Crops: temporary crops, next campaign Crops: permanent crops Livestock Milk, eggs and other animal productions Aquaculture and fisheries
9. Pro ction shocks and coping mechanisms

2.16 The four AGRIS rotating modules will collect data on the following topics:

<u>ROTATING MODULE 1: ECONOMY</u>

1. ans of production (no labour)

Land tenure Property of livestock Storage capacity
2. In me
Total income Income from agricultural activities Income from other gainful activities Subsidies/aid received
3. osts of production
Linked to crop production Linked to livestock production Salaries Insurance Linked to other gainful activities
4. M n commercial networks for the production
5. redit and access to financing
6. ccess to information and other issues

ROTATING MODULE 2: LABOUR FORCE

1. ousehold members' contribution to the agricultural holding (HH sector only)
Basic demographics information Participation in agricultural activities of the AH (incl. salary/wages; employment/own use production, etc.) Participation in diversification activities of the AH (incl. salary/wages; employment/own use production, etc.) Participation in other activities (incl. unpaid domestic activities, care, other activities related to own family AH) Managerial role in the agricultural activities on the AH
2. ousehold members' other working activities - diversification (HH sector only)
3. ired labour of the AH (HH and non HH sectors)
Basic demographic information Participation in agricultural activities (incl. salary/wages) Participation in diversification activities of the AH (incl. salary/wages) Wages / labour cost Work conditions (incl. decent work, informality, etc.)
4. ther labour force used in the AH (HH and non HH sectors)
Non-permanent employees (seasonal) Agricultural work carried out by a specialised company Other labour force

ROTATING MODULE 3:MACHINERY AND EQUIPMENT
(Types and quantities in use, access and ownership)

1. M hinery and Equipment - types & quantities in use, access & ownership
Manually operated equipment Animal powered equipment Machines for general farm use Tractors, bulldozers and other vehicles Land preparation and planting machinery and equipment Crop maintenance machinery and equipment Crop harvesting machinery and equipment Post-harvest machinery and equipment Livestock machinery and equipment Aquaculture machinery and equipment Energy production machinery and equipment Storage and marketing machinery and equipment Water management machinery and equipment
2. ontractors and services, activities
3. istribution of Managerial Decisions in the holding

ROTATING MODULE 4: PRODUCTION METHODS & ENVIRONMENT
(Quantities, types and areas)

1. Use of Natural Resources
Land use Energy sources Soil management Irrigation and drainage
2. Crops production systems and resources
Fertilizers Plant protection products Crops and seeds varieties and resources Rice cultivation, specificities Type of non-residential buildings
3. Livestock production systems and resources
Type of livestock production system Livestock types and resources Animal breeding and reproduction Animal housing, manure management, equipment and transportation of animals Veterinary products and use of traditional medical methods Feed and use of pastures
4. On farm processing of agricultural products and by-products
5. Organic farming (certified or in conversion to organic)
6. Agro forestry
7. Access to and use of services, infrastructure and natural resources
Agricultural extension services (incl. veterinary) Infrastructure (incl. IT, communications, access to market) Access to natural and common property resources
8. Greenhouse gas and environment
9. Adaptation to climate change and mitigation strategies
10. Waste Management

2.17 The AGRIS Toolkit provides additional resources to guide in the design and customization of the questionnaires. Specific guidelines will synthetize costs/benefits dimensions of different options for the sequencing of the rotating modules, for different farming systems.

Data access

2.18 When AGRIS is initiated at country level, a detailed release calendar will be published by the national agencies responsible, to announce the survey outputs available to each category of users, and under which conditions. This release calendar shall be user friendly and consistent with both the national dissemination policy in place and the international best practices (such as open data protocols).

2.19 FAO will maintain a DDI-compliant[3] AGRIS Central Catalog, in line with the practices of and tools made available by the International Household Survey Network4. In addition to all relevant metadata, questionnaires and survey outputs, the AGRIS Central Catalog will provide easy and safe access to anonymized microdata, for research purposes. The exact access terms for each survey dataset will be agreed between national agencies and FAO, and will fall under either of two categories: "public use file" and "licensed file". When anonymized microdatasets cannot be made available, the catalog will still provide detailed metadata at the variable level. The AGRIS Central Catalog will be connected to the national catalogs and to relevant international catalogs such as the World Bank Microdata Catalog or the IHSN Central Survey Catalog, for automatic harvesting and data exchanges. National agencies will have access to detailed usage statistics on their own products.

2.20 The AGRIS Central Catalog will be critical for ensuring long-term preservation of and access to AGRIS resources.

2.21 Partnerships with local universities will be recommended, to build the long-term capacity to understand and use complex microdatasets and the associated econometrics techniques. This is expected to increase statistical literacy, fuel research and inform civil society on policy choices.

The AGRIS Toolkit

2.22 The national agencies that are willing to design and implement a customized AGRIS will find, in the AGRIS Toolkit, the necessary resources in terms of (1) technical methodology, (2) the specialized survey tools and instruments that use the latest knowledge and technology, and that cover the full range of survey steps, and (3) budgetary and institutional framework guidelines.

2.23 The AGRIS Toolkit is being developed by FAO in consultations with partner agencies and external experts. These parties rely heavily on the research conducted and the guidelines produced within the framework of the Global Strategy. Customization of the generic survey tools to meet specific country data needs and statistical infrastructure is a prerequisite for a successful implementation. FAO and other partners can provide technical assistance and training in this process, as requested by national agencies.

3. Implementation

National implementation

3.1 AGRIS is designed as a national survey program, implemented by national agencies under an official mandate to produce statistical data.

Alignment with national priorities and capacity-building

3.2 In the context of developing countries with limited statistical capacity, the priority is to respond to the demands that have already been expressed. In particular, 12 African countries have identified the design and implementation of AGRIS as a priority[6]. Alignment with national priorities as identified in national statistical strategies[7] and work programs will continue to be an overarching principle of AGRIS' implementation. AGRIS will strengthen national systems and will provide an opportunity for the enforcement of national and international standards, thus eventually contributing to the enhancement of statistical capacity and literacy.

3.3 FAO will proactively promote AGRIS in countries where this approach can fill some of the identified data gaps. When financial and/or technical assistance is required, customized work programs will be designed.

3.4 All agencies that are willing to design and implement AGRIS are encouraged to use the resources available in the AGRIS Toolkit, and to customize them to their specific needs. Agencies are encouraged to share survey outputs so that these too can be shared also through the AGRIS Central Catalog.

International coordination: the GRAInS Partnership

3.5 In addition to its involvement in the Global Strategy, FAO works closely with relevant international organizations and interagency groups. In particular, FAO works closely with other relevant survey programmes, such as the World Bank LSMS-ISA. FAO is also a member of the Inter Secretariat Working Group on Household Surveys (ISWGHS).

3.6 A multi-agency survey hub is being established in Rome, Italy, to advance the common goal of facilitating the production and use of household and farm survey data for evidence-based policymaking by improving survey methods, generating high-quality data, and strengthening statistical capacities in low and middle-income countries. In this respect, on 13 November 2015, FAO, the International Fund for Agricultural Development (IFAD), and the World Bank signed a Memorandum of Understanding as a first step towards a broader alliance on agricultural and rural policy data.

---

[6] Identification of technical assistance needs in agricultural statistics of African countries, Action Plan for Africa of the Global Strategy, GS/AfDB report, February 2015

[7] Examples of these strategies include the Strategic Plans for Agriculture and Rural Statistics which are being designed in the context of the Global Strategy, as well as the generic National Strategies for the Development of Statistics.

3.7 AGRIS will be implemented within the framework of the Global Rural and Agricultural Integrated Surveys (GRAInS) Partnership. GRAInS is a joint initiative of several key international agencies – including FAO and the World Bank – which are involved in the funding or methodological design of agricultural and rural surveys. The longer-term vision is for GRAInS to be formally established as a separate institutional entity and for a common financing instrument (e.g. a multidonor fund) to be created. This will enable the pooling of resources and thus attain a truly joint programme.

3.8 To achieve greater coordination and foster methodological coherence among related survey initiatives, including AGRIS and LSMS-ISA, as well as to promote methodological and technological advances in the collection, dissemination and use of agricultural data, the following are identified as common objectives of the GRAInS Partnership, which should catalyse joint or closely coordinated activities:

- to work towards the methodological and operational integration of the AGRIS and LSMS-ISA programs and to strengthen methodological standards in household and farm surveys in developing countries;
- to enhance the ability of international agencies, in close coordination with regional partners, to provide technical assistance to countries and build capacity in the design and implementation of integrated surveys on agriculture and the rural space;
- to develop and test technological innovations to promote the integration and usability of different data sources and reduce the cost of data collection, while improving quality and timeliness: examples include the enhanced application of sensors, mobile phones, GPS, satellite imagery, and various forms of Big Data, which may complement and add value to more traditional data collection methods such as household and farm surveys.

F35

SAMPLING STRATEGIES AND ESTIMATION METHODS FOR INTEGRATION IN AGRICULTURE STATISTICS

Session Organizer
P.D. Falorsi | Istat | Rome | Italy

ABSTRACT

The collection of statistical data by integrating information from different sources, including both censuses and surveys, is increasingly a requirement for the production of statistics, with a view to expand knowledge capacity and to guarantee a higher quality of statistical data. At the national level, the need to cope with a growing demand for ever more information, interlinked by demo-socio-economic factors, is fundamental for decision and policy making at national and international levels, and entails a greater effort in terms of organization and budgeting for the conduct of large-scale statistical surveys. The efficient use of all available information to produce accurate and timely statistics, in the most appropriate and necessary areas, is therefore a fundamental challenge. Moreover, several recent development studies acknowledge the importance of agriculture for the national economies of developing countries and its key role for overall economic growth, increased incomes, poverty reduction and the fight against hunger.

The session is focused on defining sampling strategies allowing to foster data integration and producing consistent estimates in agricultural statistics, considering the different steps of a generic data process:

- Sampling design: the (i) How to collect consistent data for statistical populations including different statistical units (eg. Farms and households); (ii) how to ensure the integration of different surveys in the phase of sampling design; (iii) how
- Record linkage: how to link microdata having common statistical units;
- Sampling estimate: how to ensure consistency for survey data having different sampling designs, but with a common set of variables.
- This should enable the development of relevant means for achieving integration in the various circumstances that characterize developing countries.

ABSTRACT

In agricultural survey data, relationship between study variable (e.g., crop yield) and covariates may not be same over the study area, this phenomenon is referred to as spatial nonstationarity. Small area estimates based on the widely-used area-level model proposed in Fay and Herriot (1979) assume that the area level direct estimates are spatially nonstationary. We propose an extension to the Fay-Herriot model that accounts for the presence of spatial nonstationarity in the area level data. We refer to the predictor based on this extended model as the nonstationary empirical best linear unbiased predictor (NSEBLUP). We also develop two different estimators for the MSE of the NSEBLUP. The first estimator uses approximations similar to those in Opsomer et al. (2008). The second estimator is based on the parametric bootstrapping approach. Results from simulation studies using spatially nonstationary data indicate that the NSEBLUP compares favourably with alternative area-level predictors that ignore this spatial nonstationarity. Both of the proposed methods of MSE estimation for the NSEBLUP seem to perform adequately. Developed small area estimation method is applied to produce district level estimates of crop yield in the State of Uttar Pradesh using the data on crop cutting experiments supervised under Improvement of Crop Statistics scheme (data collected with much reduced sample size, however, the quality of data is very high) and the secondary data from the Census. The results show a considerable gain in precision in estimates produced applying small area estimation. These estimates will provide invaluable information to policy-analysts and decision-makers.

Keywords: District level estimates, small area estimation, spatial nonstationarity, geographical weighted regression, Census

1. Introduction

Sample surveys are usually designed so that direct estimators for larger domains lead to reliable estimates, where by direct estimators here we mean estimators that use only the sample data from the domain of interest. However, direct estimation is typically inefficient for smaller domains where sample sizes can be small, and cannot be used when there are no sample units in the domain. Following standard practice, we refer to these smaller domains as 'small areas' or just 'areas' from now on. Indirect (i.e. model-based) small area estimation (SAE) techniques are now widely employed to produce estimates and measures of precision for these small areas. In this context, we differentiate between SAE methods based on unit-level models and those based on area-level models. In the former case these models are for the individual survey measurements and include area effects, while in the latter case these models are used to smooth out the variability in the unstable area-level direct estimates. Area-level modelling is typically used when unit-level data are unavailable, or, as is often the case, where model covariates (e.g. census variables) are only available in aggregate form. Fay and Herriot (1979) proposed an area-level SAE model (hereafter the FH model) that relates small area direct survey estimates to area-level covariates. The FH model is widely used because of its flexibility in combining different sources of information with different error structures, and can be described as follows. Let *i* index the *m* areas of interest and let y_i be an unbiased direct survey estimator of an unobservable population parameter (for example, the population mean) Y_i of a variable of interest *y* for area *i*. Let $\mathbf{z}_i$ be a vector of *q* auxiliary variables for area *i* that are related to the population mean Y_i. These variables are typically obtained from administrative and census records. The FH model is then defined by the two equations

$$y_i - Y_i = e_i \text{ and } Y_i - \theta - \mathbf{z}_i^T\boldsymbol{\lambda} = u_i, \quad (1)$$

where the first equation models the prediction error of the observed survey estimate y_i of the true area *i* population mean Y_i, while the second models the unobservable Y_i in terms of an overall mean θ and a linear combination of the components of the vector $\mathbf{z}_i$, and is such that the area effects u_i satisfy $E(u_i|\mathbf{z}_i) = 0$. Put $\mathbf{x}_i^T = (1, \mathbf{z}_i^T)$ with $p = q+1$ equal to the dimension of $\mathbf{x}_i$. Combining these two equations then leads to an area level linear mixed model of form

$$y_i = \mathbf{x}_i^T\boldsymbol{\beta} + u_i + e_i;\ i = 1, \ldots, m. \quad (2)$$

Here $\boldsymbol{\beta} = (\theta, \boldsymbol{\lambda}^T)^T$ is a *p*-vector of unknown fixed effect parameters, the area effects u_i are independently and identically distributed, with $E(u_i|\mathbf{z}_i)=0$ and $\mathrm{Var}(u_i|\mathbf{z}_i)=\sigma_u^2$, and the prediction errors e_i are independently distributed, with $E(e_i|\mathbf{z}_i)=0$ and $\mathrm{Var}(e_i|\mathbf{z}_i)=\sigma_{ei}^2$. The area effects and the prediction errors are assumed to be independent of each other within and across areas. An important additional assumption that is usually made is that the prediction variances σ_{ei}^2 are known.

Since the parameters $\boldsymbol{\beta}$ and σ_u^2 are the same for every area, they can be estimated using the data from all *m* areas. This is usually accomplished by 'stacking' the area level direct estimates to produce an overall area level mixed model of the form

$$\mathbf{y}=\mathbf{X}\boldsymbol{\beta}+\mathbf{u}+\mathbf{e}, \tag{3}$$

where $\mathbf{y}=(y_1,...,y_m)^T$ is the $m\times 1$ vector of direct survey estimates, $\mathbf{X}=(\mathbf{x}_1,\ldots,\mathbf{x}_m)^T$ is the $m\times p$ matrix whose *i*-th row is given by $\mathbf{x}_i^T$, $\mathbf{u}=(u_1,...,u_m)^T$ is the *m*-vector of random area effects and $\mathbf{e}=(e_1,...,e_m)^T$ is the *m*-vector of prediction errors. This model can be generalised by replacing **u** in (3) by **Du**, where **D** is diagonal matrix of dimension $m\times m$ of area-specific covariates that can be used to characterise heteroskedasticity in the area effects. In the interests of avoiding unnecessary notational complexity, we ignore this generalisation here. It is assumed that the vector of area effects **u** is distributed independently of the prediction errors $\mathbf{e}$, so that the covariance matrix of the vector $\mathbf{y}$ is given by $\mathrm{Var}(\mathbf{y})=\mathbf{V}=\sigma_u^2\mathbf{I}_m+\boldsymbol{\Sigma}_e$, where $\mathbf{I}_m$ is the identity matrix of order *m* and $\boldsymbol{\Sigma}_e=diag\{\sigma_{ei}^2;1\le i\le m\}$ is the known matrix of prediction variances. The parameters σ_u^2 and $\boldsymbol{\Sigma}_e$ are sometimes referred to as the variance components of (3). Under the assumption that **u** is Gaussian, σ_u^2 can be estimated using maximum likelihood (ML) or restricted maximum likelihood (REML). Let $\hat{\sigma}_u^2$ denote the resulting estimator of σ_u^2 and define the plug-in estimator $\hat{\mathbf{V}}=\hat{\sigma}_u^2\mathbf{I}_m+\boldsymbol{\Sigma}_e=diag\{\hat{\sigma}_u^2+\sigma_{ei}^2;i=1,\ldots,m\}$ of the covariance matrix $\mathbf{V}$. Under (3), the empirical best linear unbiased estimator (EBLUE) of $\boldsymbol{\beta}$ and the empirical best linear unbiased predictor (EBLUP) of $\mathbf{u}$ are then

$$\hat{\boldsymbol{\beta}}=(\mathbf{X}^T\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}\mathbf{X}^T\hat{\mathbf{V}}^{-1}\mathbf{y} \tag{4}$$

and

$$\hat{\mathbf{u}}=\hat{\sigma}_u^2\hat{\mathbf{V}}^{-1}(\mathbf{y}-\mathbf{X}\hat{\boldsymbol{\beta}}), \tag{5}$$

respectively. Under (2), the EBLUP estimate of Y_i is (Henderson, 1975; Fay & Herriot, 1979)

$$\hat{Y}_i=\mathbf{x}_i^T\hat{\boldsymbol{\beta}}+\boldsymbol{\delta}_i^T\hat{\sigma}_u^2\hat{\mathbf{V}}^{-1}(\mathbf{y}-\mathbf{X}\hat{\boldsymbol{\beta}})=\mathbf{x}_i^T\hat{\boldsymbol{\beta}}+\hat{u}_i, \tag{6}$$

where $\boldsymbol{\delta}_i^T$ denotes the i^{th} row of $\mathbf{I}_m$. Note that the corresponding EBLUP of the area effect u_i is therefore $\hat{u}_i=\hat{\gamma}_i(y_i-\mathbf{x}_i^T\hat{\boldsymbol{\beta}})$, where $\hat{\gamma}_i=\hat{\sigma}_u^2\left(\hat{\sigma}_u^2+\sigma_{ei}^2\right)^{-1}$ defines the shrinkage effect for area *i*. See Rao (2003, chapter 5) for further details.

In practice areas are unplanned domains, and so many of them have zero sample sizes. These areas are referred to as non-sampled areas. The conventional approach for estimating area means in this case is synthetic estimation (Rao, 2003, pp. 46), based on a suitable model fitted to the data from the sampled areas. Let $\mathbf{z}_{j,out}$ denote the vector of covariates associated with non-sampled area *j*, and put $\mathbf{x}_{j,out}^T=(1,\mathbf{z}_{j,out}^T)$. Under model (2), the synthetic EBLUP predictor for the unknown population value $Y_{j,out}$ of area *j* is then

$$\hat{Y}_{j,out}=\mathbf{x}_{j,out}^T\hat{\boldsymbol{\beta}} \tag{7}$$

where $\hat{\boldsymbol{\beta}}$ is given by (4). We refer to this predictor as SYN in what follows.

Model (2) implicitly assumes that direct estimates from different areas are uncorrelated. However the boundaries that define an area are typically arbitrarily set, and there appears to be no good reason why neighbouring areas should not be correlated. This can be the case, for example, with agricultural, environmental, economic and epidemiological data. It is therefore often reasonable to assume that the effects of neighbouring areas, defined via a contiguity criterion, are correlated. Cressie (1991), Singh *et al.* (2005) and Pratesi and Salvati (2008) extend the mixed model (3) to allow for spatially correlated random effects using conditional autoregressive (CAR) and simultaneous autoregressive (SAR) specifications for **u** (Anselin, 1992). These models allow for spatial correlation in the area effects, while keeping the fixed effects parameters spatially invariant. Under the area level version of this spatial mixed model, Singh *et al.* (2005) and Pratesi and Salvati (2008) define the spatial empirical best linear unbiased predictor (SEBLUP) for a small area mean and also derive an approximately unbiased estimator of the MSE of the SEBLUP.

An alternative approach to incorporating spatial information in SAE is to assume that the model for $E(Y_i|\mathbf{z}_i)$ varies spatially. There are currently two approaches to specifying such a model. The first uses a spatially varying surface to model the mean structure of (2). For example, Giusti *et al.* (2012) extend the unit level nonparametric spatial spline approximation of Opsomer *et al.* (2008) in order to define a spatially non-linear area level model. These authors then develop the corresponding area-level nonparametric empirical best linear unbiased predictor (NPEBLUP) for a small area mean. A key feature of this approach is that it assumes that the regression parameters associated with the model do not vary spatially. Instead, spatial variability is accommodated by adding spatially varying covariates to the model specification. There are situations, however, where this assumption is inappropriate, a phenomenon referred to as spatial nonstationarity, see for example Brunsdon *et al.* (1996) and the references therein. The second approach therefore replaces the global regression model (2) by one where the regression specification varies locally. Such a model can be fitted using geographically weighted regression (GWR), a method that is widely used for data exhibiting spatial nonstationarity (Brunsdon *et al.*, 1996, Fotheringham *et al.*, 2002). Note that the model underpinning GWR is a local linear model, i.e. a linear model for the conditional expectation of *y* given **z** at a specified location. Under GWR the data are assumed to follow a location specific linear regression function, with geographically defined weights used to estimate the parameters of this local regression function. We use the GWR concept to extend the FH model (2) to spatially nonstationary area level data. We refer to this extended model as a spatially nonstationary FH model, and investigate its suitability for SAE with area level data that exhibit spatial nonstationarity. Note that we have not provided simulation results, bootstrap approach of MSE estimation and many other analytical details in this paper. Readers are suggested to refer Chandra *et al.* (2015) for these details. The rest of paper is organized as follows. The nonstationary version of the area level linear mixed model and the estimator of a small area mean under this model are described in Section 2. Section 3 presents the theoretical expression for mean squared error of this predictor and an estimator for this mean squared error. Given that the approach is for the spatially nonstationary situation, a bootstrap procedure to test for the presence of spatial nonstationarity is also proposed in this Section. Section 4 presents an application of proposed method in a real data from agriculture survey to produce the crop yield estimates at small area level. Finally, Section 5 discusses concluding remarks.

2. A Spatially Nonstationary Area Level Model

Under (1), the parameters making up the vector $\boldsymbol{\lambda}$ are spatially invariant, i.e. the expected value of Y_i given $\mathbf{z}_i$ is the same at any two points in the study area that have the same set of values for this covariate. However, there are situations, for example in agricultural and environmental data, where this relationship is not constant, i.e. where there is spatial nonstationarity in the area level population parameters. In order to accommodate this situation, we now define a spatially nonstationary version of the FH model. To start, let the spatial location of area *i* correspond to the coordinates of an arbitrarily defined spatial location in the area, e.g. its centroid, which we denote by loc_i. Let $d(loc_i, loc_j)$ be an appropriate measure of the distance between the spatial locations of areas *i* and *j*, and define the spatial contiguity of these two locations to be $\omega_{ij} = \left(1 + d(loc_i, loc_j)\right)^{-1}$. Let $\mathbf{\Omega} = \left[\omega_{ij}\right]$ denote the positive definite $m \times m$ matrix of spatial contiguities defined by the loc_i. This matrix is assumed to be known. We consider a spatially nonstationary extension of the FH model (1) for area *i* of the form

$$y_i - Y_i = e_i \quad \text{and} \quad Y_i - \theta(loc_i) - \mathbf{z}_i^T \boldsymbol{\lambda}(loc_i) = u_i \tag{8}$$

where $\left(\theta(loc_i), \boldsymbol{\lambda}^T(loc_i)\right)^T = \left(\theta, \boldsymbol{\lambda}^T\right)^T + \boldsymbol{\gamma}(loc_i)$ and $\boldsymbol{\gamma}(loc) = \left(\gamma_k(loc); k = 1, \ldots, p\right)$ is a spatially varying multivariate random process of dimension p . Put $\mathbf{y} = \left(y_1, \ldots, y_m\right)^T$, $\mathbf{z} = \left(\mathbf{z}_1^T, \ldots, \mathbf{z}_m^T\right)^T$, $\mathbf{\Gamma} = \left(\boldsymbol{\gamma}^T(loc_1), \ldots, \boldsymbol{\gamma}^T(loc_m)\right)^T$ and $\mathbf{loc} = \{loc_1, \ldots, loc_m\}$, i.e. the set of locations for the *m* areas. Then

$$\mathrm{E}\left(\mathbf{\Gamma} | \mathbf{z}, \mathbf{loc}\right) = \mathbf{0}_{pm \times 1}.$$

Since a general specification for the covariance structure of $\boldsymbol{\gamma}(loc)$ is complex, we follow Datta *et al*. (1998) and assume a separable working model for the second order spatial moments of $\boldsymbol{\gamma}(loc)$. This is a model of the form

$$\mathrm{Var}\left(\Gamma | \mathbf{z}, \mathbf{loc}\right) = \mathbf{\Sigma} = \mathbf{\Omega} \otimes \mathbf{C} \tag{9}$$

where $\mathbf{C} = \left[c_{kl}\right]$ is a $p \times p$ covariance matrix that characterises the correlations between the components of $\boldsymbol{\gamma}$ at an arbitrary location loc and $\otimes$ denotes Kronecker product. Under (8) and (9),

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{\Psi}\mathbf{\Gamma} + \mathbf{u} + \mathbf{e} \tag{10}$$

where $\boldsymbol{\beta} = \left(\theta, \boldsymbol{\lambda}^T\right)^T$ and $\mathbf{\Psi} = diag\left(\mathbf{x}_i^T; i = 1, \ldots, m\right)$. Then

$$\mathrm{E}\left(\mathbf{y} | \mathbf{z}, \mathbf{loc}\right) = \mathbf{X}\boldsymbol{\beta}$$

$$Var\left(\mathbf{y} | \mathbf{z}, \mathbf{loc}\right) = \mathbf{V} = \mathbf{\Psi}\mathbf{\Sigma}\mathbf{\Psi}^T + \sigma_u^2 \mathbf{I}_m + diag\left\{\sigma_{ei}^2; i = 1, \ldots, m\right\} \tag{11}$$

$$\mathrm{Cov}\left(Y_i, \mathbf{y} | \mathbf{z}, \mathbf{loc}\right) = \mathbf{\Psi}_i \mathbf{\Sigma} \mathbf{\Psi}^T + \sigma_u^2 \boldsymbol{\delta}_i^T \tag{12}$$

where $\mathbf{\Psi}_i$ is the i^{th} row of $\mathbf{\Psi}$. The minimum mean squared error (MMSE) predictor of Y_i under (8) - (12) is the expected value of Y_i given **y**, **z** and **loc**. Under a Gaussian errors assumption, and assuming the inverse of **V** exists, this is

$$\tilde{Y}_i = \mathbf{x}_i^T \boldsymbol{\beta} + \mathrm{Cov}\left(Y_i, \mathbf{y} | \mathbf{z}, \mathbf{loc}\right) \mathbf{V}^{-1} \left(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\right). \tag{13}$$

The vector of MMSE predictors for the population values in **Y** is therefore

$$\tilde{\mathbf{Y}} = \mathbf{X}\boldsymbol{\beta} + \left(\mathbf{\Psi}\mathbf{\Sigma}\mathbf{\Psi}^T + \sigma_u^2 \mathbf{I}_m\right) \mathbf{V}^{-1} \left(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\right) \tag{14}$$

where **V** is defined by (11). The best linear unbiased estimator (BLUE) of $\boldsymbol{\beta}$ is then

$$\tilde{\boldsymbol{\beta}} = \left(\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X}\right)^{-1} \mathbf{X}^T \mathbf{V}^{-1} \mathbf{y}, \tag{15}$$

and the best linear unbiased predictors (BLUPs) of $\boldsymbol{\gamma} = \left(\boldsymbol{\gamma}(loc_1)^T, \ldots, \boldsymbol{\gamma}(loc_m)^T\right)^T$ and $\mathbf{u}$ are

$$\tilde{\boldsymbol{\gamma}} = \mathbf{\Sigma}\mathbf{\Psi}^T \mathbf{V}^{-1} \left(\mathbf{y} - \mathbf{X}\tilde{\boldsymbol{\beta}}\right) \tag{16}$$

$$\tilde{\mathbf{u}} = \sigma_u^2 \mathbf{V}^{-1} \left(\mathbf{y} - \mathbf{X}\tilde{\boldsymbol{\beta}}\right). \tag{17}$$

The corresponding BLUP of the vector $\mathbf{Y}$ is $\tilde{\mathbf{Y}} = \mathbf{X}\tilde{\boldsymbol{\beta}} + \boldsymbol{\Psi}\tilde{\boldsymbol{\gamma}} + \tilde{\mathbf{u}}$. In particular, for small area *i*, the BLUP of Y_i , which we refer to below as the nonstationary BLUP, or NSBLUP, is

$$\tilde{Y}_i = \mathbf{x}_i^T\tilde{\boldsymbol{\beta}} + \left(\boldsymbol{\Psi}_i\boldsymbol{\Sigma}\boldsymbol{\Psi}^T + \sigma_u^2\boldsymbol{\delta}_i^T\right)\mathbf{V}^{-1}\left(\mathbf{y} - \mathbf{X}\tilde{\boldsymbol{\beta}}\right) = \mathbf{x}_i^T\tilde{\boldsymbol{\beta}} + \boldsymbol{\Psi}_i\tilde{\boldsymbol{\gamma}} + \tilde{u}_i . \qquad (18)$$

In practice the parameters σ_u^2 and $\mathbf{C}$ are unknown and have to be estimated from the data. Replacing these unknown parameters by their estimated values ^{2}
plug-in estimators by a 'hat', we obtain the empirical BLUE (EBLUE) of $\boldsymbol{\beta}$ as $\hat{\boldsymbol{\beta}} = \left[\mathbf{X}^T\hat{\mathbf{V}}^{-1}\mathbf{X}\right]^{-1}\left[\mathbf{X}^T\hat{\mathbf{V}}^{-1}\mathbf{y}\right]$ and the empirical BLUP (EBLUP) of Y_i as

$$\hat{Y}_i = \mathbf{x}_i^T\hat{\boldsymbol{\beta}} + \boldsymbol{\Psi}_i\hat{\boldsymbol{\gamma}} + \hat{u}_i . \qquad (19)$$

We refer to (19) as the nonstationary EBLUP, or NSEBLUP, of Y_i.

We now consider synthetic prediction for non-sampled areas under (10). Suppose that there are m_{out} of these non-sampled areas, indexed by *j*. We assume that the covariate vectors $\mathbf{z}_{out,j}$ and the spatial locations $loc_{out,j}$ (e.g. the centroids) of these areas are known. Let $\mathbf{z}_{out}$ and $\mathbf{loc}_{out}$ denote these auxiliary data. The spatially nonstationary predictor (denoted by NSSYN) of the vector of population values $\mathbf{Y}_{out}$ for the non-sampled areas is the plug-in estimator of the MMSE predictor of $\mathbf{Y}_{out}$ given **y**, **z**, **loc**, $\mathbf{z}_{out}$ and $\mathbf{loc}_{out}$,

$$\hat{\mathbf{Y}}_{out} = \mathbf{X}_{out}\hat{\boldsymbol{\beta}} + \boldsymbol{\Psi}_{out}\hat{\boldsymbol{\gamma}}_{out}$$

where $\mathbf{X}_{out}$ is the $m_{out} \times p$ matrix of covariates for the non-sampled areas,

$$\boldsymbol{\Psi}_{out} = diag\left\{\mathbf{x}_{j,out}^T; j = 1,\ldots,m_{out}\right\},\ \hat{\boldsymbol{\gamma}}_{out} = \hat{\boldsymbol{\Sigma}}_{out/in}\boldsymbol{\Psi}^T\hat{\mathbf{V}}^{-1}\left(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}\right), \text{ with } \hat{\boldsymbol{\Sigma}}_{out/in} = \boldsymbol{\Omega}_{out/in} \otimes \hat{\mathbf{C}} .$$

Here $\boldsymbol{\Omega}_{out/in}$ is the known $m_{out} \times m$ matrix of spatial contiguities between the non-sampled areas and the sampled areas. In particular, for non-sampled area *j*, we have

$$\hat{Y}_{j,out} = \mathbf{x}_{j,out}^T\hat{\boldsymbol{\beta}} + \boldsymbol{\Psi}_{j,out}\hat{\boldsymbol{\gamma}}_{out} \qquad (20)$$

where $\boldsymbol{\Psi}_{j,out}$ denotes the row of $\boldsymbol{\Psi}_{out}$ corresponding to this non-sampled area. We refer to the predictor (20) as the NSSYN predictor. In contrast to the SYN predictor (7), the NSSYN predictor uses the location data for the non-sampled areas to 'borrow strength' from neighbouring sampled areas, and so has the potential to improve conventional synthetic prediction for non-sampled areas. In particular, we expect that if in fact the population data exhibit spatial nonstationarity, then the NSSYN predictor (20) will exhibit less bias than the standard SYN predictor (7).

2.1 Parameter estimation

In what follows we restrict our development to the simple single parameter specification $\mathbf{C} = \eta\mathbf{I}_p$ for the matrix $\mathbf{C}$, where $\mathbf{I}_p$ denotes the identity matrix of order *p*. That is, the components of the random vector $\boldsymbol{\gamma}$ are uncorrelated at any particular location, with the parameter $\eta \geq 0$ reflecting the strength or 'intensity' of spatial clustering in the data, and $\eta = 0$ corresponding to the situation where the model is spatially homogeneous (no spatial correlation in Y_i). In this case there are just 2 parameters (η and σ_u^2) that need to be estimated. This can be done by maximising a restricted maximum likelihood under a Gaussian assumption. Put $\boldsymbol{\varphi} = \left\{\eta, \sigma_u^2\right\} = \left(\varphi_1, \varphi_2\right)$. Under (10), the restricted log-likelihood function is then

$$l\left(\boldsymbol{\varphi}\right) = const - \frac{1}{2}\log\left|\mathbf{P}^T\mathbf{V}\mathbf{P}\right| - \frac{1}{2}\left(\mathbf{P}^T\mathbf{y}\right)^T(\mathbf{P}^T\mathbf{V}\mathbf{P})^{-1}\left(\mathbf{P}^T\mathbf{y}\right) \qquad (21)$$

where $\mathbf{P} = \mathbf{V}^{-1} - \mathbf{V}^{-1}\mathbf{X}(\mathbf{X}^T\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}^T\mathbf{V}^{-1}$ and, for $s = 1,2$

$$\frac{\partial l(\boldsymbol{\varphi})}{\partial \varphi_s} = -\frac{1}{2} tr\left(\mathbf{P}\mathbf{V}_{(s)}\right) + \frac{1}{2}\mathbf{y}^T \mathbf{P}\mathbf{V}_{(s)}\mathbf{P}\mathbf{y} \tag{22}$$

with

$$\mathbf{V}_{(1)} = \frac{\partial \mathbf{V}}{\partial \varphi_1} = \frac{\partial \mathbf{V}}{\partial \eta} = \boldsymbol{\Psi}\left(\boldsymbol{\Omega} \otimes \mathbf{I}_p\right)\boldsymbol{\Psi}^T \tag{23}$$

$$\mathbf{V}_{(2)} = \frac{\partial \mathbf{V}}{\partial \varphi_2} = \frac{\partial \mathbf{V}}{\partial \sigma_u^2} = \mathbf{I}_m . \tag{24}$$

The restricted ML estimate of $\boldsymbol{\varphi}$ can be obtained by setting the system of equations (22) to zero and solving for $\boldsymbol{\varphi}$. This can be done using a Fisher scoring algorithm as follows:

1. Compute the distance matrix $\boldsymbol{\Omega}$ between the centroids of the areas and define a starting value for $\boldsymbol{\varphi}$.
2. Use the current values of $\boldsymbol{\varphi}$ to calculate $\boldsymbol{\Sigma}$ and $\mathbf{V}$.
3. Update $\hat{\boldsymbol{\beta}}$ and **P**.
4. Calculate the value $\hat{\boldsymbol{\varphi}}$ such that the components of (22) are zero.
5. Return to step 3 and repeat the procedure until the estimates converge, i.e. when difference between the estimated model parameters $\hat{\boldsymbol{\beta}}$ and $\hat{\boldsymbol{\varphi}}$ obtained from two successive iterations is less than a very small value.

R code (R Development Core Team, 2010) that implements this algorithm is available from the authors.

3. Mean Squared Error Estimation

3.1 Analytic mean squared error estimation

Analytic estimation of the mean squared error (MSE) of the EBLUP (6) is usually carried out using the estimator of Prasad and Rao (1990). A corresponding analytic approach to estimating the MSE of the NSEBLUP (19) is developed below. After some algebra, we can show that the prediction error of the NSBLUP is

$$\tilde{Y}_i - Y_i = \mathbf{b}_i(\tilde{\boldsymbol{\beta}} - \boldsymbol{\beta}) + \mathbf{h}_i\left\{\boldsymbol{\Sigma}_H \mathbf{H}^T \mathbf{V}^{-1}\left(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\right) - \boldsymbol{\zeta}\right\}, \tag{25}$$

where $\mathbf{b}_i = \mathbf{x}_i^T - \left(\boldsymbol{\Psi}_i \boldsymbol{\Sigma} \boldsymbol{\Psi}^T + \sigma_u^2 \boldsymbol{\delta}_i^T\right)\mathbf{V}^{-1}\mathbf{X} = \mathbf{x}_i^T - \mathbf{h}_i \boldsymbol{\Sigma}_H \mathbf{H}^T \mathbf{V}^{-1}\mathbf{X}$, $\mathbf{H} = \left[\boldsymbol{\Psi}\ \ \mathbf{I}_m\right]$, $\boldsymbol{\zeta} = (\boldsymbol{\gamma}^T, \mathbf{u}^T)^T$ and $\boldsymbol{\Sigma}_H = \begin{bmatrix} \boldsymbol{\Sigma} & \mathbf{0} \\ \mathbf{0} & \sigma_u^2 \mathbf{I}_m \end{bmatrix}$. Put $\boldsymbol{\varphi} = \left\{\eta, \sigma_u^2\right\}$. The MSE of the NSBLUP is then

$$E\left(\tilde{Y}_i - Y_i\right)^2 = M_1(\boldsymbol{\varphi}) + M_2(\boldsymbol{\varphi}), \tag{26}$$

where

$$M_1(\boldsymbol{\varphi}) = \mathbf{h}_i \boldsymbol{\Sigma}_H \left\{\mathbf{I}_{pm+m} - \mathbf{H}^T \mathbf{V}^{-1} \mathbf{H} \boldsymbol{\Sigma}_H\right\} \mathbf{h}_i^T$$

and

$$M_2(\boldsymbol{\varphi}) = \mathbf{b}_i \left(\mathbf{X}^T \mathbf{V}^{-1} \mathbf{X}\right)^{-1} \mathbf{b}_i^T .$$

Similarly, we can express the prediction error of the NSEBLUP (19) as

$$\hat{Y}_i - Y_i = \hat{\mathbf{b}}_i(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}) + \mathbf{h}_i\left\{\hat{\boldsymbol{\Sigma}}_H \mathbf{H}^T \hat{\mathbf{V}}^{-1}\left(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\right) - \boldsymbol{\zeta}\right\}, \tag{27}$$

with $\hat{\mathbf{b}}_i = \mathbf{x}_i^T - \mathbf{h}_i \hat{\boldsymbol{\Sigma}}_H \mathbf{H}^T \hat{\mathbf{V}}^{-1}\mathbf{X}$. Following Opsomer *et al.* (2008), and again using $\boldsymbol{\varphi} = \left(\varphi_1, \varphi_2\right)$ to denote the variance components, define **S** to be the matrix with rows ($s = 1,2$)

$$\mathbf{S}_s = \mathbf{h}_i \left(\frac{\partial \boldsymbol{\Sigma}_H}{\partial \varphi_s} \mathbf{H}^T \mathbf{V}^{-1} + \boldsymbol{\Sigma}_H \mathbf{H}^T \frac{\partial \mathbf{V}^{-1}}{\partial \varphi_s} \right)$$

where $\frac{\partial \boldsymbol{\Sigma}_H}{\partial \varphi_1} = diag\left(\boldsymbol{\Omega} \otimes \mathbf{I}_p, \mathbf{0}_m\right)$, $\frac{\partial \boldsymbol{\Sigma}_H}{\partial \varphi_2} = diag\left(\mathbf{0}_{pm}, \mathbf{I}_m\right)$ and $\frac{\partial \mathbf{V}^{-1}}{\partial \varphi_s} = -\mathbf{V}^{-1}\mathbf{L}_s\mathbf{V}^{-1}$ with $\mathbf{L}_s = \frac{\partial \mathbf{V}}{\partial \varphi_s}$. Here $\mathbf{L}_1 = \boldsymbol{\Psi}\left(\boldsymbol{\Omega} \otimes \mathbf{I}_p\right)\boldsymbol{\Psi}^T$ and $\mathbf{L}_2 = \mathbf{I}$. Note also that the 2×2 Fisher information matrix $\boldsymbol{\Phi}$ with respect to $\boldsymbol{\varphi}$ contains elements $\phi_{rs} = 0.5 \times tr(\mathbf{P}\mathbf{L}_r\mathbf{P}\mathbf{L}_s)$. Replacing the unknown variance components in $\mathbf{S}$ and $\boldsymbol{\Phi}$ by their restricted maximum likelihood estimates then leads to the following estimator of the Prediction MSE (PMSE) of the NSEBLUP

$$\begin{aligned}\widehat{PMSE}\left(\hat{Y}_i\right) &= M_1(\hat{\boldsymbol{\varphi}}) + M_2(\hat{\boldsymbol{\varphi}}) + 2M_3(\hat{\boldsymbol{\varphi}}) \\ &= \mathbf{h}_i \hat{\boldsymbol{\Sigma}}_H \left\{\mathbf{I}_{pm+m} - \mathbf{H}^T \hat{\mathbf{V}}^{-1} \mathbf{H} \hat{\boldsymbol{\Sigma}}_H\right\} \mathbf{h}_i^T + \hat{\mathbf{b}}_i \left(\mathbf{X}^T \hat{\mathbf{V}}^{-1} \mathbf{X}\right)^{-1} \hat{\mathbf{b}}_i^T \\ &\quad + 2\left(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}\right)^T \hat{\mathbf{S}}^T \hat{\boldsymbol{\Phi}}^{-1} \hat{\mathbf{S}} \left(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}\right).\end{aligned} \tag{28}$$

The asymptotic behaviour of (28) can be developed along the same lines as set out in Opsomer *et al.* (2008). In particular, we then have

$$E\left[\widehat{PMSE}\left(\hat{Y}_i\right)\right] = PMSE\left(\hat{Y}_i\right) + o\left(m^{-1}L_m^2\right)$$

provided that regularity conditions described in Chandra *et al.* (2015) are met. The mean cross product error (MCPE) matrix defined by the vector $\hat{\mathbf{Y}}_{out} = \mathbf{X}_{out}\hat{\boldsymbol{\beta}} + \boldsymbol{\Psi}_{out}\hat{\boldsymbol{\gamma}}_{out}$ of values of the NSSYN predictor (20) is estimated in a similar fashion. Noting that

$$\begin{aligned}E(\mathbf{D}\mathbf{D}^T) &= \boldsymbol{\Psi}_{out}\left\{\boldsymbol{\Sigma}_{out/out} + \boldsymbol{\Sigma}_{out/in}\boldsymbol{\Psi}^T\mathbf{V}^{-1}\boldsymbol{\Psi}\boldsymbol{\Sigma}_{out/in}^T - 2\boldsymbol{\Sigma}_{out/in}\boldsymbol{\Psi}^T\mathbf{V}^{-1}\boldsymbol{\Psi}Cov\left[\boldsymbol{\gamma}, \boldsymbol{\gamma}_{out}\right]\right\}\boldsymbol{\Psi}_{out}^T \\ &= \boldsymbol{\Psi}_{out}\left\{\boldsymbol{\Sigma}_{out/out} - \boldsymbol{\Sigma}_{out/in}\boldsymbol{\Psi}^T\mathbf{V}^{-1}\boldsymbol{\Psi}\boldsymbol{\Sigma}_{out/in}^T\right\}\boldsymbol{\Psi}_{out}^T\end{aligned}$$

where $\mathbf{D} = \boldsymbol{\Psi}_{out}\boldsymbol{\Sigma}_{out/in}\boldsymbol{\Psi}^T\mathbf{V}^{-1}\left(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\right) - \boldsymbol{\Psi}_{out}\boldsymbol{\gamma}_{out}$, this estimator is given by

$$\begin{aligned}\widehat{MCPE}\left(\hat{\mathbf{Y}}_{out}\right) &= \boldsymbol{\Psi}_{out}\left\{\hat{\boldsymbol{\Sigma}}_{out/out} - \hat{\boldsymbol{\Sigma}}_{out/in}\boldsymbol{\Psi}^T\hat{\mathbf{V}}^{-1}\boldsymbol{\Psi}\hat{\boldsymbol{\Sigma}}_{out/in}^T\right\}\boldsymbol{\Psi}_{out}^T \\ &\quad + \mathbf{X}_{out}\left(\mathbf{X}^T\hat{\mathbf{V}}^{-1}\mathbf{X}\right)^{-1}\mathbf{X}_{out}^T + \hat{\sigma}_u^2.\end{aligned} \tag{29}$$

Here $\hat{\boldsymbol{\Sigma}}_{out/out} = \hat{\eta}\boldsymbol{\Omega}_{out/out} \otimes \left(\mathbf{1}_p\mathbf{1}_p^T\right)$ and $\boldsymbol{\Omega}_{out/out}$ is the $m_{out} \times m_{out}$ matrix of distances between the non-sampled areas.

3.2 Bootstrap procedure for mean squared error estimation

This Section describes an alternative procedure for estimating the MSE of the NSEBLUP based on the parametric bootstrap procedure of Gonzalez-Manteiga *et al.* (2008). Note that the MSE estimator defined by this procedure is consistent provided the model parameter estimators are consistent. The steps of this parametric bootstrap procedure are as follows.

1) Given $\mathbf{y}$, maximise the restricted log-likelihood (21) using the method described in Section 2.1. Let $\hat{\boldsymbol{\varphi}} = \left(\hat{\eta}, \hat{\sigma}_u^2\right)$ and $\hat{\boldsymbol{\beta}}$ denote the resulting estimates.
2) Given the estimates obtained in step 1, generate a vector $\mathbf{t}_1^*$ of length *pm* corresponding to a realisation from the $N\left(\mathbf{0}, \boldsymbol{\Omega} \otimes \mathbf{I}_p\right)$ distribution. Construct the bootstrap vector $\boldsymbol{\gamma}^*\left(loc\right) = \hat{\eta}^{1/2}\mathbf{t}_1^*$.
3) Generate a vector $\mathbf{t}_2^*$ whose elements are *m* independent realisations of a *N*(0,1) variable, independently of the generation of $\mathbf{t}_1^*$. Construct the bootstrap vector $\mathbf{u}^* = \hat{\sigma}_u\mathbf{t}_2^*$.

4) Calculate the bootstrap realisation $\mathbf{Y}^* = \mathbf{X}\hat{\boldsymbol{\beta}} + \boldsymbol{\Psi}\hat{\boldsymbol{\gamma}}^* + \hat{\mathbf{u}}^* = \left(Y_1^*,\ldots,Y_m^*\right)^T$ of the population quantities of interest.
5) Generate a vector $\mathbf{t}_3^*$ whose elements are *m* independent realisations of a *N*(0,1) variable, independently of the generation of $\mathbf{t}_1^*$ and $\mathbf{t}_2^*$, and construct the vector of random prediction errors $\mathbf{e}^*$ where $e_i^* = \sigma_{ei} t_{3i}^*$.
6) Construct the bootstrap vector $\mathbf{y}^* = \mathbf{Y}^* + \mathbf{e}^* = \mathbf{X}\hat{\boldsymbol{\beta}} + \boldsymbol{\Psi}\boldsymbol{\gamma}^* + \mathbf{u}^* + \mathbf{e}^*$ of direct estimates.
7) Using these bootstrap values $\mathbf{y}^*$, as well as the values of $\mathbf{X}$ and **loc**, calculate the bootstrap estimators $\hat{\boldsymbol{\beta}}^*$ and $\hat{\boldsymbol{\varphi}}^*$ using the method described in Section 2.1.
8) Combining the formula (19) with these values of $\hat{\boldsymbol{\beta}}^*$ and $\hat{\boldsymbol{\varphi}}^*$, calculate the bootstrap value $\hat{Y}_i^*$ of the NSEBLUP.
9) Repeat steps 2 - 8 B times. In the *b*-th bootstrap replication, let $\hat{Y}_i^{*(b)}$ be the bootstrap NSEBLUP in area *i*. The bootstrap estimator for the MSE of the actual NSEBLUP $\hat{Y}_i$, see (19), for area *i* is then

$$MSE_{boot}\left(\hat{Y}_i\right) = B^{-1}\sum_{b=1}^{B}\left\{\hat{Y}_i^{*(b)} - \hat{Y}_i\right\}^2 . \qquad (30)$$

3.3. A diagnostic for spatial nonstationarity

Following Opsomer *et al.* (2008), we describe a bootstrap procedure to test the hypothesis $H_{0\eta}:\eta=0$ versus the one-sided alternative $H_{1\eta}:\eta>0$. This involves first calculating the value $\ell_\eta = 2\left(\ell_1 - \ell_0\right)$, where ℓ_0 denotes the restricted log-likelihood under the null $H_{0\eta}$ and ℓ_1 denotes the corresponding value under the alternative $H_{1\eta}$. The level of significance of ℓ_η is then calculated via a parametric bootstrap. That is, if we put $\hat{\sigma}_u^2$ and $\hat{\boldsymbol{\beta}}$ equal to the estimates of σ_u^2 and $\boldsymbol{\beta}$ obtained under the null, then we generate bootstrap realisations of **y** as $\mathbf{y}^{*(b)} = \mathbf{X}\hat{\boldsymbol{\beta}} + \mathbf{u}^{*(b)} + \mathbf{e}^{*(b)}$, where $\mathbf{u}^{*(b)}$ and $\mathbf{e}^{*(b)}$ are generated as in Section 3.2. For each bootstrap replication, the null and the alternative models are then fitted and $\ell_\eta^{*(b)}$ is calculated. The significance of the calculated value of ℓ_η is evaluated by comparing it with the bootstrap distribution of $\ell_\eta^{*(b)}$. A word of caution is appropriate at this point. A significant result from the above bootstrap-based test does not mean that the model (10) with $\mathbf{C} = \eta\mathbf{I}_p$ provides a good representation of the data, i.e. the set of direct estimates $\mathbf{y}$. It only means that this particular spatially non-homogeneous model provides a significant improvement in fit compared with the usual Fay-Herriot approach that ignores spatial heterogeneity.

4. Application

In Section we illustrate an application of NSEBLUP method of SAE to real agriculture survey data collected by the National Sample Survey Office (NSSO), India under the scheme titled 'Improvement of Crop Statistics (ICS)'. In particular, aim is to estimate average yield for paddy (green) crop at small area (or district) levels in the State of Uttar Pradesh in India by linking data generated under ICS scheme by NSSO (data collected with much reduced sample size, however, the quality of data is very high) and the Census information. In this application we adopt an area level small area model (2) as well as nonstationary version of area level model (10) for SAE. We applied the EBLUP and the NSEBLUP estimator for SAE described in Table 1.

Table 1. Definition of various estimators.

Acronym	Description	MSE Estimator
EBLUP	Predictor (6) under model (2)	Prasad & Rao (1990)
NSEBLUP	Predictor (19) under model (10)	Expression (28)
SYN	Predictor (7) under model (2)	Prasad & Rao (1990)
NSSYN	Predictor (20) under model (10)	Expression (29)

Here we are working under aggregated or area level version of small area models. As a consequence, this approach of SAE requires area-specific information on direct survey estimates and covariates. In particular, two types of variables are required for this analysis.

(i) The variable of interest for which small area estimates are required is yield for paddy (green) crop. We use data pertaining to supervised CCE on paddy (green) crop under ICS scheme for kharif season for the State of Uttar Pradesh in India collected during the year 2009-10. We are interested in estimating the average yield for paddy (green) crop at the district level. In the State of Uttar Pradesh CCE is carried out in the plots of form equilateral triangle of side 10 meter each and with total area of 43.30 meter^2. Therefore, yield rate for paddy (green) crop is recorded as gram per 43.12 meter^2.

(ii) The covariates (auxiliary variables) known for the population are drawn from the Population Census 2001. Note that use of covariates from the 2001 Population Census to model yield data of paddy crop from the 2009-10 ICS scheme data may raise issues of comparability. However, the covariates used in this study are not expected to change significantly over a short period of time.

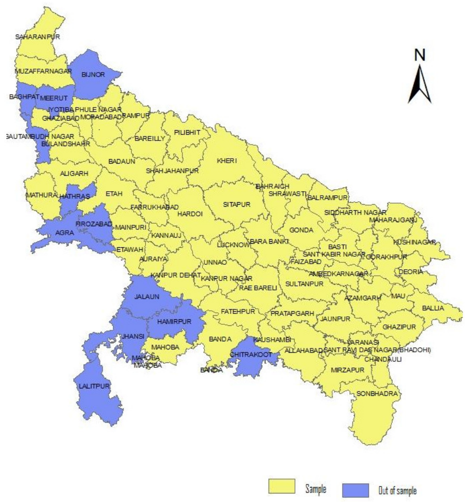

Figure 1. *Map of districts in the State of Uttar Pradesh in India.*

In the State of Uttar Pradesh there are 70 districts however supervision, on a sub-sample, of CCEs work under ICS scheme is carried out in 58 districts only and there is no sample data for the remaining 12 districts. We refer these 12 districts as the out of sample districts. These 70 (58 in sample and 12 out of sample) districts are the small areas for which we are interested in producing the estimates. Figure 1 shows the map of these 70 districts in the State of Uttar Pradesh. In this map the districts in sample are shown in yellow color while out of sample districts are shown in blue color. The area specific sample sizes for 58 sample districts range from minimum of 4 to maximum of 28 CCE with average of 11 (see Figure 2). A total of 655 CCE were supervised for recording yield data in the State of Uttar Pradesh for paddy crop for the year 2009-10. We see that in few districts the sample size is small so the traditional sample survey estimation approaches lead to unstable estimate. In addition, in 12 districts due to non availability of sample under ICS, we cannot estimate paddy yield**.** Indeed, there is no design based solution to provide estimates for these 12 out of sample districts. The SAE is an obvious choice for such cases.

There were 121 covariates available from the Population Census to consider for modeling and choosing appropriate covariates for this analysis. For this purpose, we used data of 58 sampled districts and did some exploratory data analysis, for example, first we segregated group of covariates with significant correlation with target variable and subsequently we implemented step wise regression analysis for identification of such covariates. Finally we identified two significant variables, average household size (HH_SIZE) and female population of marginal household (MARG_HH_F) with 26 per cent R^2 for the SAE. Although, the value of R^2 for this data is very good but this is best possible model we obtained from the available information. Note that for SAE of 12 out of sampled districts we used the same two covariates since we assume that the underlying model for sample areas also holds for out of sample districts.

For fitting the geographically weighted linear mixed model, i.e. spatial nonstationarity version of Fay Herriot model (1) we also require coordinates of different small areas. The developed SAE method is suitable for the data exhibiting the *spatial nonstationarity*. That is, if spatial nonstationarity is present in the data then the developed method of SAE accounts for nonstationarity while generating small area estimates.

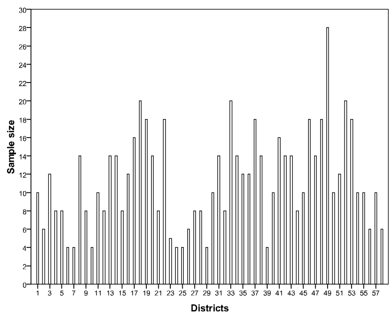

Figure 2. *Distribution of district-specific sample sizes in sample districts.*

We did some exploratory data analysis to examine whether the ICS data used in this small area analysis (particularly, from sampled districts) have spatial nonstationarity. For this purpose, we computed the district-specific regression coefficients by fitting the spatial nonstationarity version of Fay Herriot model (10). We also obtained the global regression coefficients by fitting the Fay Herriot model (2). In the fitted model we have two covariates, average household size (HH_SIZE) and female population of marginal household (MARG_HH_F), therefore we have three regression coefficients (i.e., intercepts + two slope parameters with respect to HH_SIZE and MARG_HH_F). Table 2 reports the district wise estimates of regression coefficients for ICS data by fitting the spatial nonstationarity version of Fay Herriot model (10). Estimates of regression coefficients for ICS data by fitting the Fay Herriot model (2) are reported in Table 3. Surface plot of regression coefficients for ICS data by fitting the spatial nonstationarity version of Fay Herriot model (10) are shown in Figure 3. The diagnostic procedure to test the spatial nonstationarity described in Section 3.3, that is, the hypothesis $H_{0\eta}:\eta=0$ versus the one-sided alternative $H_{1\eta}:\eta>0$ is applied to NSSO data. Nonstationarity test is significant (p value 0.01), that is, rejected the null hypothesis of spatial stationarity of the model parameters of nonstationarity Fay Herriot model (10). Hence, there is evidence of nonstationarity in the data. In addition, the values of regression coefficients shown in Table 2 and in Figure 3 clearly indicate that the ICS data is not stationary. There is a marginal nonstationarity in the model parameters. Looking at the minimum, maximum, average and median values of model parameters of geographically weighted linear mixed model in Table 2 and the values of model parameters (i.e. global parameters) of linear mixed model in Table 3, we observe that there is evidence spatial nonstationarity in the model parameters. The surface plots of model parameters in Figure 3 and the conclusion from test result also confirm this. It is therefore interesting to apply the developed SAE method with ICS data. As there is evidence of spatial nonstationarity in the data, we expect a slightly better performance of small area estimates with the newly developed method of SAE.

Figure 3. *Surface plot of regression coefficients for ICS data by fitting the spatial nonstationarity version of Fay Herriot model (10).*

The coefficient of variation (CV) is used to assess the comparative precision of different small area estimates. The CVs show the sampling variability as a percentage of the estimate. Estimates with large CVs are considered unreliable (i.e. smaller is better). In general, there are no internationally accepted tables available that allow us to judge what is "*too large*". Different organization used different cut off for CV to release their estimate for the public use. For example, Office for National Statistics, United Kingdom has cut off CV value of 20% for acceptable estimates. We computed the percentage CV of direct estimates and two different model based estimates (i.e. EBLUP and NSEBLUP). Besides, comparison of model-based estimates versus direct estimates, we also want to compare the precision of two model-based estimates (i.e. EBLUP and NSEBLUP). Table 4 shows the district-wise distribution of the percentage CVs for the direct estimates and two different model-based estimates defined in Table 1. Figure 4 presents the percentage CV of direct estimates and two different model based estimates for sample districts.

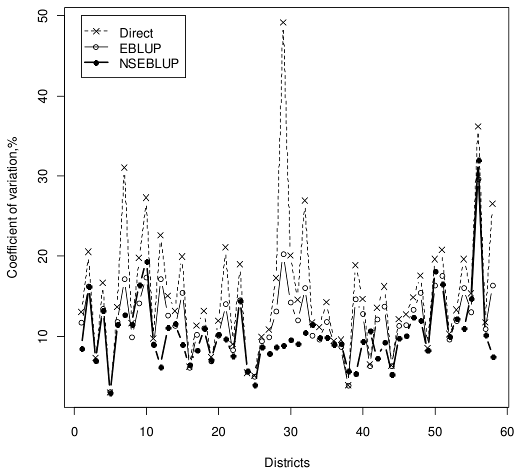

Figure 4. *District-wise plot of percent coefficient of variation for the Direct (dash line,×), EBLUP (thin line, o) and NSEBLUP (solid line, •) estimators.*

Two things stand out from Table 4 and Figure 4. First, the estimated CVs of two model-based estimators (i.e., EBLUP and NSEBLUP) are smaller than the traditional design-based direct estimator. Second, between two model based estimators, the NSEBLUP is better than the EBLUP. That is, the estimated CVs for the model-based estimates have a higher degree of reliability when compared to the direct estimates. In general, relative performance of model based estimates are better as sample size decreases. This result reveals that if spatial nonstationarity is incorporated in SAE it leads to significant gains in efficiency of small area estimates. It is interesting to note that out of 70 districts there are 12 districts with no sample data. For these 12 districts we cannot produce the direct estimates, however, model based estimates generated for these districts have reasonably good CV values and that to within the acceptable limit. In Table 4 If we look at the percent CV it is apparent that the standard errors of the direct estimates are large and therefore the estimates are unreliable. Further, for 12 out of sample districts we observed a significant gain in application of NSEBLUP as compared to the EBLUP method. That is, the NSEBLUP method leads to a drastic gain in precision when estimates were produced for out of sample districts.

5. Concluding Remarks

This paper illustrates that the SAE technique can be satisfactorily applied to produce reliable district level estimates of crop yield using CCE supervised under ICS scheme. Although the ICS supervised CCEs number only 30,000 in the entire country i.e. the sample size is very low, the collected data is of very high quality. The estimates generated using this data are expected to be relatively free from various sources of non-sampling errors. Further SAE provides estimates for those districts where there is no sample information under ICS and so direct estimates cannot be computed. It is, therefore, recommended that wherever it is not possible to conduct adequate number of CCEs due to constraints of cost or infrastructure or both, SAE technique can be gainfully used to generate reliable estimates of crop yield based on a smaller sample. In addition, when there is spatial nonstationarity in the data developed method should be used to improve these disaggregate level estimates. We noticed that the ICS data have evidence of spatial nonstationarity. As a consequence the developed NSEBLUP method when applied to ICS data enhanced the efficiency of small area estimates.

Assisting total estimation in spatial populations

Vagheggini, A., Bruno, F. and Cocchi, D.
Department of Statistical Sciences, University of Bologna
DOI: 10.1481/icasVII.2016.f35b

Abstract

In the last decade, we witnessed a reappraisal of design-based techniques for inference on synthetic values (i.e., mean or total) for spatially distributed populations. Some authors use splines to incorporate the geographical information in estimation, while others treat the sampling design as a covariate. Our proposal is able to exploit the geographical relationships between the locations in the domain to enrich estimation. Weights are defined as standardized functions of the Euclidean distances. Some statistical properties of the estimator are derived. Results of a Monte Carlo simulation are presented in order to better appreciate the performances of our proposal when compared to other alternatives not able to exploit the spatial information of the data.

keywords: Geographically weighted estimator; Generalized regression estimator.

1 Introduction

In finite population inference, the estimation of population quantities, like the total or the individual mean, enjoys a number of design-based results that do not consider the spatial characteristics of the population. Spatial features, rather, enter in the solution via super-population models; different versions of kriging are a popular tool in this direction. However, model specification is a critical point, and research tends towards estimators that maintain good properties when such superpopulation models are mis-specified. The proposal of introducing the spatial characteristics of the population in a design-based estimator needs to take into account a predefined function of the distance between each element of the population, potentially entering in the sample, and any other element. This was the content of work of Bruno et al. (2013), dealing with design-based spatial individual estimators. These estimators, which accommodate in a statistical framework the non-stochastic proposal of Shepard (1968), are competitive with respect to estimators based on kriging, which however suffer the risk of model misspecification.

Estimation of population quantities like means and totals leads to stronger statistical properties than the estimation of individual values, being based on the properties of the sum of random quantities, exploiting the finite version of the central limit theorem (Hájek and Dupac, 1981). The present paper proposes a design-based model assisted estimator of a spatial population total, say GWGREG, that emphasizes local properties. This is obtained by incorporating the theory of geographically weighted estimation (Fotheringham et al., 2003) into the finite population generalized regression estimation, extensively analyzed since the seminal work of Särndal et al. (1992). The desirable and well known properties of GREG are tailored to our GWGREG estimator, using, when needed, the results of Breidt and Opsomer (2000). They succeed in keeping local relationships into account via a local polynomial regression that adjusts an estimator of global syntheses of the population. Our proposal might be compared with Cicchitelli and Montanari (2012) who propose to estimate synthetic population quantities exploiting a spline-based correction in a spatial framework.

Our synthesis summarizes the ideas contained in Cicchitelli and Montanari (2012) and Breidt and Opsomer (2000) providing an estimator of global population characteristics that exploits local relationships in space, adapting into a finite population proper context the proposal of GWR due to Fotheringham et al. (2003). We are motivated by an innovative way of considering the auxiliary information contained in the geographical coordinates available for the whole population. Such method is exposed in Bruno et al. (2013) and assesses geographical population characteristics in an intersubjective way that may be compared to the variogram estimation needed for kriging. The present solution, in the spirit of the model-assisted design-based paradigm, emphasizes design-based properties which mitigate the risks of a totally model based proposal and lie in the mainstream of the search for robustness.

2 Geographically Weighted Regression

The usual WLS parameter estimator is able to take into account a wide variety of theoretical situations; however, in a spatial context, the geographical relationship between locations ought to be considered in order to provide better results. Geographically Weighted Regression (GWR) has been firstly proposed by Brunsdon et al. (1998) and since then has gained a lot of praise. It is a very flexible tool which aims to capture the spatial nature of the study variable by means of the associated geographical information. In a given spatial domain $\mathcal{D}$, generally continuous, where only a set $L = \{\mathbf{u}_1, \ldots, \mathbf{u}_i, \ldots, \mathbf{u}_n\}$ of n locations is known, GWR is a *local* statistical model able to take into account the spatial varying behavior. For any location in the domain $\mathcal{D}$, identified by some geographical references $\mathbf{u} = (u_x, u_y)$, usually latitude and longitude, an *individual* (i.e. local) linear regression model is specified

$$z(\mathbf{u}) = \mathbf{x}^\top \boldsymbol{\beta}(\mathbf{u}) + \varepsilon(\mathbf{u}), \tag{1}$$

where $\mathbf{x}$ is the p-dimensional vector of auxiliary variables and $\varepsilon(\mathbf{u}) \sim \mathcal{N}(0, \sigma^2(\mathbf{u}))$ (i.e. errors are assumed heteroscedastic). GWR postulates the existence a vector $\boldsymbol{\beta}(\mathbf{u})$ of size $p \times 1$ for each element of the domain. Any unobserved value at the generic location $\mathbf{u}$ can be estimated as

$$\hat{z}(\mathbf{u}) = \mathbf{x}^\top \mathbf{b}(\mathbf{u}),$$

where

$$\mathbf{b}(\mathbf{u}) = (\mathbf{X}^\top \boldsymbol{\Phi}(\mathbf{u})\mathbf{X})^{-1}\mathbf{X}^\top \boldsymbol{\Phi}(\mathbf{u})\mathbf{z}. \tag{2}$$

The individual n-dimensional diagonal matrix $\mathbf{\Phi}(\mathbf{u})$ contains the values of a decreasing function of the Euclidean distances between $\mathbf{u}$ and all the locations belonging to L, rather than the reciprocal of the individual variances as in the classical WLS estimator.

2.1 Proposals on the weighting matrix

For any location in the domain, the n-dimensional diagonal matrix $\mathbf{\Phi}(\mathbf{u})$ assumes a key role, since it contains the information about the population spatial structure. Its values are computed through a decreasing function of the Euclidean distances between the generic location $\mathbf{u}$ and the ones belonging to set L

$$\mathbf{\Phi}(\mathbf{u}) = \mathrm{diag}(\phi_i(\mathbf{u})) = \mathrm{diag}(f(\|\mathbf{u}_i - \mathbf{u}\|)), \quad i = 1, \ldots, n.$$

Each element of matrix $\mathbf{\Phi}(\mathbf{u})$ assigns a decreasing weight to observations at farther distances from $\mathbf{u}$ accordingly to function $f(\cdot)$.

Brunsdon et al. (1998), as a first suggestion, propose the use of the step function

$$\phi_i(\mathbf{u}) = \begin{cases} 1, & \text{if } d_i(\mathbf{u}) \leq h; \\ 0, & \text{otherwise;} \end{cases}$$

where h is the chosen radius of the neighbourhood and $d_i(\mathbf{u})$ is the Euclidean distance between two locations $d_i(\mathbf{u}) = \|\mathbf{u}_i - \mathbf{u}\|$.

Successively, Fotheringham et al. (2003) propose the use of continuous functions to remove the problem of weights' spatial discontinuity. Bell-like kernels are able to replicate more accurately the spatial structure according to the well known Tobler's first law of geography. A straightforward choice is the Gaussian kernel

$$\phi_i(\mathbf{u}) = \exp\left\{-\frac{d_i(\mathbf{u})^2}{2h^2}\right\},$$

where h is the bandwidth which manages the width of the kernel. The bi-square kernel is an alternative bell-like function: it is steeper than the Gaussian up to the bandwidth value and assigns zero values to farther distances

$$\phi_i(\mathbf{u}) = \begin{cases} \left(1 - \dfrac{d_i(\mathbf{u})^2}{h^2}\right)^2, & \text{if } d_i(\mathbf{u}) \leq h; \\ 0, & \text{otherwise.} \end{cases}$$

Figure 1 shows the behavior of the Gaussian and bi-square kernels.

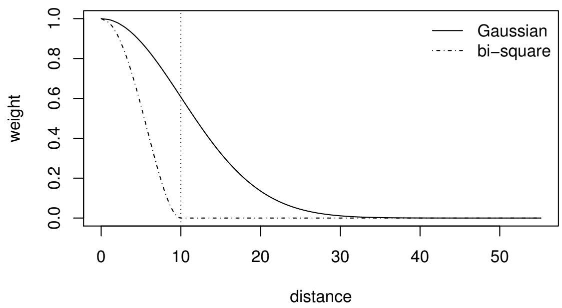

Figure 1: Functions of the Euclidean distances for the Gaussian and bi-square kernels.

3 Introducing GWR in GREG estimation of finite population quantities

When moving from a generic dataset to the estimation of finite population syntheses (i.e. totals or means) via probabilistic sampling, one has to take into account the relevance of the sampling error.

Let us consider a population $\mathcal{P}$ of size N; a fixed size sample s is drawn from $\mathcal{P}$ with probability $p_N(s)$ accordingly to a probabilistic sampling design $p_N(\cdot)$. Let n be the size of s and $f = n/N$ the sample fraction. Inclusion in the sample of the generic population element i is managed by the Bernoulli random variable $\mathcal{I}_{(i\in s)}$ such that $\pi_i = \Pr(i \in s) > 0$ for all $i \in \mathcal{P}$; analogously, inclusion of the generic couple i, j is managed by $\mathcal{I}_{(i,j\in s)}$ such that $\pi_{i,j} = \Pr(i, j \in s) > 0$ for all $i, j \in \mathcal{P}$. Quantities π_i and $\pi_{i,j}$ are the first- and second-order inclusion probabilities, respectively. For sake of simplicity, whenever it will not be explicitly needed, we will write $\mathcal{I}_i$ in place of $\mathcal{I}_{(i\in s)}$.

Usually one needs to estimate the population total $T(z)$ of the study variable, which is observed only for $i \in s$. In such a framework, the well-known and widely adopted Horvitz-Thompson (Horvitz and Thompson, 1952) design-unbiased estimator is

$$\hat{T}_{HT}(z) = \sum_{i \in s} \frac{z_i}{\pi_i} = \sum_{i \in \mathcal{P}} \frac{z_i \mathcal{I}_i}{\pi_i}. \tag{3}$$

Its variance is given by

$$\mathrm{V}[\hat{T}_{HT}(z)] = \sum_{i,j \in s} (\pi_{i,j} - \pi_i \pi_j) \frac{z_i}{\pi_i} \frac{z_j}{\pi_j}.$$

Let us now consider the case where a vector $\mathbf{x}_i$ of p auxiliary variables is known for each population element, or at least its total $T(\mathbf{x})$ over the population is known and the $\mathbf{x}_i$ are available for the sampled elements. The generalized regression (GREG) estimator of the population total $T(z)$ is defined (see e.g. Särndal et al., 1992) as

$$\hat{T}_{GREG}(z) = \hat{T}_{HT}(z) + (T(\mathbf{x}) - \hat{T}_{HT}(\mathbf{x}))^\top \hat{\mathbf{b}}_{GREG}, \tag{4}$$

where $\hat{T}_{HT}(\cdot)$ is the Horwitz-Thompson estimator defined in (3) and

$$\begin{aligned} \hat{\mathbf{b}}_{GREG} &= (\mathbf{X}_s^\top \mathbf{W}_s^{-1} \mathbf{\Pi}_s^{-1} \mathbf{X}_s)^{-1} (\mathbf{X}_s^\top \mathbf{W}_s^{-1} \mathbf{\Pi}_s^{-1} \mathbf{z}_s) \\ &= \left(\sum_{i \in s} \frac{\mathbf{x}_i \mathbf{x}_i^\top}{\pi_i \sigma_i^2} \right)^{-1} \sum_{i \in s} \frac{\mathbf{x}_i z_i}{\pi_i \sigma_i^2}. \end{aligned} \tag{5}$$

Matrix $\mathbf{X}_s$ is the $n \times p$ matrix of the auxiliary variables for the sampled units and $\mathbf{x}_i^\top$ is its ith row vector, $\mathbf{W}_s$ is the usual n-dimensional diagonal matrix of the variances σ_i^2 of the study variable for the sampled units and $\mathbf{\Pi}_s$ is the n-dimensional diagonal matrix of the first-order inclusion probabilities for the sampled elements. Vector $\hat{\mathbf{b}}_{GREG}$ is the estimate of the WLS regression coefficient vector

$$\mathbf{b} = (\mathbf{X}^\top \mathbf{W}^{-1} \mathbf{X})^{-1} (\mathbf{X}^\top \mathbf{W}^{-1} \mathbf{z}).$$

through the first-order inclusion probabilities of the n-dimensional sample collected in matrix $\mathbf{\Pi}_s$. Easy manipulations of (4) give

$$\hat{T}_{GREG}(z) = \sum_{i\in s} \frac{z_i}{\pi_i} + \sum_{i\in \mathcal{P}} \mathbf{x}_i{}^\top \hat{\mathbf{b}}_{GREG} - \sum_{i\in s} \frac{\mathbf{x}_i^\top}{\pi_i} \hat{\mathbf{b}}_{GREG}$$
$$= \sum_{i\in s} \frac{z_i - \mathbf{x}_i^\top \hat{\mathbf{b}}_{GREG}}{\pi_i} + \sum_{i\in \mathcal{P}} \mathbf{x}_i^\top \hat{\mathbf{b}}_{GREG}. \tag{6}$$

In this expression sums explicitly refer to sample s and population $\mathcal{P}$,respectively.

Let us now move to a spatial setting. Suppose that a (regular) finite grid of N cells has been superimposed over the spatial domain $\mathcal{D}$ or that we are interested in N locations in it; in this way stating the coincidence of domain $\mathcal{D}$ and population $\mathcal{P}$. Thus, model (1) can be adopted, where an individual vector of parameters $\boldsymbol{\beta}(\mathbf{u}_i)$, rather than a global one, needs to be specified for each population element. Moreover, the sample is constituted by n locations drawn from $\mathcal{P}$; therefore, the first- and second-order inclusion probabilities now refer explicitly to the selection of population locations in the sample.

The proposal of a local regression model for the relationship between auxiliary variables and the study variable can suitably manage the geographical information. We propose to encompass the geographical relationships between locations in GREG estimation by means of GWR. Thus, analogously to (6), we write the Geographically Weighted Generalized Regression (GW-GREG) estimator as

$$\hat{T}_{GWGREG}(z) = \sum_{i\in s} \frac{z(\mathbf{u}_i) - \hat{z}(\mathbf{u}_i)}{\pi_i} + \sum_{i\in \mathcal{P}} \hat{z}(\mathbf{u}_i). \tag{7}$$

The value of the study variable at the generic location $\mathbf{u}_i$ is estimated by means of

$$\hat{z}(\mathbf{u}_i) = \mathbf{x}_i^\top \hat{\mathbf{b}}_{GWGREG}(\mathbf{u}_i)$$
$$= \mathbf{x}_i^\top (\mathbf{X}_s^\top \mathbf{\Phi}_s(\mathbf{u}_i)\mathbf{\Pi}_s^{-1}\mathbf{X}_s)^{-1}\mathbf{X}_s^\top \mathbf{\Phi}_s(\mathbf{u}_i)\mathbf{\Pi}_s^{-1}\mathbf{z}_s = \hat{\mathbf{w}}_s(\mathbf{u}_i)^\top \mathbf{z}_s$$
$$= \mathbf{x}_i^\top \left(\sum_{j\in s} \frac{\mathbf{x}_i \mathbf{x}_i^\top \phi_{sj}(\mathbf{u}_i)}{\pi_j} \right)^{-1} \sum_{j\in s} \frac{\mathbf{x}_i z(\mathbf{u}_j)\phi_{sj}(\mathbf{u}_i)}{\pi_j}, \tag{8}$$

where the individual $\hat{\mathbf{b}}_{GWGREG}(\mathbf{u}_i)$ is highlighted. The n-dimensional diagonal matrix $\mathbf{\Phi}_s(\mathbf{u}_i)$ collects the values of the decreasing function of the

Euclidean distances between location $\mathbf{u}_i$ and all the sampled ones. In equation (8) the scalar standardized weights

$$\hat{w}_{sj}(\mathbf{u}_i) = \mathbf{x}_i^\top \left(\sum_{j\in s} \frac{\mathbf{x}_i \mathbf{x}_i^\top \phi_{sj}(\mathbf{u}_i)}{\pi_j} \right)^{-1} \frac{\mathbf{x}_i z(\mathbf{u}_j)\phi_{sj}(\mathbf{u}_j)}{\pi_j} = \mathbf{x}_i^\top \hat{\mathbf{H}}_1(\mathbf{u}_i)^{-1} \hat{\mathbf{h}}_2(\mathbf{u}_i) \tag{9}$$

can be isolated, while matrix $\hat{\mathbf{H}}_1(\mathbf{u}_i)$ and vector $\hat{\mathbf{h}}_2(\mathbf{u}_i)$ highlight suitable quantities summarizing the two main factors.

Estimator (7) is linear in the sampled values $z(\mathbf{u}_i)$; it may be rewritten as follows

$$\begin{aligned}
\hat{T}_{GWGREG}(z) &= \sum_{i\in s} \frac{z(\mathbf{u}_i) - \hat{z}(\mathbf{u}_i)}{\pi_i} + \sum_{i\in \mathcal{P}} \hat{z}(\mathbf{u}_i) \\
&= \sum_{i\in s} \frac{z(\mathbf{u}_i)}{\pi_i} + \sum_{j\in \mathcal{P}} \hat{z}(\mathbf{u}_j) - \sum_{j\in s} \frac{\hat{z}(\mathbf{u}_j)}{\pi_j} \\
&= \sum_{i\in s} \frac{z(\mathbf{u}_i)}{\pi_i} + \sum_{j\in \mathcal{P}} \sum_{i\in s} \hat{w}_{sj}(\mathbf{u}_i) z(\mathbf{u}_i) - \sum_{j\in \mathcal{P}} \frac{\mathcal{I}_{j\in S}}{\pi_j} \sum_{i\in s} \hat{w}_{sj}(\mathbf{u}_i) z(\mathbf{u}_i) \\
&= \sum_{i\in s} \frac{z(\mathbf{u}_i)}{\pi_i} + \sum_{i\in s} \sum_{j\in \mathcal{P}} \hat{\mathbf{w}}_s(\mathbf{u}_j)^\top \mathbf{e}_i z(\mathbf{u}_i) - \sum_{i\in s} \sum_{j\in \mathcal{P}} \frac{\mathcal{I}_{j\in S}}{\pi_j} \hat{\mathbf{w}}_s(\mathbf{u}_j)^\top \mathbf{e}_i z(\mathbf{u}_i) \\
&= \sum_{i\in s} \left(\frac{1}{\pi_i} + \sum_{j\in \mathcal{P}} \left(1 - \frac{\mathcal{I}_{j\in S}}{\pi_j} \right) \hat{\mathbf{w}}_s(\mathbf{u}_j)^\top \mathbf{e}_i \right) z(\mathbf{u}_i),
\end{aligned}$$

where $\mathbf{e}_i$ is the ith canonical basis of the n-dimensional space, weighting vector $\hat{\mathbf{w}}_s(\mathbf{u}_j)$ has been defined in equation (8) and $\mathcal{I}_i$ is the Bernoulli random variable managing the inclusion of location $\mathbf{u}_i$ in the sample. The last line of the previous equation identifies the g-weights (Särndal et al., 1992)

$$g(\mathbf{u}_i) = \frac{1}{\pi_i} + \sum_{j\in \mathcal{P}} \left(1 - \frac{\mathcal{I}_{j\in S}}{\pi_j} \right) \hat{\mathbf{w}}_s(\mathbf{u}_j)^\top \mathbf{e}_i, \tag{10}$$

which are useful for estimating the variance of (7).

3.1 The case without auxiliary variables

Let us now consider the GWGREG estimator in the special case where no auxiliary variable is available and the conditions for the applicability of

GREG estimation do not hold. On the contrary the GWGREG estimator can be adopted because the spatial information states relationships between population elements. Thus, the GWRGREG estimator of equations (8) and (9) becomes

$$\hat{z}(\mathbf{u}_i) = (\mathbf{1}_n^\top \mathbf{\Phi}_s(\mathbf{u}_i)\mathbf{\Pi}_s^{-1}\mathbf{1}_n)^{-1}\mathbf{1}_n^\top \mathbf{\Phi}_s(\mathbf{u}_i)\mathbf{\Pi}_s^{-1}\mathbf{z}_s = \hat{\mathbf{w}}_s(\mathbf{u}_i)^\top \mathbf{z}_s$$
$$= \left(\sum_{j\in s}\frac{\phi_{sj}(\mathbf{u}_i)}{\pi_j}\right)^{-1}\sum_{j\in s}\frac{\phi_{sj}(\mathbf{u}_i)z(\mathbf{u}_j)}{\pi_j} = \hat{h}_1(\mathbf{u}_i)^{-1}\hat{h}_2(\mathbf{u}_i). \quad (11)$$

In (11), weights (9) reduce to

$$\hat{w}_{sj}(\mathbf{u}_i) = \frac{\phi_{sj}(\mathbf{u}_i)}{\sum_{i\in s}\phi_{sj}(\mathbf{u}_i)} = \frac{f(\|\mathbf{u}_i - \mathbf{u}\|)}{\sum_{i\in s} f(\|\mathbf{u}_i - \mathbf{u}\|)}$$

and the quantities involved consequently reduces to scalars $\hat{h}_1(\mathbf{u}_i)$ and $\hat{h}_2(\mathbf{u}_i)$.

4 Variance and its estimation

From the GREG theory (Särndal et al., 1992), the approximated variance of the GWGREG estimator $\hat{T}_{GWREG}(z)$ is

$$\mathrm{V}[\hat{t}\hat{t}_{GWREG}(z)] \simeq \sum\sum_{i,j\in\mathcal{D}}(\pi_{ij} - \pi_i\pi_j)\frac{z(\mathbf{u}_i) - \hat{z}(\mathbf{u}_i)}{\pi_i}\frac{z(\mathbf{u}_j) - \hat{z}(\mathbf{u}_j)}{\pi_j}.$$

it is estimated by

$$\hat{\mathrm{V}}[\hat{T}_{GWREG}(z)] = \sum\sum_{i,j\in s}\frac{\pi_{ij} - \pi_i\pi_j}{\pi_{ij}}\frac{z(\mathbf{u}_i) - \hat{z}(\mathbf{u}_i)}{\pi_i}\frac{z(\mathbf{u}_j) - \hat{z}(\mathbf{u}_j)}{\pi_j}.$$

Alternatively, the variance estimator can be obtained by employing the g-weights of formula (10) is

$$\hat{\mathrm{V}}[\hat{T}_{GWREG}(z)] = \sum\sum_{i,j\in s}\frac{\pi_{ij} - \pi_i\pi_j}{\pi_{ij}}\frac{g_i(z(\mathbf{u}_i) - \hat{z}(\mathbf{u}_i))}{\pi_i}\frac{g_j(z(\mathbf{u}_j) - \hat{z}(\mathbf{u}_j))}{\pi_j}.$$

Accordingly to the asymptotic results by Breidt and Opsomer (2000), we make the following assumptions:

A1 the errors of the superpopulation model ε_i have zero mean, finite variance and compact support uniformly for all N;

A2 for all N the locations are fixed;

A3 the spatial mean $m(\mathbf{u}_i)$ is smooth and the variance $v(\mathbf{u}_i) = \sigma_i^2$ continuous and strictly positive;

A4 as $N \to \infty$, $n/N \to f \in (0, 1)$;

A5 for all N: $\min_{i \in \mathcal{D}} \pi_i \geq \lambda > 0$, $\min_{i,j \in \mathcal{D}} \pi_{ij} \geq \lambda^* > 0$ and

$$\limsup_{N \to \infty} n \max_{i,j \in \mathcal{D}; i \neq j} \mid \pi_{ij} - \pi_i \pi_j \mid < \infty;$$

A6 for any t-tuple $G_{t,N}$ of t elements $(i_1, i_2, \ldots, i_t)$ in the domain:

$$\lim_{N \to \infty} n^2 \max_{i_1, \ldots, i_4 \in G_{4,N}} \mid \mathrm{E}[(\mathcal{I}_{i_1} - \pi_{i_1}) \cdots (\mathcal{I}_{i_4} - \pi_{i_4})] \mid < \infty$$

$$\lim_{N \to \infty} \max_{i_1, \ldots, i_4 \in G_{4,N}} \mid \mathrm{E}[(\mathcal{I}_{i_1} \mathcal{I}_{i_2} - \pi_{i_1} \pi_{i_2})(\mathcal{I}_{i_3} \mathcal{I}_{i_4} - \pi_{i_3} \pi_{i_4})] \mid = 0$$

$$\limsup_{N \to \infty} n \max_{i_1, \ldots, i_3 \in G_{3,N}} \mid \mathrm{E}[(\mathcal{I}_{i_1} - \pi_{i_1})^2 (\mathcal{I}_{i_2} - \pi_{i_2})(\mathcal{I}_{i_3} - \pi_{i_3})] \mid < \infty$$

Then assuming A1-A6, it results

$$\frac{N^{-1}(\hat{T}_{GWREG}(z) - t(z))}{\sqrt{N^{-1} \mathrm{V}[\hat{T}_{GWREG}(z)]}} \xrightarrow{\ell} \mathcal{N}(0, 1)$$

and

$$\frac{N^{-1}(\hat{T}_{GWREG}(z) - t(z))}{\sqrt{N^{-1} \hat{\mathrm{V}}[\hat{T}_{GWREG}(z)]}} \xrightarrow{\ell} \mathcal{N}(0, 1).$$

Therefore, we can derive the confidence interval at level $(1 - \alpha)$

$$\left(\hat{T}_{GWREG}(z) - z_{1-\alpha/2} \hat{\mathrm{V}}[\hat{T}_{GWREG}(z)]^{1/2}, \hat{T}_{GWREG}(z) + z_{1-\alpha/2} \hat{\mathrm{V}}[\hat{T}_{GWREG}(z)]^{1/2} \right).$$

5 The simulation study

Three populations were generated over a 60×60 regular grid on the unit square (see Figure 2):

- a realization of a Gaussian random field having Gaussian semivariogram with mean $\mu = 10$ and sill $\sigma^2 = 8$, the effective range is $\phi = 0.7$;
- a realization of a Gaussian random field having exponential semivariogram with mean $\mu = 10$ and sill $\sigma^2 = 8$, the effective range is $\phi = 0.7$;
- a realization of a pure nugget process with mean $\mu = 10$ and variance $\sigma^2 = 8$.

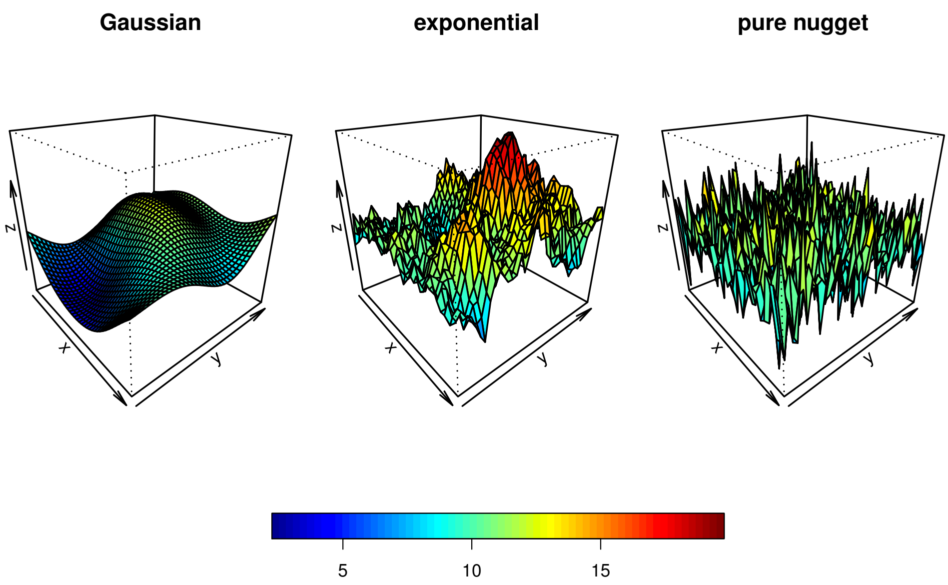

Figure 2: 3-d plot of the three popultions generated for the simulations.

For each population 1000 random samples have been drawn at four different sampling fractions ($f = 0.025, 0.050, 0.075, 0.100$) with SRSWoR.

Four different estimators of the population total have been computed for each sample:

- the GWRGREG estimator adopting the inverse squared Euclidean distances (idw);

- the GWRGREG estimator employing Gaussian kernel with bandwidth 1/8 (k.8) and 1/16 (k.16) of the maximum distance in the domain;
- the expansion estimator (Exp).

The performances of the four estimators are compared by means of:

- the relative bias;
- the relative RMSE;
- the coverage of the 95% confidence interval.

For all the population analysed, the relative bias (Figure 3) is almost null regardless of the sampling fraction and the estimator adopted. The relative bias of the estimators in the exponential and pure nugget population behave slightly better than in the Gaussian.

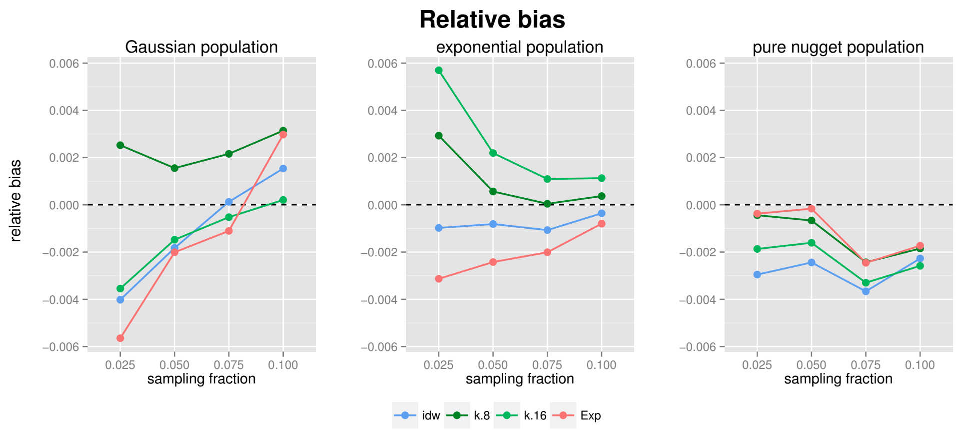

Figure 3: Relative bias of the four estimators analyzed in the simulation study.

The increase of the sampling fraction substantially reduces the relative RMSE (Figure 4) regardless of the population analysed and the sampling fraction. The GWGREG estimator performs better than the expansion estimator for the Gaussian population and less so for the exponential population. Moreover, employing the Gaussian kernel estimator with a bandwidth of 1/16

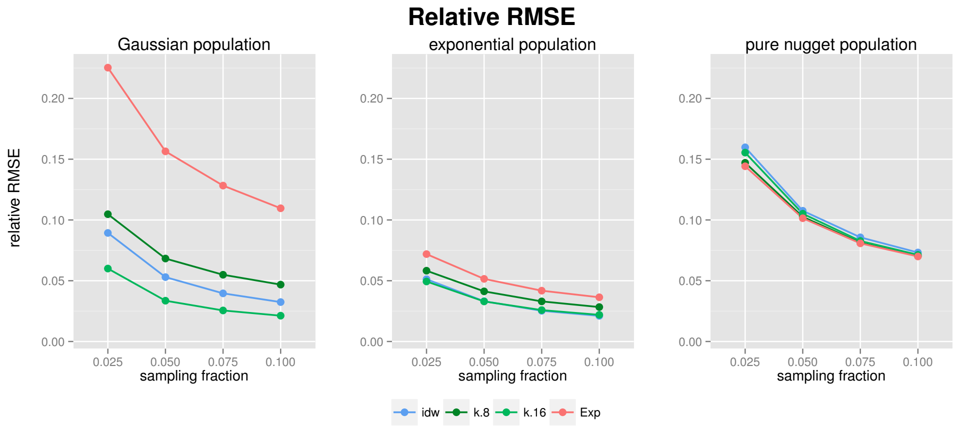

Figure 4: Relative RMSE of the four estimators analyzed in the simulation study.

the maximum distance or the inverse squared distance produces better performances.

The coverages (Figure 5) of the analysed estimators are close to the 95% nominal level, apart for the Gaussian kernel with bandwidth 1/16 of the maximum distance which, however, substantially improves its performances as the sampling fraction increases.

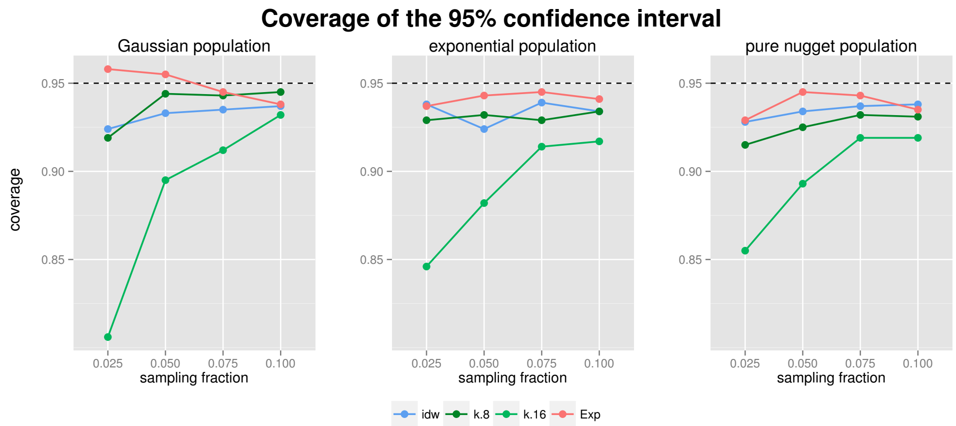

Figure 5: Coverage of the 95% confidence interval of the four estimators analyzed in the simulation study.

6 Discussion and future developments

Employing the GWR in a design-based framework allows to obtain a GREG estimator able to take into account the spatial setting in a simple and intuitive way by means of local models.

The GWGREG estimator is almost unbiased.

When compared to the usual expansion estimator, the GWGREG estimator shows good performances especially in terms of relative RMSE.

The coverage of the GWGREG estimator is close to the nominal level especially as the sample fraction increases.

The simulation study has shown different behaviours for the three functions of the Euclidean distances taken into account; perhaps a preliminary cross-validation study may help in identifying the best function.

It may be of interest to consider different sampling designs, such the stratified or spatially balanced designs.

Effects of the auxiliary variables will be analysed.

Analyses on the estimation of the variance of the GWGREG estimator have been conducted only for the π estimator; a thorough simulation study encompassing the variance estimators based on the g-weights and on resampling techniques will be conducted.

ABSTRACT

Since 2011, Eurostat began a reorganization of EU social statistics. This project has evolved over time up to the final version presented at the meeting of Directors of Social Statistics, held in September 2014.

The model proposed by Eurostat is based on an approach in modules of target variables which, by construction, can be pooled and, where possible, can exploit the use of information measured at different surveys for the construction of the estimates.

Eurostat also presented a roadmap (Eurostat, 2013j) for the implementation of the project which contemplates short, medium and long term studies. The first study focuses on methods for pooling estimates to be made with the overlap of samples on which were recorded the same variables, regardless of the drawings below; in the medium term the study focuses on redesign of sample surveys aimed to optimize sample size and allocation and exploiting the new modular approach; in the long term a final study for the integrated micro-database for social statistics, powered by both surveys and the information from the statistical registers.

This paper presents a possible scenario for the integration of social surveys which arises from a specific strategy associated with a specific sampling design. The whole purpose is to achieve a complete integration of the system of social surveys and ensure maximum integration with the registries system present in National Statistical Institute.

A Montecarlo simulation study using Census 2011 data has been carried out. In the simulation 200 samples has been drawn for each of 4 very important Istat surveys, referring to two regions Trentino-Altoadige and Marche. In particular the surveys considered are the Labour Force survey, the Multipurpose survey, the Eusilc survey and the Consumer Expenditure survey.

Finally an empirical evaluation is performed on different estimators of the labour force characteristics (employed and unemployed), for different domains, computing the traditional Monte Carlo indicators base on the difference with respect to the census values in order to evaluate the empirical performances of estimator in terms of bias and variability.

Keywords: Integration, pooling, projection

1. Introduction

There are several alternative scenarios studied and proposed by Istat for the System for integration of Social Surveys (SINTESY). These scenarios are in line with the Eurostat project of modernization of social surveys, aimed to obtain a complete integration of the social surveys SINTESY could be exploited for the estimation of hypercube of the next permanent census. The methodologies studied – both at survey design stage and in the estimation phase- is aimed to limit the use of direct survey for the collection of data on socio-economic variables, focusing on a strategy based on the use of administrative sources and on the integration of social surveys. In the paper, paragraph 2 describes the classification of the target variables and auxiliary variables considered in the system. Paragraph 3 presents the integration scenario called *"One survey occasion with pooled sample"* used in the empirical study. Paragraph 4 discusses the estimation strategies with reference to the scenario proposed; paragraph 5 describes the simulation study carried out and the results obtained.

2. Classification of variables

The classification of variables proposed in the paper follows the Eurostat's approach and is aimed to group in homogeneous basic building blocks, called modules, both the variables of interest that the auxiliary variables. These groups of variables are to be kept together for analytical/ data collection reasons.

The modules considered are:

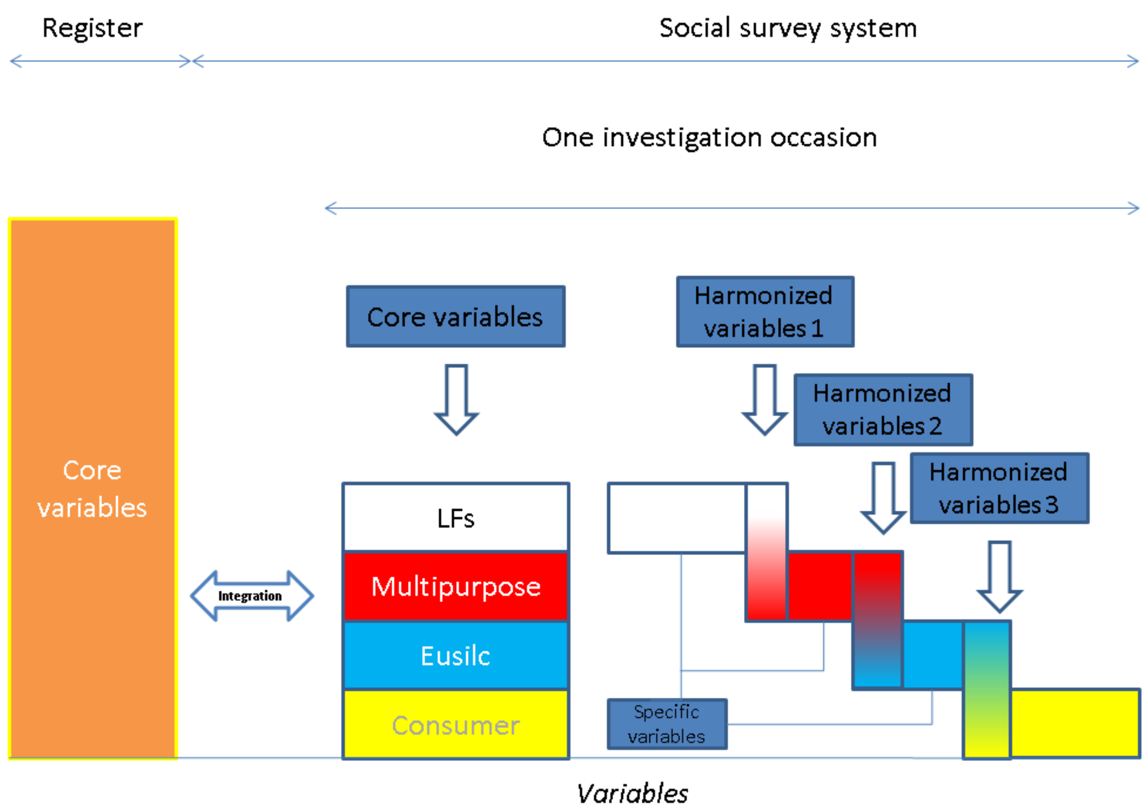
- *Core modules*: in this module are included core variables available in all data collections (samples and register). Furthermore, we consider core variables also those variables available from administrative register whose quality level is not currently considered sufficient for the production of estimates by aggregation of individual administrative register data;
- *Specific modules*: inside this module there are variables observed in only one survey. For example, are specific variables the people looking for job from the Labour Force survey and the income by type collected by the Eusilc survey;
- *Harmonised modules*: this module includes variables observed by more than one survey but often with different statistical domains. For example, fall into this module the income class currently collected by different social surveys.

3. One survey occasion with pooled sample

This scenario is based on a survey instrument design that provides that the households included in a given sub-sample, relative to a specific survey, are interviewed in a single occasion during the year, in which are collected at the same time all the variables of interest, both the structural variables, the harmonized variables and the specialized variables specific to that instrument.

Figure 1 shows the scenario taken into account in the paper. Each sub-sample is composed by different households. In this scenario, all the variables of interest are measured together in a single wave. The pooled sample so constructed allows the use of the same information observed in different surveys/instruments. The ARCHIMEDE register (Integrated archive of economic and demographic micro data) has been integrated with the sample data. This register has the aim of creating bases of useful micro-data for the study of socio-economic phenomena through the integration of variables extracted from 19 different administrative registers. In paragraph 5 will be descripted the ARCHIMEDE's variable considered in the simulation study.

Figure 1: *One survey occasion with pooled sample*



4. Estimation methods

The scenario presented in previous paragraph, thanks to the collection of both specific and auxiliary variables, offers the possibility of pooling information using model based or model assisted estimation techniques methodologies. In particular, the variables can be pooled with model assisted (Kim and Rao, 2012) or model based (Battese et al. 1988) projection estimators.

This approach involves the identification of a working-model linking the dependent variable and the auxiliary variables observed in the different sub-samples and presents in the register. Fitting the model on the data collected in the specific survey it is possible to project the variable of interest, by means the parameters of the estimated model and the auxiliary variables, both on the pooled sample or on the register. This method requires a high level of quality of the auxiliary variables and a high goodness-of-fit of the working-models to provide considerable advantages both in terms of statistical properties of the estimators that in terms of detail of the information that can be produced.

The considered design-based estimators are:

1. Generalized regression (GREG) estimators: built separately for each sub-sample;
2. GREG estimators applied to the pooled sample: obtained by applying direct estimator to the pooled sample;
3. Projection from LFS to Pooled sample: obtained computing the predicted values on the pooled sample based on the working-model fitted on the LF sample data;
4. Projection from LFS to register: determined by defining the predicted values on the population register data based on the model fitted on the LF sample data.
5. Projection from Pooled sample to register: obtained by evaluating the predicted values on the population register data based on the model fitted on the pooled sample data.

Instead, within the case of model-based estimators is considered:

6. EBLUP unit level estimator: obtained computing the predicted values using the population totals of the auxiliary variables included in the working-model fitted on the LF sample data.

5. Simulation study

The simulation study aims to evaluate the quality of the estimators previously presented for different sub-regional domains obtainable either by design-based methods (projection estimators) and model-based estimators (Small Area Estimators, SAE) using the potential of the pooled sample. In particular, we consider three types of sub-regional territorial domains: provinces, aggregation of Local Labour Market Areas (macro-LLMA) and Local Labour Market Areas (LLMA). Only for the variables employed also the municipality estimates have been carried out.

The simulation based on a Monte Carlo experiment is aimed to compare the empirical properties of the estimates in terms of bias and mean square error. 200 samples have been drawn from the 2011 Italian population census, for two Italian regions, Trentino-Alto-Adige and Marche. The target variables are the total of persons employed and unemployed in these two regions. Linear model for the projection estimator have been fitted, with a fixed intercept at macro-LLMA level. The auxiliary variables used in the models are: marital status, educational level, citizenship, not in labour force, cross classification gender-age. The models were also enriched with information from the ARCHIMEDE register, which were linked with the 2011 census and so available for all individuals. Specifically, the variable used is a binary variable that indicates for every individual if he has a signal or not in at least one administrative source related to the employment world.

The working-models studied are summarized in the table below.

Table 1: *Working-models details*

Projection on pooled sample	*Variables*
Full model	*Marital status, educational level, citizenship, not in labor force, cross classification gender-age, ARCHIMEDE variable by regions*
Reduced model	*Marital status, educational level, citizenship, cross classification gender-age, ARCHIMEDE variable by regions*
Projection on register	
Minimal model	*Marital status, citizenship, cross classification gender-age, ARCHIMEDE variable by regions*

Once model selection and fitting has been completed, the prediction properties of the different estimates, obtained on the basis of the selected models, have been evaluated. All the estimators were compared by means of the standard indicators of accuracy of prediction: the Mean Absolute Relative Error (MARE) and Average Relative Root Mean Squared Error (ARRMSE). We further considered the $\boldsymbol{R^2}$ values to compare the goodness of fit of each model and so to evaluate the explanatory power of the different external variables considered in the application.

The indicators are formulated as follows:

$$MARE = \frac{1}{D}\sum_{d=1}^{D}\left|\frac{1}{R}\sum_{r=1}^{200}\hat{y}_{rd} - Y_d\right|$$

$$ARRMSE = \frac{1}{D}\frac{1}{R}\sum_{d=1}^{D}\sum_{r=1}^{R}\frac{\sqrt{(\hat{y}_{rd} - Y_d)^2}}{Y_d}$$

Where $\hat{y}_{rd}$ and Y_d are respectively the predicted value and the correspondent true value of the target variable.

The results for the variable *employed* are shown in Table 2, in which the $\boldsymbol{R^2}$ shows very high values for all the models. The MARE and the ARRMSE indicators are computed for the four type of domains described above. At province level the best results are obtained by the Projection estimator using the register, but also good performances are obtained for direct GREG estimator. At Macro-LLMA level the GREG estimator loose its good properties showed at provinces level, presenting a huge increase of variability (ARRMSE 21.36%). The Pooled estimators presents still good results on this level, very closed to the Projection estimator using the register. At LLMA and at municipality level the estimators both based on the LF data or on the pooled sample show very poor results with respect to those referred to macro-LLM. This is due to the fact that on 54 LLM areas included in the regions only 26 are always present in the 200 simulations, while for the municipalities on 572 areas only 27 are always included in the simulations. For this reason, the synthetic estimators (projection on register and SAE estimator) show similar results in terms of bias and variability as well.

Table 2: *MARE and ARRMSE for the variable employed*

Mean Absolute Relative Error - Employed							
	GREG LFS	Projection LFS-Pooled *Reduced model*	Projection LFS-Pooled *Full model*	Projection LSF-Register *Minimal model*	Projection Pooled-Register *Minimal model*	Pooled	Eblup
R^2	-	**89**	**95**	**89**	**89**	-	-
PROV (7)	0,33	0,55	0,56	0,12	0,08	0,6	-
Macro LLMA (14)	1,97	0,47	0,49	0,14	0,09	0,44	2,42

LLMA (54)	264	109	110	2.6	1.9	108	4
MUNIC. (527)	1791	608	608	3	2.5	610	4.62

The results for the variable un*employed* are shown in Table 3. For this variable the $\boldsymbol{R^2}$ value is similar using the *reduced* and the *minimal* model (14-15%) while goes up to the 33% using the *full* model. As well as for the employed, at provinces level and at Macro-LLMA good results are obtained from the GREG estimator and from the Pooled estimator, especially in terms of bias. At LLMA level only the projection on register estimator show good performance both with the MARE and the ARRMSE indicators below the threshold of the 13% and the 30%. The table 3 shows that considering only the 26 LLMAs always sampled in the 200 simulations, the bias estimates goes down up to the 5%.

ABSTRACT

In many developing countries, Agricultural data are mainly derived from decennial censuses providing structural data on agricultural holdings and benchmark data serving as reference for furthers yearly estimates from sample surveys. When conducted through complete enumeration, agricultural censuses also provide a sampling frame for intercensus sample surveys. Samples for current agricultural surveys are drawn from the sampling frame of the last agricultural census to provide annual updates on some of the agricultural data items and variables such as agricultural area, production etc. These annual estimates are based on the agriculture structure during the last census.

Very often, when a new census is conducted, there are discrepancies between the time series coming from the annual surveys conducted since the last census and the results of the new census. Although discrepancies may be due to legitimate changes in the already dynamic agriculture structure, common sources of these discrepancies are related to changes in the sampling frame, survey methods, concepts and definitions. These especially occur when the intercensal period is too long (more than the ten-year period that is usually recommended by FAO).

Even though this is a very common problem, even in countries with more advanced statisticalsystems, there are very limited studies and methodological guidance to address the issuessystematically after each census.

This paper analyses the possible sources of the discrepancies between time series fromintercensus annual surveys and the results of the new census. It reviews the statistical methodsthat can be used to address them; taking into account country experiences, and results of asimulation conducted on real data form a pilot country. It will present strategies and methodologicaloptions that can be considered on the ways to systematically reconcile inter-censuses surveysdata and results of a new census. The paper builds on the content of a technical report prepared inthe framework of the Research Programme of the Global Strategy to Improve Agricultural andRural Statistics.

Keywords: Reconciliation, Regression, Sampling.

1. Introduction

A census of agriculture (or agricultural census) is a statistical operation aimed at collecting, processing and disseminating data on the structure of agriculture, over the whole or a significant part of a country. Typical structural data collected in an agricultural census are the number and size of holdings (broken down by region, province, district, village, etc.), land tenure, land use, crop area harvested, irrigation, livestock numbers, labour and other agricultural inputs. In an agricultural census, data are collected directly from agricultural holdings, although some community-level data may also be collected. A census of agriculture normally involves collecting key structural data, by means of a complete enumeration of all agricultural holdings, and more detailed structural data, using surveys and sampling methods.

Data from agricultural censuses are useful in a variety of economic and social domains, including agricultural- and rural-sector planning and policymaking, as well as monitoring progress towards the Millennium Development Goals and addressing problems relating to poverty, food security and gender. Agricultural census data are also used in the establishment of agricultural indicator benchmarks and tools, to assess and improve current agricultural statistics during inter-census periods. In several developing countries, agricultural data are derived mainly from decennial censuses, which provide structural data on agricultural holdings and benchmark data that serve as references for yearly estimates subsequently computed on the basis of sample surveys. When conducted by means of complete enumeration, agricultural censuses also provide a sampling frame that can be used in designing inter-census sample surveys. Samples for current agricultural surveys are drawn from the sampling frame established for the most recent agricultural census, aiming to provide annual estimates on certain agricultural data items and variables, such as planted or harvested agricultural area, production and yield. These annual estimates are based on the structure of agriculture identified in the latest census.

When a new census is conducted, discrepancies are often found between its results and the time series derived from the annual sample surveys conducted since the most recent census. Countries tend to encounter difficulties in reconciling crop or livestock data from the most recent agricultural census with the agricultural statistical series obtained from sample survey data. In some cases, there may be valid statistical reasons for these differences. For example, the geographic area covered by one of collections may be incomplete, as urban areas have been excluded. Certain types of holdings, such as small holdings, may have been omitted from one of the collections. Different concepts and definitions may have been applied in the treatment of mixed cropping. There may be inconsistencies in the reference periods or in the definition of crop seasons. Subnational data may be inconsistent because the agricultural census collects data on the basis of the holder‟s place of abode, and not the location of the land or livestock. If sampling is involved, the sample results may suffer from sampling errors. These discrepancies easily arise when the inter-census period is excessively long.

Although this is a common problem, few studies and methodological guidances systematically address the issues arising after each census, even in countries with more advanced statistical systems.

2. Objectives

The main objective of the study is to deeply explore the methodologies displayed in the literature review and to develop an appropriated statistical methodology for reconciling agricultural census and survey data. Simulated data are used to assess the proposed method.

3. Source of Discrepancies

The sampling frame reflects the structure of agriculture at the time of its construction. Agricultural censuses conducted ten years apart may present inconsistencies in their data, especially if these have not been adjusted during the intercensal period. The sources of data discrepancy are the following:

a) Changes in the sampling frame

Measurements may be sought from agricultural holdings during annual surveys, to take into account any changes in the holdings‟ practices and therefore any changes in the performance of the agricultural holdings sampled. However, if survey weights are not revised to capture the changes in the number of agricultural holdings and their distribution by size or strata, this may lead to inconsistency between data.

In the United States of America, the National Agricultural Statistics Service (NASS) conducts several data collection operations. Two of these are the June Agricultural Survey (JAS) and the Census of Agriculture. The JAS is based on an area frame and is conducted annually, whereas the Census of Agriculture is conducted every five years. In 2012, a capture-recapture approach was used to produce estimates for the Census of Agriculture. The capture-recapture methods require two independent surveys to be conducted: the Census of Agriculture and the JAS were chosen for the purpose. Records that have responded to the census questionnaire as farms are assigned weights that adjust forundercoverage, non-response and misclassification. Generally, follow-on surveys to the Census of Agriculture, conducted during the intercensal years, have been based on the assumption that the NASS list frame – which is the foundation for the census mailing list – is complete. Although continual efforts are made to update the list frame, undercoverage persists. Failure of these follow-on surveys to account for such undercoverage has resulted in estimates that are biased downward. In 2016, for its local foods survey, the NASS used a list frame obtained by means of web scraping; capture-recapture methods were used to compute adjusted weights for the list frame records.

In Brazil, during the 2006 agricultural census, it was found that 11 per cent of holdings had ceased to provide information on production, while in previous years (specifically, 1980, 1985 and 1996), this rate was only 2 per cent, approximately. Furthermore, the results of the production of certain products that could be compared with estimates from other sources – or from the supply balance based on information processing, exports, imports and inventory changes – indicated that the census data was affected by significant underestimation at national level. For soybeans, the underestimation is in the order of 13.6 per cent; for cane sugar, 17.2 per cent; and for orange, 42.9 per cent (Guedes& Oliveira, 2013).

When the surveys are conducted with a panel of agricultural holdings selected from the data of the most recent general agricultural census, the discrepancies between census and survey data could be ascribed to the disappearance, division, or merger of holdings over time due to endogenous or exogenous events. Phenomena occurring in the population may also impair sample quality. These changes adversely affect panel quality because they directly influence sample size and the weight of the statistical units (Global Strategy, 2015).

b) Misclassification

Misclassification occurs when an operating arrangement that meets the definition of a farm is incorrectly classified as a non-farm, or when a non-farm arrangement is incorrectly classified as a farm. In the US, the census data consist of responses to a list-based survey, the mailing list for which is created and maintained wholly independently of the JAS area frame. The census data can be used to assess the degree of misclassification occurring in the survey. For this purpose, when analysing the 2012 Census of Agriculture, the NASS matched each 2012 JAS tract to its 2012 census record. Disagreements in the conferral of farm status between the census and the JAS occurred when (1) tracts identified as non-farms in the JAS were subsequently identified as farmsin the census, or (2) tracts identified as farms in the JAS were identified as non-farms in the census. If the tract was identified as a farm in either the JAS or the census, then the tract was considered to be a farm.

For the censuses prior to and including that of 2007, the analysis assumed that there had been no misclassification in the JAS. However, in 2009, the Farm Numbers Research Project (FNRP) was conducted. Twenty per cent of the new JAS records were revisited, as these had been added to the sample and that had been estimated to be or designated as non-agricultural during the pre-screening process. This demonstrated that there had been a substantial degree of misclassification; if the rest of the sample was affected by the same rate of misclassification, then the estimate should have included 580,000 more farms (Abreu et al., 2010). This was the first indication of an underlying cause that could help to explain the discrepancy in the published estimates.

c) Varying concepts and definitions

In an integrated agricultural statistics system, it is recommended that concepts and definitions be harmonized between agricultural censuses, other censuses (such as population censuses) and agricultural statistical surveys. Inconsistencies in data may be due to changes or variations of concepts and definitions. Serious changes in concepts and definitions may affect estimates, as the series of data collected in different years do not measure the same variable,or measure the same variable for different survey populations. Either of these variations introduces inconsistencies.

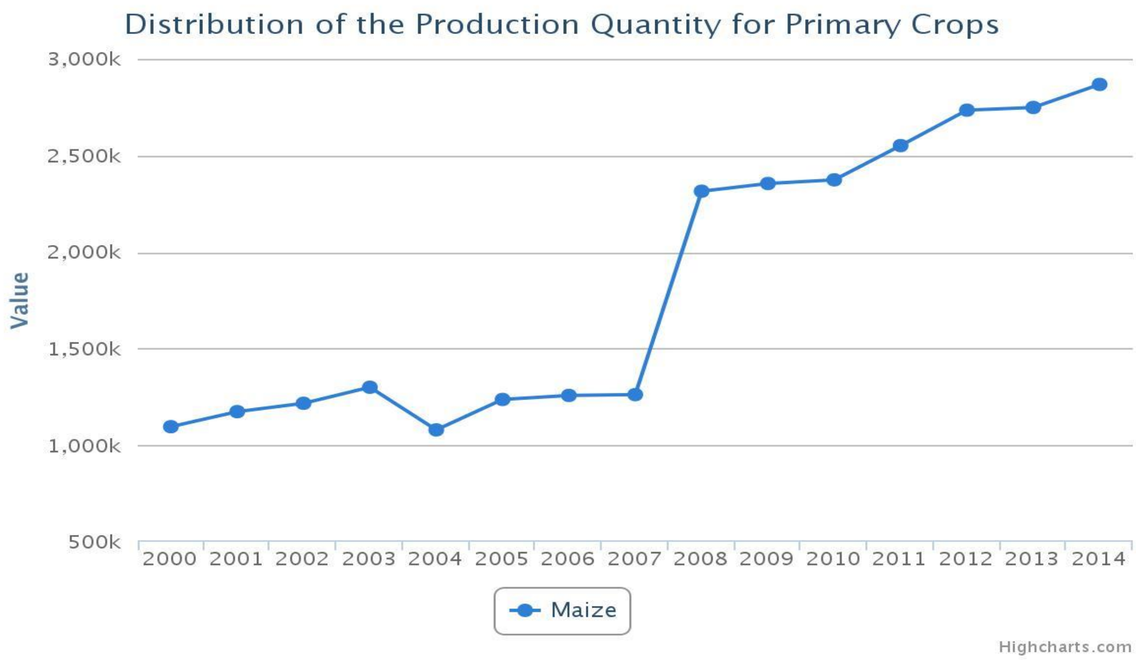

Figure 1. Example of discrepancy in time series data. Source: CountrySTAT-Uganda

d) Greater reliability of data from latest agricultural census and surveys based

on census sampling frame

The most recent agricultural census and surveys based on the census sampling frame may provide more reliable data than those gained in previous collection efforts, and thus lead to discrepancies.

These may be caused by the following:

- The frame has changed because of changes in the structure and number of holdings and their distribution;
- Improvements in methodology;
- Improvements in the supervision and control system;
- Improvements in the relevant technology (new tools, GPS, tablets, etc.).

e) Non-response

Non-response occurs in all censuses and surveys. To address the problem, several countries estimate the missing data, even though this increases the uncertainty associated with the estimates and may lead to bias. In the US, reporting is mandatory for the census, but is voluntary for surveys. However, legal measures are usually not invoked, to avoid the spectacle of prosecuting farmers. Censuses thus suffer a non-response rate similar to that of surveys. To take into account this non-response, the NASS adjusts the weights for responding records. This also increases uncertainty and may result in bias.

f) Other non-sampling errors

Other non-sampling errors may arise due to inadequate questionnaires or defective methods of data collection, tabulation, coding, etc.

g) Sampling errors

The sampling errors noted in the literature can clearly be considered sources of discrepancy between the results of surveys and censuses.

Sampling errors arise solely from the drawing of a probability sample, and not from the conduction of a complete enumeration. The methods to address theseerrors may determine a gap between census and survey data. Sampling errors may be linked to several factors, including a lack of representativeness due to insufficient sample size, errors in the sample selection process or a failure to validate some assumptions made in the sampling theory. For example, in two-stage sampling, the selection probability of an SSU is the product of the selection probability of the corresponding PSU and the conditional selection probability of an SSU for the given PSU. If PPS sampling is applied, this probability is proportional to a measure of size. This measure of size, seen as an auxiliary variable, should at least be positively correlated to the variable of interest, to reflect the correct weights of the sampled units in the population. This means that in repeated PPS sampling, the Horvitz-Thompson estimator usually used to compute estimates during survey operations is an unbiased estimator for the finite population total. However, if the probability of inclusion and the variable of interest are not closely related, this procedure may be rather inefficient due to variation in the selection probabilities. For example, if the measure of size is the number of agricultural households in an Enumeration Area (EA) and the variable of interest is the area harvested, it must be assumed that the number of agricultural households in the EA is at least positively correlated with the area harvested, to ensure that valid sampling weights are obtained. The contrary is also possible, and a sample based on this auxiliary variable should lead to biased estimates of the variable of interest. This generates inconsistency with the data from the new census.

4. Methodological Approach

Changes in sample design or in the interview process and shifts in the sampling frame may lead to unrealistic changes in aggregates over a short period of time. The purpose of survey weights is to ensure that the sample represents the population. Therefore, these weights play an important role in creating consistent aggregates over time. Surveys select different holdings with different inclusion probabilities due to both intentional design and accidental factors. Some farms are therefore overrepresented compared to others; if the sample estimates are to reflect the population accurately, each farm must be weighted according to its „true" inclusion probability.

Each farm is weighted by the inverse of its probability of inclusion in the sample (Deaton, 1997). This is reasonable because a household with a low probability of selection represents a large number of households in the population, while a household with a high probability of selection tends to be a minority-type household in the population. These weights are often referred to as "raising" or "inflation" factors, because they inflate the sample to resemble the total population. Divergences in weights across households arise from differences in selection probabilities, which may be ascribed, in turn, to both planned and accidental factors. Accidental differences may arise due to measurement errors and sampling errors; such as use of an obsolete sampling frame or non-response.

4.1. ChangepointDetection

Several methods have been proposed to estimate the point at which the statistical properties of a sequence of observations change. The most common approach to identify multiple changepoints in the literature is to minimise

$$\sum_{i=1}^{m+1} [C(y_{(t_{i-1}+1):t_i})] + \beta f(m) \qquad (a)$$

where C is a cost function for a segment e.g., negative log-likelihood and $\beta f(m)$ is a penalty to guard against over fitting. The changepointdetection could be implements three multiple changepoint algorithms that minimise (a); Binary Segmentation (Edwardsand Cavalli-Sforza, 1965), Segment Neighbourhoods (Auger and Lawrence, 1989) and therecently proposed Pruned Exact Linear Time

(PELT) (Killick et al., 2012). The R packages*changepoint*and *changepoint.np*could be used at this regard.

The figure 1 shows the plots of the time series for 4 crops. The point is to identified whether the year of the census is a changepoint. The table 1 presents the results for the selected crops. The method used is the PELT method, the empirical distribution is used to compute the statistical test and the Modified Bayes Information Criterion (MBIC) has value 8.124151. For all crops, 2007 is the location of the changepoint. The implementation of the 2008 censuscould explain the break in the time series data. For Rice Paddy, the method identifies 2007 as the changepoint, while on the plot is not clear. For sorghum, 2004 has been identified as a changepoint. Since any census have been done in this year, the break in the time series cannot be the result of the implementation of a new census. The method allows to identify a changepoint, but since we intend to reconcile census and survey data, only changepoint in the year of the census could be taken into consideration.

Crop	Maize	Sorghum	Cassava	Rice Paddy
Changepoint Locations	2007	2004, 2007	2007	2007

Table 1. Identification of the change point (number of quantiles=3)

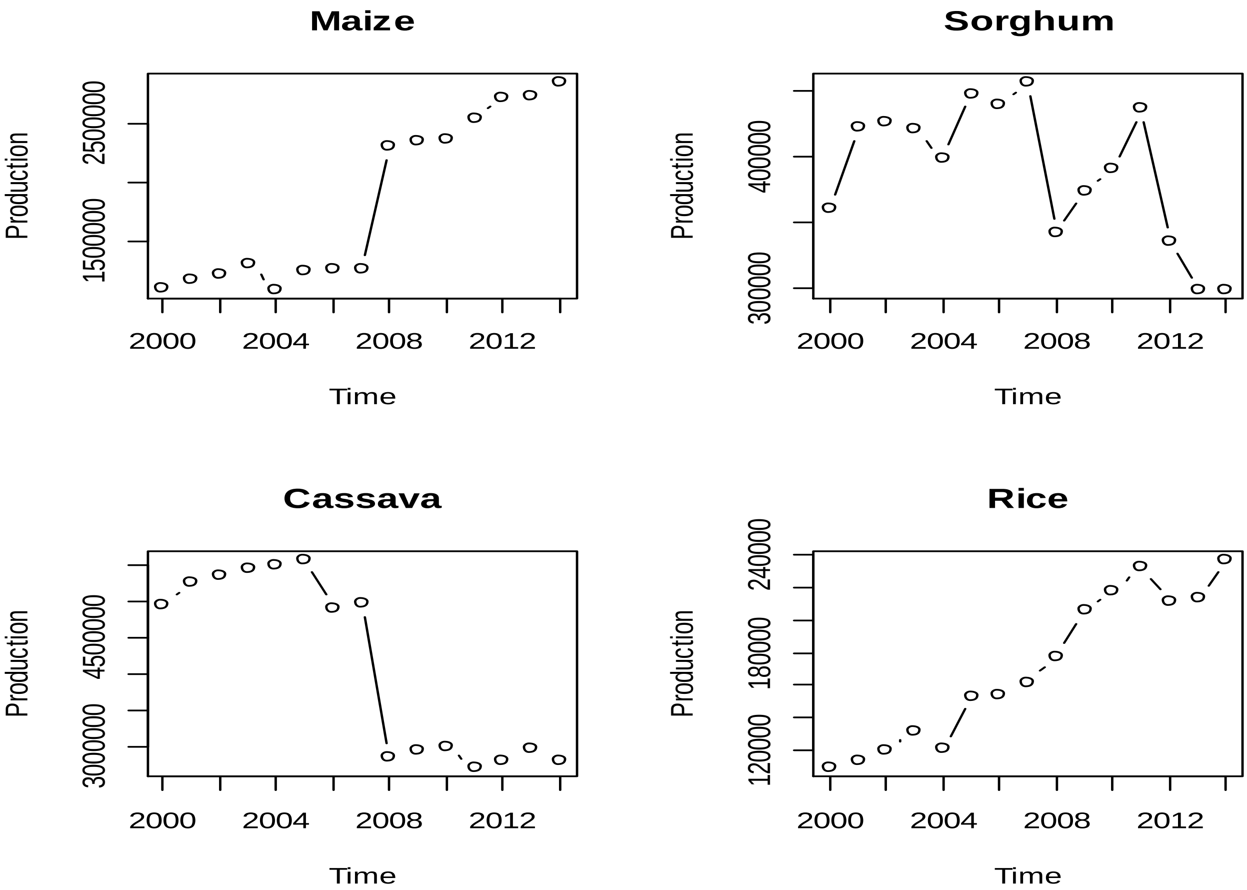

Figure 1. Plot of the time series of different crop. Source: CountrySTAT Uganda.

4.2. Cross Entropy Estimation Method

Calibration estimation can be described as a method to adjust the original design weights so that the known population totals of the auxiliary variables may be incorporated. Generally, the calibration procedure selects the adjusted weights that minimize distance between the original weights and the adjusted weights, while also satisfying a set of constraints relating to the auxiliary variable information.

The estimation approach represents an efficient "information processing rule" using an estimation criterion based on an entropy measure of information. The survey household weights are treated as a prior. *New weights are estimated that are close to the prior using a cross-entropy metric and that are also consistent with the additional information.* These additional information is about the adding-up normalization constraint of the probabilities and a moment consistency constraint. Using this method, information from the census can be capitalized to adjust survey sampling weights.

In particular, the model consists of an objective function which is minimized subject to constraints. An extrapolation method can be used on census data in order to obtain a *prior* data in the year of the survey. This extrapolation can be done by using trend estimation.

$\bar{S}_k$ is the original sampling survey weight for a given statistical unit, S_k is the new sampling survey weight used for the reconciliation, C_k is the prior obtained from an extrapolation based on census data, w_l error weights estimated in the Cross-Entropy procedure, $\bar{w}_{k,l}$ is its prior, $\bar{v}_{k,l}$ is the error support set, f_t represents a general aggregator and p_k a probability or a sample weight.

$$Min_{S,w} \sum_k S_k \ln\left(\frac{S_k}{\bar{S}_k}\right) + \sum_{k,l} w_{k,l} \ln\left(\frac{w_l}{\bar{w}_l}\right) \quad (1)$$

subject to

$$\sum_k p_k\, f_t\,(S_k) = C_t + \sum_l w_{t,l}\bar{v}_{k,l}\,, \quad t \in [1, \dots, T], l \in [1, \dots, L] \quad (2)$$

and additional adding-up constraints on the error weights

$$\sum_k p_k = 1, \ \ and \ \sum_l w_{k,l} = 1 \quad (3)$$

$$Min\{\bar{S}_k, C_k\} \le S_k \le Max\{\bar{S}_k, C_k\} \quad (4)$$

The set l defines the dimension of the support set for the error distribution and the number of weights that must be estimated for each error. The prior variance of these errors is given by:

$$\sigma = \sum_l \bar{w}_{i,l}\bar{v}_{i,j}{}^2$$

$\bar{w}_{i,l}$ is the prior weights on the error support set.

Assuming a prior distribution with zero mean and a standard error equal to σ , we used a support set with five terms equal to (-3 σ , - σ ,0, σ, 3 σ). Assuming normality of the prior distribution, the prior values of the weights can be computed given only knowledge of the prior mean and standard error. The constraint (2) is stochastic, where C_t is assumed to have a measurement error. The minimization is performed by a non-linear optimization algorithm. Constraint (4) makes sure that

S_k lies between the original $\bar{S}_k$ andC_k. The minimization is performed by a non-linear optimization algorithm (Ouedraogo & Nyamsi, 2016).

The challenge lies in identifying the correct moment consistency constraint. For example, with regard to livestock reconciliation data, the intercensal growth rate between two censuses may be used to estimate an aggregate value in the survey year. Therefore, a moment consistency constraint can be determined by means of this aggregate. A household consumption data could be used as auxiliary information.

4.3. Post-stratification Method

Post-stratification can be seen as a form of re-weighting. The post-stratification methodology is to re-consider the size of the strata based on the last census, and re-calculate the probability of inclusion, and therefore the sampling weight using new information based on the new census. Based on the information of the new census, new strata are "re-defined" (post-strata), and new weights are calculated considering the part of sample units included in the new strata. This "re-definition" is necessary, if the previous strata are no longer valid.

Let Y be the variable of interest and H the number of post-strata (After the redefinition of strata).

- N_h is the number of agricultural holdings in the post-stratum h
- S_h is the set of agricultural holdings in the stratum h
- $Y_h = \sum_{k \in S_h} y_k$ is the total of Y in the post-stratum h

- Let U_h be the part of the sample included in the post-stratum h. The number of holdings in U_h is n_h.
- $\bar{y}_h = \frac{1}{n_h} \sum_{k \in U_h} y_k$ is the mean of the variable of interest in the post-stratum h.

The Post-Stratified Estimator of the total Y is given by

$$\hat{Y}_{post} = \sum_{h=1}^{H} N_h \bar{y}_h$$

If the true value of N_h is used this estimator is unbiased.

4.4. Time series Smoothing Techniques

Weighted Moving Average (WMA) could be used to reduce the gap in the time series. WMA assigns a heavier weighting to more current data points since they are more relevant than data points in the distant past. The new value use the WMA method could be compute at a local level and for any strata, and the national total could be obtained.

It could be combined with the cross-entropy method. It could be used to define the relation in (2), in fact C_t could be the total based on WMA method for a given year.

Other technique such as**Exponential Smoothing** could be also used to adjust the trend.

4.5. Handling Misclassification

Abreu*et al.* (2011a) identify misclassification as a direct cause of the undercount of the number of farms produced by the JAS in the US. One approach to correct for this undercount is to use the NASS's sampling list frame, which is independent of the area frame. However, the list frame does not present a farm/non-farm status classification. Abreu *et al.* (2011b) used matched records from the 2009 JAS, the 2009 list frame, and the 2009 Farm Numbers Research Project (Abreu *et al.*, 2010) to explore the characteristics of the inaccuracies in the list frame farm status. They then developed an estimator of the probability that a 2011 list frame record was a farm using logistic regression, and used this estimator as a foundation for providing an adjusted number of farms for the 2011 JAS. The two estimators were based upon two assumptions: (1) the adjustment was independent of the original JAS estimator of the number of farms; and (2) the previous census farm rates provided a good estimate of the probability of farm status for each list frame record. However, both of these assumptions were questionable.

To address the concerns raised by the previous approach, and to obtain a coherent set of methods for the agricultural census and the JAS, Abreu *et al.* (2014) developed a capture-recapture approach to estimate the number of US farms from the JAS. They proposed the following estimator for the number of farms from the JAS, with an adjustment for misclassification:

$$T_2 = \sum_{i \in SARJ} \frac{t_i}{\pi_i} \frac{\hat{p}_i(F \mid SARJ)}{\hat{p}_i(J \mid SARF)\hat{p}_i(R \mid SAF)\hat{p}_i(A \mid SF)},$$

where

i = indexes tract on the JAS

t_i = proportion of a farm represented by tract i

π_i = sample inclusion probability for tract i

S = tract is within the sample

A = tract passes the agricultural screening process

R = tract responds to the survey

F = tract is truly a farm

Logistic regression was used to estimate each of the above probabilities. Based on this estimator, at US level, the estimated misclassification rate for farms was 9.4 per cent.

4.6. Non response

Generally, in case of non-response, the data required are estimated. Therefore, the problem of non-response is related to the estimator error. A vast body of literature exists on how to account for non-response.

To reduce non-response bias in sample surveys, a common method of adjusting for non-response consists in multiplying the respondent‟s sampling weight by the inverse of the estimated response probability. Kim and Kim (2007) demonstrate that this approach is generally more efficient than relying upon an estimator that uses the true response probability, provided that the parameters governing this probability are estimated by reference to maximum likelihood. Based on a limited simulation study, they also compare variance estimation methods that account for the effect of using the estimated response probability, and present the extensions to the regression estimator. The authors found that adjustment using the estimated response probability improves the point estimator‟s efficiency and also reduces bias, because it incorporates additional information from the auxiliary variables used in the response model. In this case, the variance estimators discussed account for the variance reduction related to the estimation of the response probability.

McCarthy et al. (2010) have modelled non-response in NASS surveys using classification trees. They describe the use of classification trees to predict survey refusals and inaccessible respondents.

The methods for solving non-response issues may be applied during the reconciliation of census and survey data, if this has not been done during survey data estimation. Most of these methodologies do not use census data and can thus be applied before the census year. If they have been applied, problems relating to non-response are considered to be estimation problems.

4.7. Model-Based and Model-Assisted Methods

We assume that the variable of interest Y (Production or Area) is related to a number of variables observed within the population throughout the years.

We have:

$$Y=f(X)$$

The idea is to assess f based on the census data and impute data for unobserved units during the survey.

The total production can also be written as

$$T = 1_s^T y_s + 1_r^T y_r = 1_s^T y_s + 1_r^T f(X_r)$$

where 1_s^T and 1_r^T are vectors of n sampled units (sample size) and *N-n* non sampled units respectively. The population matrix of covariates is $X = [X_s, X_r]^T$ where $X_s$is the *n x p* matrix for sampled units and X_r is the *(N-n) x p* matrix for non-sampled units.

The estimated weight is

$$\widehat{w}_s = \frac{1_s^T y_s + 1_r^T \hat{f}(X_r)}{1_s^T y_s} = \frac{\sum_{s=1}^{n} y_s + \sum_{r=1}^{N-n} \hat{f}(X_r}{\sum_{s=1}^{n} y_s}$$

The accuracy of the method lies in determining *f*.

a) Spline Regression Method

We are interested to the estimates, not necessary to the *f* itself, therefore the appropriate method is the semi-parametric regression since the OLS regression are influenced by extreme values.

This method uses the regression model $y_i = m(X_i) + e_i,\ e_i \sim N(0, D_i)$, where m is the spline function using a linear combination of truncated polynomials.

(Henry K. & Valliant, 2012) shows that

$$\hat{T}_{Spline} = \sum_{i \in s} w_i y_i$$

with

$$w_i = \pi_i^{-1} - (\frac{\widehat{m}_i}{\pi_i} - \frac{\sum_i \widehat{m}_i}{n})/y_i$$

With this non-parametrical model, unit with the same characteristics X will have closed estimates of the variable of interested. The effect dues to misspecification in this case are reduced.

b) Generalized Regression Method (GREG)

This method is a calibration approach that involves minimizing a distance function between the base weights and final weights to obtain an optimal set of survey weights. Here optimal means that the final weights produce totals that match external population totals for the auxiliary variables X within a margin of error.

Specifying alternative calibration distance functions produces alternative estimators. A least squares distance function produces the general regression estimator (GREG)

$$\hat{T}_{GREG} = \hat{T}_{HT} + \hat{\boldsymbol{\beta}}^T(T_X - \hat{T}_{XHT})$$

where $\hat{\hat{T}}_{XHT} = \sum_{i \in s} w_i x_i$ is the vector of Horvitz-Thompson totals for the auxiliary variables,$\hat{T}_X = \sum_{i \in s} x_i$ is the corresponding vector of known totals, $\hat{T}_{HT}$ is the Horvitz-Thompson estimator used to estimate the total of the variable of interest during the surveys and $\hat{\boldsymbol{\beta}}$ is the regression coefficient estimated from census data.

The term $\hat{\boldsymbol{\beta}}^T(T_X - \hat{T}_{XHT})$ represents the estimate of the difference between the total value of the variable of interest and the HT estimates. This term could be positive, when the HT calculations underestimates the true total value and negative, when it overestimates.

5. Other Methods to Adjust data

Some methods could be performed to adjust data, as required. However, reconciliation of the survey data with the census data may still be necessary after these techniques are applied. These are to be implemented when the survey is being conducted. In fact, it is important take some actions in order to avoid the gap in the time series. Adjustment in data, could be done throughout the intercensal period.

a) Additional samples

Due to population movements, over a certain period of time, new statistical units may appear in the population of households or farms. Therefore, discrepancies may arise between the estimates based on survey data and the data from the previous census. If the list frame of these units is available (e.g. from administrative files), an additional sample of the new units can be drawn. The population of new units may be considered as a stratum, and the new estimates can be obtained (Global Strategy, 2015).

b) Tracking

Changes in statistical units adversely affect their representativeness and make estimates less precise, thus generating inconsistencies between census data and survey data. These changes must be corrected if the integrity of the units is to be maintained. When a part of a unit does not exist at the time of collection, this part will have to be tracked, especially if its absence is not random. For example, if a portion of a farm changes ownership due to a conflict over land, arrangements should be made with the new owner to collect data on this part (Global Strategy, 2015).

c) Weight-sharing methods

When the surveys are conducted with a panel of agricultural holdings selected from the data of the most recent general agricultural census, changes in statistical units may also be corrected by means of weight-sharing methods, including the General Weight Share Method developed by Lavallée (2007). These methods are explored in further detail in another important publication of the Global Strategy: the Guidelines for the Integrated Survey Framework (Global Strategy, 2015).

If a sample panel is used, these methods of adjustment may be of great assistance to the reconciliation with census data.

d) Oversampling

To cope with the disappearance of statistical units in a region or in a stratum, the size of the sample size may be increased to anticipate the loss of statistical units. This helps to maintain sample accuracy, but does not prevent bias (Global Strategy, 2015). This technique is applied when the sample is selected, before obtaining the survey results necessary for the reconciliation. Therefore, even after its implementation, it may still be necessary to proceed to the reconciliation with census data.

e) Update Sampling Frame

A good system to update the sampling frame should be settled. For instance, a part of the sampling frame could be update each year while implementing the survey. It will allow to minimize discrepancies related to the sampling frame.

6. The Experience of Canada

Not all agricultural survey results should be changed when agricultural census estimates are compared. Indeed, the sampled units of some surveys may not be the farm operator (but millers, for example), or some survey variables may not be measured by the census (such as greenhouse area). Consideration is given to historical events that may have introduced a supply or demand shock between census years, to maintain the characteristics of such events during the revision. However, if a shock occurs during the census year, this information will not be used for trend adjustment. In addition, the source of the information will affect decisions on a possible update. For example, administrative data generated from regulatory sources that are widely used across the industry are likely to remain unchanged, unless a clear explanation can be provided.

A) General considerations

Data from agricultural censuses is used for benchmarking at macro level and for data confrontation and verification. The survey estimates are revised to match the census numbers as closely as possible, adjusted for seasonal variation as appropriate. The revisions made on commodities can be summarized as either a wedge adjustment or a logarithmic adjustment, depending on the characteristics of the data and the commodity. Only the trend is adjusted – not the magnitude of the change from year to year. Variables such as area (and, in some cases, expenses) are first compared between surveys and the agricultural census, to determine the extent of the frame change and the potential intercensal adjustments.

Ratios are also used in various ways for the commodities, to support their analysis: (a) the ratio of published numbers to census numbers; (b) the ratio of census numbers to survey-level estimates; (c) the ratio of average yield (from the survey) and total area (from the census), to adjust production; (d) the census inventory data adjusted for seasonal variation (for e.g. cattle and sheep), etc.

When reconciling, the supply and demand outputs are respected as much as possible. Crop supply and disposition tables can still be revised to maintain balance and validate production, in light of any changes that may have occurred in the relevant area.

The livestock balance sheet follows a similar procedure, examining international and inter-provincial trades, inventory and slaughter. For cattle, adjustments are made to "softer" categories such as calves and heifers. Similarly, in financial terms, the agricultural census may trigger revisions for intercensal years to capital value, farm cash receipts and operating expenses, in light of the new production and inventory values fed from the commodity-adjusted estimates. The intercensal revisions provide an opportunity to include modifications to compilation methods or concepts that have not yet been integrated in published data. Census data is also used to revise the value of a number of commodities for which annual data is not available.

The expense benchmarks established during intercensal revisions are typically within 2 per cent of the census estimates. The trends and levels of tax-based estimates (the source of annual estimates of agricultural expenses) are taken into account when determining the exact level, and indicators, of input price and quantity changes. Information on undercoverage, edit, imputation and validation procedures and the historical relationships between tax and census levels are taken into consideration, as are any changes in the questionnaire (e.g. grouping of expense items). Once the benchmarks have been fixed, a smoothing process is applied which only slightly adjusts the annual changes of the intervening years.

The top contributors are compared, to identify the farms missing from the survey frame. As for the census estimates, this enables any changes in subsectors or emerging agricultural sectors to be better identified. This also provides an opportunity to address these changes in survey questionnaires for future years. For a given commodity or geographic area, in future sample selection, a respondent may be included in a different stratum, in light of its relative importance since the previous census.

B) Census validation using survey data

The main objectives of data validation are to guarantee the quality and consistency of the agricultural census data and to make recommendations for their publication before being released to the Canadian public. Data validation is a complex process in which human judgement is vital. Validators follow a Data Validation Plan and a Data Validation Checklist as guidelines to the data validation tools available on the Central Processing System (CPS). However, validators will ultimately have to solve problems and make decisions based on the analysis of background information, respondent feedback, expert consultation and common sense.

First, the analysis is focused at the macro level. Aggregate census data are analysed at the provincial and subprovincial levels and compared to the expectations outlined in the senior validator‟s Data Validation Plan.

The analysis is then directed to the micro level. Changes to individual records must be made when appropriate, to guarantee the quality of provincial and small-area data and the usefulness of the agricultural census data as a sampling frame. Due to resource and time constraints, micro editing is done using a "top-down" approach, in which those records with the largest contribution to a variable estimate are reviewed first.

Finally, the results of analysis for a province – including the final estimates of the variables under study and recommendations for their publication – are presented to a certification committee.

C) Certification

Revised survey estimates are verified by other members of the team. Provincial experts are also consulted to obtain their views on the possible extent of revision.

D) Communication plan

A communication plan is established to inform all key users that new intercensal revisions have been made available. Typically, users know that estimates are revised every five years.

E) Timelines

Intercensal revisions to agricultural commodities are usually completed one to two years after the census data are released. Corresponding revisions to the financial variables (farm cash receipts, operating expenses and net income) are released two to three years after the census data release. Revisions from a new census benchmark normally cover the five-year period back to the previous census. (Statistics Canada, 2011)

F) Lessons Learnt

Data reconciliation techniques such as ratios and trends may be useful when revising survey data. Furthermore, these revised data should be consolidated as much as possible with other data, such as supply and demand outputs. The new estimates should be validated by a pool of experts prior to publication. It is important for personnel who were involved in data collection and estimation to be part of this pool.

7. Concluding remarks

There is scarce published literature on reconciling census data and survey data in the field of agriculture. However, several techniques applied to produce sampling weight and trend adjustment may be a basis for data reconciliation. This technical paper has reviewed some of these methods. It has also explored the sources of discrepancy between census data and survey data, and the gap to be addressed to provide countries with guidelines on data reconciliation.

An updated sampling frame is one of the keys issue in order to avoid discrepancy in data. It is also necessary to have updated explainable variables. This can be a limitation of that method: The capacity to have accurate and update correlated variable. Some variables as the size of the holding, the number of holding in an area, the variable to the owning of equipment (tractor, etc.) are collected during the census and they can be updated using other data sources (population census, administrative file or other survey).

In some of the examples presented in this paper, explicit formulas for weights could be obtained. Methods that incorporate realistic models will improve the estimates of totals. By incorporating the relationship between the survey variable and some known auxiliary information, the estimates of the totals may have lower mean square errors. When the model is specified correctly, the associated estimators are optimal. However, when the model does not hold, or if the sample contains outliers, several robust alternative estimators could be developed.

The generalized design-based method smooths weights by modeling them as functions of the observations y. The weight of each unit is then replaced by its regression prediction. Non-response and post-stratification methods are designed to reduce biases or variances.

All of these methodologies are being tested to identify the most suitable ones for each type of problem, and to provide countries with effective and workable guidelines.

ABSTRACT

The growing demand by policy and decision makers for statistics based on information that is interlinked in economic, social, and environmental aspects, requires a large-scale expansion, in terms of organization and budget, of efforts to implement statistical surveys. In developing countries, agriculture (broadly including fisheries and forestry) is the predominant activity that is interconnected with all these sectors.

Required data to support the development of agricultural projects are usually collected by sector, using different sampling frames and methodologies, without any possibility to measure the cross-sector impact of a given action, consequently affecting the quality of the statistics generated by scattered and manifold data collection methodologies.

Developing a sampling frame for a sector as complex as the rural sector is difficult and expensive for many countries and it is often impossible to establish a frame for certain specific statistical units.
For most countries, the General Census of Agriculture and Population Census, which are usually conducted every ten years, are the only statistical operation that builds lists for agricultural surveys. However, these sources alone cannot provide a sampling frame for all statistical units of interest for data collection in the rural sector, therefore possible lists could be incomplete, unavailable or obsolete.

The *Indirect Sampling* with the application of the *Generalized Weighted Sampling Method (GWSM)* could represent a suitable cost-effective method, capable of offsetting the shortcomings of lists, for rural and agriculture data collection. This method produces estimates for the unknown population object of interest, by calculating the weights of each sampled statistical unit for which there is no list, using the weights of the sampled units of a population for which a sampling frame exists. The essential requirement is the existence of a relationship between the units of the available frame and the units of the target population compared to the phenomenon to be surveyed.

Based on the Indirect Sampling and GWSM, a further extension which observes two populations jointly has been analysed to develop an integrated survey framework that can propose an alternative to the current multipurpose surveys, with the aim of reducing implementation costs as well as producing unbiased estimations and improving the quality of data collection.

Works on the application of the indirect sampling method on agricultural surveys have been developed by the lead of the Research Program of Global Strategy to Improve Agricultural and Rural Statistics.

Keywords: Indirect sampling, Agricultural statistics, Rural statistics, Integrated survey Framework**,** Cost-effective methods, Weight Sharing Method, Link between units of different populations

1. Introduction

Agriculture sector is a vital activity of the developing countries for their economy as well as a mean of subsistence of most rural population. The "growth in the agriculture sector is about two to four times more effective in raising incomes among the poorest compared to other sectors. This is important for 78 per cent of the world's poor who live in rural areas and depend largely on farming to make a living. Agriculture is also crucial to economic growth: it accounts for one-third of gross-domestic product (GDP) and three-quarters of employment in Sub-Saharan Africa."[1]

The statistics demanded by policy and decision makers are based on information that is interlinked in economic, social, and environmental aspects, which require a large-scale expansion of national efforts to implement statistical surveys, in terms of organization and budget. An alternative approach for collecting data, by integrating information from different sources using cost-effective methods, is becoming a crucial requirement for the production of reliable statistics. Especially for developing countries, where the purpose or objectives, for which the information is required, depend on available budgetary resources and time constraints, the combination of various methodologies could be the only possible solution to generate rural and agricultural statistics.

Data collection on agricultural statistics varies by the type of data to be gathered[2] and across countries in terms of local items, periodicity and methods and is carried out by sampling methodologies (agricultural census and surveys) conducted on agricultural holdings. Indeed, other sources, such as population censuses, administrative reports and household sample surveys, though not specifically focused on the entire agricultural sector, may still provide relevant information.
Sample surveys conducted on holdings do not only collect economic data, but they can also be sources of relevant information on social dimension as well as on agricultural practices that affect the environment. Thus, the information sought should be the result of a statistical system or of a combination of different sources, which are linked to each other and share a common conceptual and methodological basis, or at least mechanisms to foster complementarities.

Although the surveys integration can improve data collection by using a single consistent sampling frame to gather data on several domains, field experience has revealed that sometimes the lists of target populations can be outdated or incomplete. The production of the related statistics would require alternative strategies to those based on the classic direct sampling methods. The proposed approach is a method that deals with cases of unknown or rare populations such as the *Indirect Sampling* with the application of the *Generalized Weight Share Method (GWSM)* developed by P. Lavallée.[3]

[2] Global Strategy, 2015. Integrated Survey framework.
- Current data. These are related to agricultural activities that are almost continuous and are repeated every year. Examples are crop area, yield and production of crops and livestock, production inputs, utilization of output, and prices. Usually, these data are collected through sample surveys on a continuous or seasonal basis, possibly several times in an agricultural year.
- Structural data. These reflect the structure of the country's agricultural economy, reporting elements such as the number of holdings, machinery, manpower, land cover and use. Since changes in this context generally do not occur very rapidly, this information need not necessarily to be compiled on a frequent basis; compilation every five or ten years is sufficient. These data are usually collected through agricultural censuses.

[3] Lavallée P. (2007), Indirect Sampling, Springer Series in Statistics, ISBN-10:0-387-70778-6

This method sets up a framework that relies mainly on the concept of relation among groups joined together by common characteristics which are identified by clusters and classified by the observational analysis subject to the study, such as economic activities, recipients of services, frequented places, recreational activities during certain periods of time and so forth.
Therefore, a statistical population can be considered as if it comprised sub-sets, which present common features and may knowingly or unknowingly have a cluster structure. Such groups are identified by the phenomenon being studied and are in relation with other statistical populations.

In practice, when a survey is conducted on a target population that is unknown or rare, the relation with the known population is not evident*,* therefore the path to tackle is to analyse the behavioural observation of statistical units between the target population (which may be rare or hard-to-reach) and another known population where the linkage between the two populations can be identified during the data collection phase. The observation defines the relation that comes out by submitting specific questionnaires. The relation, between the units of the two populations, can be either at individual level or at cluster level and is the essential component of the framework, which determines the number of links needed to calculate the weights of the target population units.

Operationally it means that, if two populations U^A and U^B are related to one another on the specific object of study and only the sampling frame of the population U^A is available, "it is possible to imagine the selection of a sample from U^A and produce an estimate for U^B using the existing links between the two populations. This is what we can refer to as *Indirect Sampling*" (P. Lavallée, 2007).
In due course, the *Generalized Weight Share Method (GWSM)* calculates the weight of each sampled unit of population U^B, using the numbers of its links with the population U^A and the weights of the sampled units of population U^A linked to it.

Furthermore, this method can be extended to develop an integrated survey framework, by observing two populations jointly who are in relation (P. Falorsi, 2014)[4]. The adoption of this framework may be the best solution when dealing with multipurpose surveys such as the following examples:

- sample surveys conducted on households, which do not only collect demographic data, they are also sources of information on the working status and economic well-being. Willing to analyze the contribution of women's work activities to agriculture, it would be interesting to use a households list which includes the entire female population (rural and urban), to extrapolate the second population related to the holdings which could include both female owners and female employers. Otherwise, the latter would have been automatically excluded if the initial list had been that of the holding. An integrated survey should jointly observe and analyze:
  1) the household sector to collect demographic data and,
  2) the holding sector, to collect data on the land tenure from which the female household members generate annual income.

  The relationship between the two sectors is defined by the various roles that women perform within the holding.

- livestock surveys, which provide significant contribution to national income as data is collected to estimate the yields of milk, eggs, meat, feeding as well as the related work-employed, and responding to environment mitigation purposes by gathering information on

[4] Global Strategy, 2014. Technical Report on ISF. Chapter 3. http://gsars.org/wp-content/uploads/2014/07/Technical_report_on-ISF-Final.pdf

management practices. Unfortunately, the surveys are usually conducted to provide data on food supply (milk, eggs, and meat) separately from specific information gathered on off-season and part-time employment for households and raw material for industries (wool, hides, skins, hair, bristles, etc.), thereby making costly and complex multipurpose surveys. Also in this case, a sample survey framework, that integrates the data collection on holdings and households starting from the holding list, should jointly observe and analyze the two statistical populations, to produce the related estimates.

In conclusion, when the traditional direct sampling strategy is not convenient due to cases of "hard-to-reach" [5] populations or budget constraints, the Indirect Sampling method can then be used because it deals with cases which present the following conditions:

1. No adequate sampling frame as it could be incomplete, obsolete or not available.
2. Possible use of a different frame, due to the relation with the units of target population.
3. A clustering tendency of the target population according to the phenomenon to be analysed.

The advantage of adopting the Indirect Sampling with GWSM is to reduce costs and implementation time, using statistical procedures through the existing and updated frames such as censuses or sample surveys, to estimate unbiased statistics of unknown populations intended as either rare populations or populations with obsolete lists. It is also possible to develop integrated surveys by observing jointly two populations that are in relation, thus improving the data quality based on harmonised statistical units, concept and definitions and classification.

This paper proposes the *Indirect Sampling* with the application of the *GWSM* on some cases in agriculture sector, describing the possible uses on unknown or obsolete lists of the target populations.

2. Indirect Sampling and GWSM applied to Agriculture

Developing countries present a strong preponderant agricultural traditional sector, considered also as subsistence agriculture and attributable to the agricultural households, so that most of the rural areas is employed in this sector. "It is for this reason that in most censuses and surveys, holdings in traditional sectors are identified through household using a list of households" [6], so that a correspondence is often assumed between the Households and traditional Agricultural Holdings [7], thus collecting data on traditional agricultural holdings is equivalent to collecting data on households. "*A farm household can be defined as a household in which any member has both an agricultural main activity and a status of "own account worker*"[8].

Although, the Guidelines for Linking Population and Housing Censuses with the Agricultural Censuses recommends and supports the coordination between the two censuses to be consistent with the reference lists, concepts and definitions, in practice many countries do not have appropriate resources in terms of budget, well-skilled technical personnel, good organizational systems to coordinate the activity of linking the two censuses, as well as keeping updated lists.

8 FAO. 2012. Guidelines Linking Population and Housing Censuses with Agricultural Censuses http://www.fao.org/docrep/015/i2680e/i2680e00.htm

In addition, the social-economic organization of the traditional agricultural systems, which is based on many relations between households and holdings, makes gathering data of small-scale farmers very difficult at this scattered and manifold level. In fact, the holdings or farm households are clustered to manage activities often carried out separately on crops, livestock and fisheries. The management structure is usually geared towards the three types of subsistence farm organizations: i) one household managing one holding, ii) one household managing more than one holding, iii) more than one household managing one holding[8].
In addition, a further organization is made up of many households, which cooperate for a common purpose in joint activities for many holdings.

In this regard, the indirect sampling, does not represent a cost-effective method only, is also a suitable approach to deal with the complex relations of the management structure based on the correspondence between household and traditional holding, worthwhile to conduct integrated socio-economic surveys by using the most updated list frames, either related to households population or holdings population. Furthermore, it is capable of obtaining most of information from heterogeneous groups of individuals at the same time instead of collecting few data from single individuals spread out in different locations, thus saving time and costs.

Figure 1 below shows the possible links that may exist between the households' population (U^A) and the holdings population (U^B), compared to the above-mentioned agricultural traditional system. In fact, the household members belonging to U^A are the individuals who participate in agricultural activities either directly by themselves or indirectly by their own relatives or workers. The holdings (clusters) belonging to U^B represent the households' economic organization.

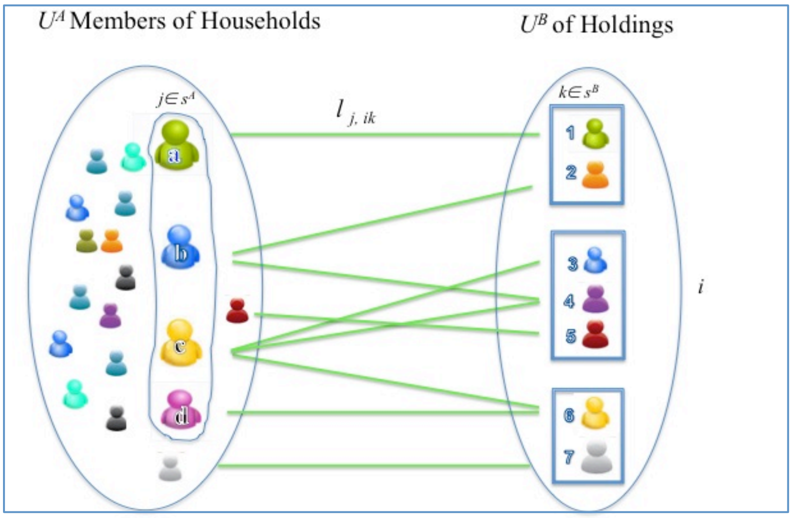

Figure 1: *The relationships between households and holdings*

The observation analysis of the relationships ($l_{j,ik}$) between each member j belonging to the U^A and each individual k of clusters i belonging to U^B, reveals the correspondences between the individuals of the two populations as well as the number of the total links.
This example, also, shows that the links can be one-to-one (case of j = a corresponding to k= 1), one-to-many (case of j = b corresponding to k= 2 and k = 4; or j= c to k= 3, 4 and 6), many-to-one (case of j = c and j=d to k= 6) and many-to-many (case of j = c and j=d to k=3,4,6).

The rectangles represent the holdings (or cluster i) of U^B. Each cluster i comprises the links and all individuals k taking part in agricultural activities, including those not in correspondence with the sampled household members $j\in s^A$ as the cases k=5 and k=7.

The links are identified between all j members of U^A and k individuals of each i cluster belonging to U^B, with $l_{j,ik} = 1$ if a link exists and with $l_{j,ik} = 0$ in other cases. Each cluster i must have at least one link[9] with one sampled individual j of U^A that is:

$$L_i^B = \sum_{k=1}^{M_i^B} \sum_{j=1}^{M^A} l_{j,ik} > 0$$

where M_i^B is the size of cluster $i \in U^B$,
M^A is the size of U^A.

Unearthing the links is an exploratory activity on the field to collect reliable information conformed to the survey's objectives, which require the submission of questionnaires as simply and appropriate as possible. A pilot survey and pre-tests could be very useful for analysing possible issues and eventually to work them out.
All individuals within the same cluster $i \in s^B$ (where s^B is the sample of clusters observed in U^B) must be interviewed in order to provide both the measure of the variable of interest y_{ik} and the number of the links $L_{ik}^B = \sum_{j=1}^{M^A} l_{j,ik}$ between ik individuals of U^B and j household members of U^A.

The final step of the framework building is the weighting procedure of the GWSM to associate the weights to each individual of U^B, by using the weights of the household sampling frame of each members $j\in s^A$.

The sections below are mainly focused on the procedure of computing the weights to produce the estimates of the target population (which may be rare) starting from a known population. It is also shown the process on how to observe two populations jointly.

2.1 Main steps of the method

The following steps describe the process to be carried out, assuming that the list of households' population U^A is available and that the holdings' population U^B is the target population.

1) Selection of the probability sample according to a certain sampling design that could be, for example, a traditional multistage Proportional to Size Stratified design of the household population and calculation of the inclusion probability for each individual to get:
   - Sample s^A that contains m^A individuals selected from U^A of size M^A.
   - Selection probability $\pi_j^A > 0$ of all sampled members $j\in s^A$.

2) Analysis and observation of the existing relationships (links) between populations U^A and U^B, to set up the clusters of the population U^B as follows:
   - Population U^B contains M^B individuals
   - U^B is broken down into N^B clusters, where cluster i contains M_i^B individuals.

[9] Lavallée P. (2007), Indirect Sampling, Springer Series in Statistics, ISBN-10:0-387-70778-6

The information on the correspondences and links between the *j* members of U^A and the *k* individuals of U^B is gathered by specific questionnaires based on the subject to be surveyed.

For instance, the questionnaires could identify the links by investigating the specific working role of the household members performed in the holdings such as holder, sub-holder, manager, worker, co-worker as well as enhancing further information about other individuals of the holding involved in the agricultural and rural activities. The questions should be submitted by a face-to-face method with a semi-fixed structure to make it possible to pose additional questions (probing) that may not be included in the original format. In this way, getting further information can facilitate the comprehension of the relations, and obtain the interviewer's collaboration, build a certain degree of confidence, verify that the response is appropriate, as well as assist the respondent if the question is difficult to understand. [10]

3) Assignment of a weight to each individual belonging to the holdings population U^B by applying the GWSM. This entails:

- computing the initial weight of each *k* individual of clusters $i \in s^B$ by the calculation of the weights of sampled *j* individuals of U^A

$$w'_{ik} = \sum_{j=1}^{M^A} \frac{t_j}{\pi_j^A} l_{j,ik}$$

where $t_j = 1$ if $j \in s^A$, and 0 otherwise,
$\pi_j^A > 0$ is the inclusion probability of individual $j \in s^A$

- calculating the total number of links for each *k* individuals of clusters $i \in s^B$

$$L_{ik}^B = \sum\nolimits_{j=1}^{M^A} l_{j,ik}$$

- computing the final weight w_i of each cluster $i \in U_i^B$

$$w_i = \frac{\sum_{k=1}^{M_i^B} w'_{ik}}{\sum_{k=1}^{M_i^B} L_{ik}^B}$$

where M_i^B is the size of cluster $i \in U^B$

- assigning $w_i = w_{ik}$ for all $k \in U_i^B$:

$$w_{ik} = \sum_{j=1}^{M^A} \frac{t_j}{\pi_j^A} \frac{L_{j,i}}{L_i^B},$$

where $L_{j,i} = \sum_{k=1}^{M_i^B} l_{j,ik}$
$L_i^B = \sum_{k=1}^{M_i^B} L_{ik}^B$ that is the total number of the links of cluster *i*.

[10] Global Strategy. 2015. "Guidelines of Integrated Surveys Framework" Chapter 3 part I, page 58.

4) Estimation of the total of the variable $\hat{Y}_B$ related to the holding population is calculated with the Horvitz-Thompson estimator using the weights computed by GWSM as follows:

$$\hat{Y}_B = \sum_{i=1}^{n^B} \sum_{k=1}^{M_i^B} w_{ik} y_{ik}$$

where n^B is the number of surveyed clusters and w_{ik} is the weight assigned to j individual belonging to i^{th} cluster.

The links may be defined at unit level or at cluster level. This is illustrated in figure 2 below where, in the case of unit level (the left hand side of the figure), the index j refers to a single individual. In this situation, the total number of links of cluster F1 is equal to 4. The case of links defined at cluster level is described on the right hand side of the figure where the index j refers to a household. The total number of links of cluster F1 is equal to 3.

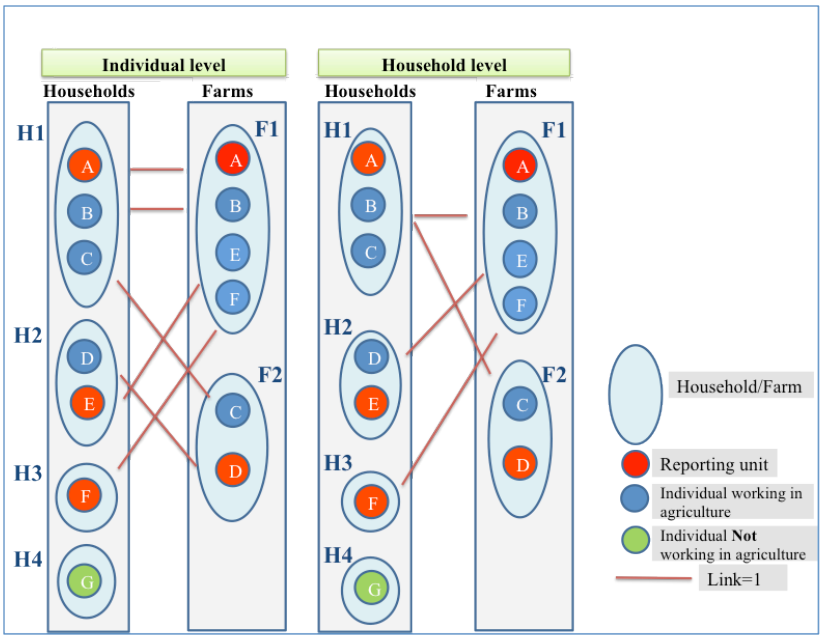

Figure 2: *Example of the links between individuals or between clusters*

2.2 Application to two populations jointly observed

There are cases where it is necessary to undertake surveys that require crossover analyses such as, for example, a study concerning the contribution of women's employment to agriculture in developing countries. In this case, the access to resources control must be gone through, collecting data on the land owned or managed by women in male-headed farms, to evaluate the use of the inputs (improved seeds, machinery, and fertilizers) and the availability of credit and financial services.

The joint observation of households and farmers can provide estimates of all inputs, by associating data at the household level on gender with data at the farm level on parcel/plot land tenure, and defining the links through the activity performed on the land as a female owner, manager or worker.

The scheme consists of a two-step procedure and depends on the available frame, such as:

- if the households list is available
  a. the households are observed in the first step and based on direct sampling,
  b. the farms are observed in the second step and based on indirect sampling.

- if the farms list is available
  a. the farms are observed, in the first step,
  b. the households are observed, in the second step.

The following example shows the case of having the availability of the households' list by selecting the sample with standard stratified multistage sampling design.

The sampling units are stratified according to geographical criteria, where the Enumeration Areas (EAs) of the Census are the Primary Sampling Units (PSU) and all households, belonging to sampled EAs, are observed as Secondary Sampling Units (SSU) with the respective inclusion probability.
In this regard, suppose that the households H1 and H3 were selected from two different EAs and hypothesize that the related inclusion probabilities were respectively equal to $\pi_{\mathrm{H1}} = 0.001$ and $\pi_{\mathrm{H3}} 0.02$ (it would mean that H1 has been selected from a set of 1000 units and H3 has been selected from a set of 50 units).[11]

At a later stage, in which the households are observed in the first step (the left hand side of figure 2), the links are defined with the support of two questionnaires to get the following result:

Step 1 The enumerator starts interviewing the first Household, the head of H1 to collect data on gender and gather information on the farm's links. It is clear that the Household is linked to Farms F1 (with two links) and F2 (with one link).

The second interview is submitted to the head of Household H3 to collect the data on gender and information on the farm's links with the same method adopted for Household H1.

Step 2 The enumerator interviews the agricultural holder of Farm F1 and collects the data on the parcel/plot tenure. Then, he gathers the information on the farm's total links which in this case are equal to 4, where

- the individuals A, B and F represent the links with the members of sampled households H1 and H3,
- the individual E which is linked to a member of H2, therefore it cannot be considered a link because H2 is not sampled.

[11] Global Strategy. 2015. ISF- Chapter 2.

The GWSM weight of farm F1 may then be computed as reported on figure 3:

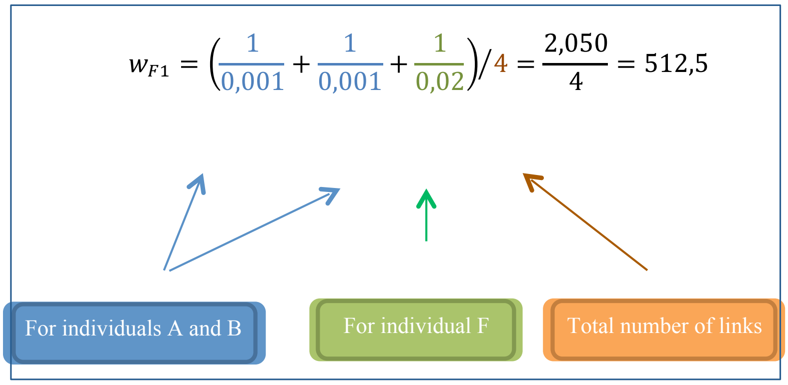

Figure 3: *Calculation of the final weight*

In the due course, the second interview is submitted to the agricultural holder of Farm F2 to collect data on the parcel/plot tenure and information on the farm's links, following the same procedure adopted for Farm F1.

Estimation

Let Y^A be the total of interest (e.g. the total number of women who perform agricultural activities in the country) referring to the population of the households, whose list is available; and let Y^B be the total of interest (e.g. the total land area in the country) referring to the population of the farms, observed indirectly.

Let s^A be the sample of observed households and s^B the sample of observed farms.

The sample estimate $\hat{Y}^A$ of the total Y^A is obtained by:

$$\hat{Y}^A = \sum_{j=1}^{s^A} y_j \, w_j$$

where y_j is the value of the variable of interest of the individual j (e.g. $y_j = 1$ if the women j within the household performs agricultural activities) and w_j is the sample design weight.

Likewise, the sample estimate $\hat{Y}^B$ of the total Y^B is simply obtained by assigning to each farm i observed in s^B a weight w_i obtained with the weight share method (see section 2.1):

$$\hat{Y}^B = \sum_{i=1}^{s^B} y_i \, w_i$$

where y_i is the value of the variable of interest (e.g. the total parcel/plot land tenure in the farm) of the farm i and w_i is the weight calculated by GWSM.

3. Case studies

The cases described below have been taken from the recent research program of the Global Strategy to Improve Agriculture and Rural Statistics (www.gsars.org.) which deals with methodologies to collect data in order to make them comparable cross over the countries, respecting the international quality standards as well as to facilitate the development of cost effective methods.

The reported examples refer to some studies to apply the indirect sampling with GWSM taken from the "Guidelines of Integrated Survey Framework" and the "Guidelines on the Enumeration of Nomadic and Semi-Nomadic Livestock" to simulate the practical use on how to build a logical framework, based on articulated questionnaire[12], as well as the running of weights calculation. They can represent some opportunities to develop integrated surveys and improve initiatives on the field to adapt this method as needed.

The following sections describe three proposals of this approach for the use in agriculture sector in:

- estimating statistics on holdings starting from a household frame,
- updating of the units weights in case of change in the statistical units,
- producing estimates for the Nomadic and Semi-Nomadic Livestock.

Detailed information on these subjects is available on the web site of the Global Strategy.

3.1 Estimating statistics on holdings starting from a household frame

An interesting application is the case carried out by Burkina Faso to conduct a national study to collect information on agriculture sites where several farmers work individually or in groups for the production of rice, corn, vegetables etc. Specifically, this study should produce estimates on the area harvested, crops production, number of farmers and farmers' incomes working in these sites. In particular, irrigated crop production is practiced mainly on a number of sites, developed by the State's funds as well as by Non Governmental Organizations (NGOs) and other private projects.

The economic-social structure is organized to provide each farm's individual with the sites and the parcels, however the limited number of developed sites does not allow several producers to obtain a parcel for irrigated production on a developed site. Thus, for many households, their links to irrigated sites are limited to the work of some of their members as permanent or temporary employees on these sites and members of the same household can work on different farms. At the same time, the head of a site's management unit is aware of the number of farmers on the site, but not of the number of households whose members work there. Therefore, for the objective of this survey it would be necessary to include all these employees in order to cover a larger number of sites.

Moreover, Burkina Faso conducts permanent annual agricultural surveys based on the "Recensement General de l'Agriculture" (RGA) sampling frame and as the purpose of the matter, here described, refers to the farm household, intended as farm household of traditional agricultural systems, the known population is represented by the available household sample frame selected from the RGA frame and used in other surveys. This sample appears to suit to our study also for the following two reasons:

[12] Global Strategy. 2015. ISF- Chapter 3. Modules and operational rules for observing farms starting from households http://gsars.org/wp-content/uploads/2015/05/ISF-Guidelines_12_05_2015-WEB.pdf

- Such a sample will enable the subsequent availability of more information to analyze the data, because the survey will be linked to other ongoing surveys,
- It also has the advantage of working with a more up-to-date sample, reflecting the changes arising in the statistical units since the sampling frame was created.

Hence, this case is featured by the initial requirements of the indirect sampling method, within the following conditions:

- The farm workers at work sites represent the unknown population.
- The farm household members frame is available to create the links framework.
- Each work site is a cluster of the unknown population.

The following steps describe the application of the above-mentioned approach.

1) Selection of the farm household members sample by a certain design sampling.
2) Analysis and observation of the relationships between the farm household members and farm workers at work sites, defining *a household linked to an irrigated production site if at least one of its members works on this site as a farmer or employee.*

   The links between the household members and the farm workers are built with the two steps procedure using respectively two questionnaires and interviewing:

   Step 1 Each household member, for collecting a great deal of possible reliable information to identify the location of the sites, its total number as well as the working status of the household member as farm owner or employee.

Household Code:	Economically Active Member code:……….
Are you a farmer on an irrigated site?	
If yes, list the sites concerned:	
• Name of Site 1..............................	
• Name of Site 2..............................	
Did you work as an employee on an irrigated site last year?	
If yes, list the sites concerned:	
• Name of Site 1..............................	
• Name of Site 2..............................	

Table 1: *Questionnaire to observe households and farm sites links*

Once the questionnaires are filled in, the enumerator should complete the list of sites linked to the household, and summarize which sites are linked to the household member. A unique code (such as geo-referential coordinates) is also assigned to each site that is linked to the respondent household member.

	Site Name	Member Respondent Code	Site Code
1.	....	....	....
2.	....	....	....

Table 2: *Summary table on links information from households*

Step 2 Each worker at work sites, for gathering information on farmers and employees, which should incorporate the same site code of the households' questionnaires submitted for the preliminary identification of the links.

Site Name:		
Site Code:		
Name of the Respondent on the Site:		
Questions to the Respondent	• In total, how many farmers are working on this site?	
	• Can you provide an estimate of the total number of employees working on the site?	

Table 3: *Questionnaire carried out on the sites*

The result of the above mentioned questionnaires is shown in the framework on figure 4, where the links $l_{j,ik}$ are drawn up between all farm household members belonging to M^A and those individuals k working in each i site belonging to M_i^B (size of each cluster). The inclusion probabilities π_j^A, of each household member $j \in s^A$, compute the initial weights of each individual $ik \in M_i^B$.

Moreover, throughout the survey, data collected in each site i have also furthered the list of the individuals to be surveyed, increasing significantly the initial information obtained from the farm household members.

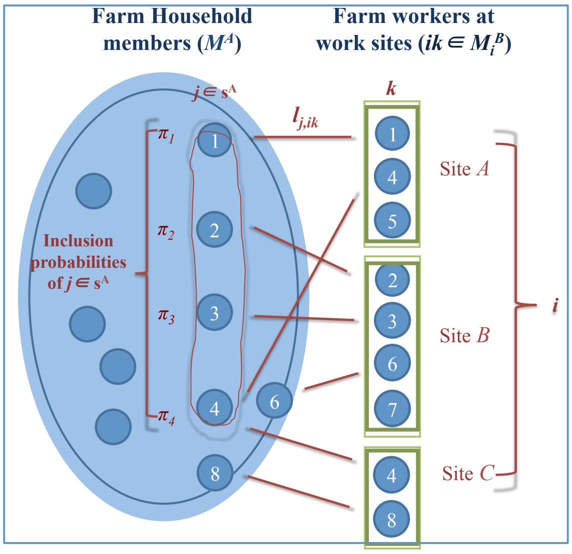

Figure 4: *Correspondences between Farm Household members and Farm workers*

3) Assignment of a weight to each farmer site by applying the GWSM as follows:

- Computing the initial weight w'_{ik} of k individuals in each i site. It is calculated[13] by summing the weights $\frac{1}{\pi_j^A}$ of farm household members $j \in M^A$ linked to each ik, with $t_j = 1$ if $j \in s^A$ (cases 1, 2, 3 and 4) and 0 otherwise (cases 6 and 8). An initial weight zero is assigned to all individuals not having a link (cases 5 and 7).

3.2 Updating of the units weights in case of change in the statistical units

This case, extracted from a more extensive discussion in the "Guidelines of Integrated Survey Framework"[14] (ISF), deals with the changes of the statistical units of surveys based on a panel agricultural holdings, mainly caused by disappearance, fusion, division and population change. This phenomenon may undergo significant modifications from one year to another, due to endogenous or exogenous events. Some solutions are presented in the ISF Guidelines[15], and among these the indirect sampling with the GWSM has been proposed as an alternative solution to handle the lists updating. The practice here reported refers to the *Changes in households* with the weight calculation**.**

In several countries and in the case of most developing countries, statistical surveys use households as statistical units, and the data are collected at the household level.

Although the current solutions are usually sufficient to solve problems related to changes in the composition of households, for cross-sectional estimates in a given year, the system may be interested in the activities, pursued by individual household members, which are relevant to agricultural statistics. In this case, each member becomes a statistical unit, and the weight of a member corresponds to his household weight; indeed, usually all members of a sampled

[14] Global Strategy. 2015. Guidelines of Integrated Survey Framework. http://gsars.org/wp-content/uploads/2015/05/ISF-Guidelines_12_05_2015-WEB.pdf

[15] Alternative methods of calculating the weights are available in the literature. Basically, there are weight-sharing methods, which use the weight of the households of the first wave of the panel (Brick and Kalton, 1994; Schonlau et al. 2013; Lavallée, 2007), and methods based on a model of household inclusion probabilities (Schonlau et al. 2013).

household are taken into account in the survey, and each year, data on all individual members of the household panel must be collected for cross-sectional estimates.

In each Wave of the panel, all households with at least one of these individuals as a member shall be taken into account. For this type of system, changes in statistical units can lead to situations in which it is difficult or impossible to calculate the weights of certain units by the conventional approach because, for example, several members of different households may combine to form a new household, which includes members of other non-sampled households. The weights of all the members of the new household become difficult to estimate.

Also in case of change in the statistical units, the Indirect Sampling with GWSM concerns all households of which at least one member was a member of a household sampled during the first Wave of the panel. Some target households may have members who were in the original sample panel, and other members who were not. Weight-sharing methods enable estimation of the weights of the individuals who were within the original sample.

In fact, the current new structure presents the following conditions:

i) the unknown weights of the household members of Wave 2,
ii) the availability of Wave 1 list to be linked to Wave 2,
iii) the members of Wave 2 are clustered by the new households structure.

As reported in the methodological observation section, the links between the two Waves are built with the support of questionnaires to collect information, by interviewing:

Step 1 Households of Wave 1, to make sure that all cluster Wave 1 Households are linked to the new structure of Wave 2 Households.

Household Code:		
Full name of head of household:		
How many members left your household between last year and this year?.........		
Among these members, how many have joined other households?		
Can you name these members and households they joined?		
Member Code	The new Household Code	Name of the head of the new household
....	....	....
....	....	....

Table 8: *Questionnaire to observe the links of Wave 1 Households*

Step 2 Households of Wave 2, to identify the total number of links with households Wave 1, that can be performed at Individual or Cluster level. In case of Wave 2 Household A (figure 4), the total number of the links is 1 because only individual A1 belongs to Wave 1, while individual E is a new entry.
An example of the questions to be posed at individual or household (cluster) level approach can be adopted as Table 9 shows below.

Type of links	Questions
Household level	1. Are there members of your household that belonged to other households last year? (Yes/No) ....

	2. In how many households did these members live? ....
Individual level	1. How many members of your household belonged to other households last year? ....

Table 9: *Questionnaire to identify the links of the two Household Waves*

The observation reveled some changes of the population panel structure between Year 1 and Year 2, Wave 1 turned into Wave 2, as figure 5 shows below:

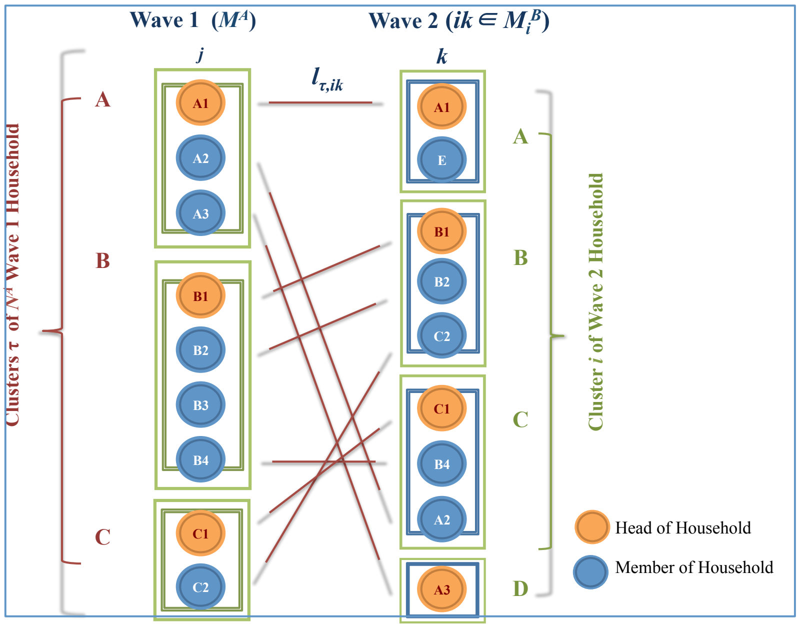

Figure 5: *Framework of changes in the composition of households*

At a later stage, the weighting procedure entails the following steps:

- Estimation of the weights $\frac{1}{\pi_\tau^A}$, for each Wave 1 of N^A cluster τ belonging to M^A, is the inverse of the inclusion probabilities π_τ^A, as Table 10 shows.

Wave 1		
Household (τ *clusters* N^A)	Household Members (*j*)	$\frac{1}{\pi_\tau^A}$

3.3 Application of Indirect sampling and GWSM to produce estimates for the Nomadic and Semi-Nomadic Livestock

The nomadic and transhumant livestock[16] enumeration is an important component of the estimate of the total national number of breeding animals, especially for those countries affected by this phenomenon. However, the difficulty and even sometimes the impossibility to collect data through the agricultural census, because of the herders' seasonal or random movements, intra country and across the countries, make the implementation of this activity considerably burdensome both on operational and budgetary aspects.

Among several approaches to data collection, those that are related to the sample surveys on ground, usually collect the information on herds by a questionnaire. It is submitted to the herders when they bring the herds to the Enumeration Points (EPs) or drinking points during the survey year (Lakes, Rivers, Ponds, Wells, Boreholes, etc.)[17]. Although, the EPs are essential sources to collect data, most of them are difficult to access so that the available lists are not often

[16] Global Strategy. 2016. Guidelines on the Enumeration of Nomadic and Semi-Nomadic Livestock, definitions of:

a. Transhumant livestock/pastoralists as not permanently settled; movements characterised by regular, cyclical, short distance movements; livelihoods depend largely on livestock
b. Nomadic livestock/pastoralists as not permanently settled; movements characterised by irregular, erratic, long distance movements; livelihoods depend almost entirely on livestock.

[17] Global Strategy. 2016. Guidelines on the Enumeration of Nomadic and Semi-Nomadic (Transhumant) Livestock. "The identification and definition of enumeration points must be made in a participatory way with all stakeholders: government, local authorities, herders' organizations, and civil society. It is also important to note that the transhumant livestock and nomadic livestock do not always have the same enumeration points. For example in Niger, the enumeration points identified were stock routes for nomadic livestock and water points for transhumant livestock".

completely exhaustive to cover the enumeration list for the entire geographical zone, thus creating many issues in obtaining the needed information.

Also this case could be dealt with the "hard-to-reach" population methods by applying the Indirect Sampling and GWSM to carry out a sample survey on ground. The purpose is to estimate the total number of herds concerning nomadic and transhumant livestock at sub-national level (province), by increasing the initial list of EPs to develop a wider exploratory inquiry on the field. This case is featured by the following conditions:

- The nomadic and transhumant herds are the unknown or rare population, which is in relation with a known population of EPs, where animals gather and are given water, so that it is possible to create a link between the two populations.
- The initial sampling frame of a known population could be made available by selecting a two-stage sampling design at sub national level:
    - the Primary Sampling Units (PSU) as the Enumeration Areas (EAs) of the census (however, it is also possible to select counties, villages or other relatively small geographical areas). The PSUs can be selected either with probabilities proportional to their sizes (which could be the number of EPs in each EA) or equal probabilities.
    - the Secondary Sampling Units (SSU), that correspond to the EPs, are selected for each PSU with equal probabilities in each stratum.
- The herds (the unknown population) can be considered as clusters which group the EPs selected by herder, who gets used to taking the animals to drink.

The observational approach is described by analysing the links between the initial sampled EPs and the real EPs frequented by the herds through the information received by the herders, defining "*a herd as linked to an enumeration point if it frequents that enumeration point at least one time during a period of time (generally a year or several months in a year)*".[18]

Table 12 below proposes a kind of the questionnaire that could be submitted to three hypothetical herders who are responsible respectively for the herds A, B and C. The interview should take place at one of the sampled EPs and should also be widened as much as possible on eventual insights to better gather all needed information that helps in drawing up the framework of the links.

Questions [19]	**Answers**
Q1: How many EPs will you likely frequent with your herd this year?	*A1.* Three EPs by Herd A. *A1.* Four EPs by Herd B. *A1.* One EP by Herd C.
Q2: What are they? (Checking if the declared EP are present in the sample or are additional)	*A2.*Three sampled EPs (1, 2 and 3) are frequented by Herd A. *A2.*Two sampled EPs (1 and 2) are frequented and two not sampled (6 and 7) by Herd B. *A2.* One sampled EP (2) is frequented by Herd C.
Q3: Do you happen to meet other herds in the EPs that you frequent?	*A3.*No
Q4: If yes, how often? And which ones	n.a.

[18] Global Strategy. 2016. Guidelines on the Enumeration of Nomadic and Semi-Nomadic (Transhumant) Livestock.
[19] In case the enumeration points are stratified, these questions must be asked for each stratum.

Table 12: *Example of a questionnaire to build the links*

Figure 6 shows the framework, resulting from the above-mentioned questionnaire submitted to the three herders in the three different EPs, with the correspondences between the EPs frequented by Herd A, B and C and the sampled EPs during the period of the survey. The inclusion probabilities π_j^A of the sampled EPs (1, 2 and 3) belonging to the population M^A are calculated by the sampling design and are used to estimate the weights $\frac{1}{\pi_j^A}$ of each EPs frequented by the Herds.

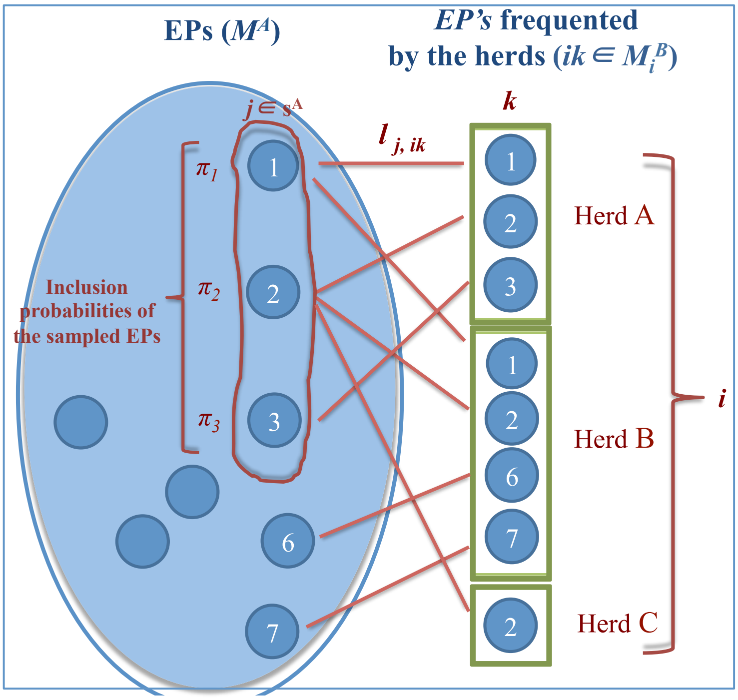

Figure 6: *Correspondences of the EPs and those frequented by Herds*

The following steps describe the application of the weighting procedure with GWSM:

- Computing the initial[20] weight w'_{ik} of the EPs clustered by each Herd. It is the sum of the weights $\frac{1}{\pi_j^A}$ of all the EPs of M^A linked to those frequented by ik Herds, with $t_j = 1$ if $j \in s^A$, and 0 otherwise.

i	k	$w'_{ik} = \sum_{j=1}^{M^A} \frac{t_j}{\pi_j^A} l_{j,ik}$
A	1	45
	2	28
	3	55
B	1	45
	2	28
	6	0
	7	0
C	2	28

[20] These figures have been made up to run the simulation.

Table 13: *Initial weight estimation of EPs frequented by Herds*

- Calculation of the total number of links for each Herd cluster *i* (quantity L_i^B), by summing for each Herd *i* all links between all EPs (M^A), both sampled and not sampled ones (quantity L_{ik}^B), and EPs clustered by the *ik* Herds belonging to M_i^B (size of the each cluster *i*).

i	k	$w'_{ik} = \sum_{j=1}^{M^A} \frac{t_j}{\pi_j^A} l_{j,ik}$	$L_{ik}^B = \sum_{j=1}^{M^A} l_{j,ik}$	$L_i^B = \sum_{k=1}^{M_i^B} L_{ik}^B$
A	1	45	1	3
	2	28	1	
	3	55	1

4. Conclusions

Developing countries have a particularly strong need to produce statistical data, develop their planning activities and measure the effectiveness of public interventions, especially in vulnerable areas. However, these countries do not always possess the resources required to build exhaustive surveys that can provide reliable estimates at national level.

Furthermore the rural sector is an especially vast and complex sector, where it is not possible to collect all data on the sector during a general agricultural census. For this reason, usually only information on their links with farms is collected. However, data for each of these structures are not collected, although this information is relevant to national statistical program and policy makers.

This is also true for some information that is indirectly related to agriculture, such as its links with the sectors of education, health and infrastructure.

Indirect sampling and the application of GWSM could help to obtain reliable data on the areas mentioned above. For each of these countries, it is necessary to diagnose information needs and existing data collections, and to analyse the possibility of using indirect sampling for integrated surveys in the rural sector while maintaining costs at a sustainable level.

These methods are very useful tools to enable the collection of information using alternative and cost-effective methods that facilitate the data gathering in case of difficulties to get information about rare and unknown populations using statistical procedures.

This paper has presented some examples applied in the agricultural sector that should be deepened and tested on the field at local level in order to meet national needs and eventually develop experiences to strengthen the statistical capacity building of the countries.

THEMATIC SET

F36

MASTER SAMPLE FRAME FOR AGRICULTURAL SURVEYS

Session Organizer
R. Benedetti | Universita degli Studi G. d'Annunzio | Chieti - Pescara | Italy
J. Gallego | EC JRC, Econometrics and Applied Statistic | ISPRA | Italy

ABSTRACT

One of the major tools for improving the cost efficiency of agricultural statistics is building a sampling frame that can be used for many types of agricultural and rural surveys, ideally all of them. The traditional fields of agricultural and rural statistics including production estimation, economic analysis and social issues are being more and more enlarged with the growing environmental concerns that pose new challenges to building flexible Master Sampling Frames.
Papers submitted to the session may present:

- Practical cases of master sampling frames that have been built or are being designed for a particular country or region.
- An overview of the topic
- Methodological analysis of specific problems that appear when building a master sampling frame.

A non-exhaustive list of aspects and problems that papers of the session can tackle is:

- Combining several sampling frames
- Use of technological tools to build a (master) sampling frame
- Challenges and solutions on the integration of different concerns of agricultural and rural statistics, including production, environmental and social aspects.

DEVELOPMENT OF MULTIPLE SAMPLING FRAMES FOR AGRICULTURAL SURVEYS IN KENYA

CROSS-THEMATIC SET F: Data sources / Data collection / Use of IT tools / Data quality

THEME TITTLE: Master sample frame for agricultural surveys

DOI: 10.1481/icasVII.2016.f36

ABSTRACT

Agriculture is the mainstay of the Kenyan economy contributing about a quarter of the Gross Domestic Product. The country covers an area of 591,971 square kilometers. Eighty per cent of the land area is arid or semi arid and largely suitable for pastoralist activities. The balance is used for crop production and livestock keeping by the sedentary population. Despite the central role played by the sector in the economy, the quantity and quality of agricultural statistics in Kenya has worsened over time due to a myriad of factors. To address these challenges, the Kenya National Bureau of Statistics (KNBS) in conjunction with stakeholders in the Agricultural Sector and with support from the World Bank is in the process of developing a multiple sampling frame, a precursor to a comprehensive survey programme to address the identified data gaps. The multiple sampling plans will entail the construction of an area frame for collecting smallholder agricultural data and a list frame for collecting data from commercial farms. This approach is motivated by the fact that the smallholder farmers are very many and with small parcels of land while commercial farms are few and hence can be completely enumerated.

The above sampling strategy envisages a survey plan where agricultural input and output data is collected on a seasonal basis to obtain annual agricultural statistics using the area frame. An annual census of commercial farms and green houses will complement data from the smallholder farmers so as to obtain the overall picture of the performance of the agricultural sector on an annual basis. This approach which is taking place in Kenya for the first time is using a collaborative approach which involves the national statistics office as the lead agency, the Ministry of Agriculture, livestock and fisheries and various Non Governmental organizations pooling their expertise and resources together to generate the required infrastructure. This approach is preferred due to the positive aspects of institutional ownership, cost saving and the high quality of the resultant agriculture statistics that will be produced.   This paper outlines the processes and sampling plans that will be undertaken to ensure that the quality of Agriculture statistics is of high quality. The International Conference on Agricultural Statistics (ICAS VII) forum is very timely as it will provide an excellent forum for validating and/or critiquing the entire process that Kenya is taking to address the quality of its Agriculture Statistics whose quality has been declining over time.

Key words: sampling frame, seasonal surveys,

INTRODUCTION

Agriculture is the mainstay of the Kenyan economy contributing about a quarter of the Gross Domestic Product (GoK, 2016). The country covers an area of 591,971 square kilometers. Eighty per cent of the land area is arid or semi-arid and largely suitable for pastoralist activities. The balance is used for crop production and livestock keeping by the sedentary population.

Despite the central role played by the sector in the economy, the quantity and quality of agricultural statistics in Kenya has worsened over time due to a myriad of factors. To address these challenges, the Kenya National Bureau of Statistics (KNBS) in conjunction with stakeholders in the Agricultural Sector and with support from the World Bank is in the process of developing a multiple sampling frame, a precursor to a comprehensive survey programme to address the identified data gaps.

The multiple sampling plans will entail the construction of an area frame for collecting smallholder agricultural data, a list frame for collecting data from commercial farms and deployment of aerial surveillance methodology for pastoral areas. This approach is motivated by the fact that the smallholder farmers are very many and with small parcels of land while commercial farms are few and hence can be completely enumerated. A census of commercial farms and greenhouses is currently being undertaken countrywide.

METHODOLOGY

The Kenya Seasonal Agricultural Survey (SAS) is intended to inform policy decision and international reporting requirements. The approach adopted in this survey is based on a similar approach learnt from Rwanda (NISR, 2014). Compared to Rwanda, Kenya occupies a much larger geographical area and has a much higher smallholder farmer population. This therefore makes it even more critical to develop as area frame to facilitate periodic smallholder agricultural data collection. It is expected that data collected will be sufficient to generate county level estimates so as to support the data needs at that level. The survey will be conducted twice a year to cover both the long and short rain seasons. The pilot survey is expected to take off in April 2017 and then the main survey in October 2017 to coincide with the short rains season. This section outlines the methodology that will be used to develop the Area Frame and conduct the first round of the Seasonal Agricultural Survey (GoK 2015).

STRATIFICATION

Base Map Layer

The 2010 Land Use Land Cover (LULC) layer from KFS (Kenya Forest Service) will be used as a base layer and updated to come up with a current stratified layer of 2015. This layer was derived from ALOS (Advanced Land Observation Satellite) images which have a 10 Meters resolution. The said images did not have much cloud cover and where there were clouds DMC (Digital Monitoring

Constellation) 22Meters and LANDSATS 30 Meters images were used as a substitute. Higher resolution images will be used in the updating of the 2010.

Stratification
Definition of Strata

1. Built Up Area (Any artificial hard surface that is manmade)
2. Forest (Areas that have trees or shrub land)
3. Uncultivated Wetland (Areas that have water more than six months in a year but do not have any croplands)
4. Waterbody (Areas having water)
5. Bare Areas (Rock outcrops, Bare soil with no definite pattern)
6. Cropland (Areas where crops are planted and cultivated)
   - Small scale/Intensive agriculture below 20 ha
   - Large scale agriculture 20 ha and above
7. Pasture land (Areas used for animal forage)
   - Leys (Having clear fenced areas, regular shaped, established pastures)
   - Natural Grassland (Continuous fenced grassland areas)
8. Grassland (Areas covered with grass that are neither rangeland nor pasture)
9. Rangeland (Free range grassland and/or shrub land in Parks, reserves, conservancies, ranches)

The 2010 base layer covers the whole country with the classes being; Forestland, Cropland, Settlement, Wetland, Grassland and Other land. Assessment of the same led to the decision on subdividing the LULC to different Strata in a three level step: Primary, Secondary and Tertiary which will cover the whole country. Secondary strata will be a subdivision of the Primary strata while Tertiary strata are a further subdivision of the Secondary strata.

Imagery

Images (High Resolution Images, Aerial photographs and Google Earth) License - High Resolution Satellite Images. The high resolution satellite images will be procured by purchasing a license which would give access to parties involved to the full archive of images from 2002 to date. This purchase of the license will be cheaper than purchase of the images. The DRSRS (Directorate of Resource Surveys and Remote Sensing) is expected to provide Aerial Images of the same resolution as the satellite images in order to compliment the satellite images in the high potential agricultural areas. Google Earth images will not be used since we are having high resolution images already. If used the challenge would be reduced efficiency. The images in Google Earth are a mosaic of images from different years hence a reduction in accuracy. Shifts in the google Earth image products would have errors trickle down to the final Strata if used. Lastly, their use in fieldwork leads to an error of 10 meters due to registration. Based on the comparisons above, commercial software will be used in the stratification process, PSU as well as SSU creation. It should be noted that the organizations represented in this the Technical Working Group already have licenses hence no additional costs will be incurred in the use of the commercial software. However, open source such as QGIS may be utilized in field map production.

Ground Truthing Strata

Ground truthing exercise is guided by the need for clarification. Since the initial interpretation and automatic classification will be based on Satellites imageries, this requires validation using ground sample points. During the stratification process areas that are difficult to interpret or having conflicting categorization by the TWG are noted down. These areas will form a basis for verification. The sample points generated will not only clarify the areas but also act as points of assessing the accuracy of the Stratification process. The ground sample points will be uploaded to the tablets for use in the field. The sample points will be required to be in the same reference datum as satellite imageries for the purpose of compatibility. As indicated in the Table 1 above. During this process clarification will be on the tertiary level of stratification since that is the basis of the entire sampling frame. The task above will be undertaken by RS/GIS specialists from the organizations involved (RCMRD, KFS, DRSRS, NEMA, KALRO among others). Drivers will be sourced from the institutions mentioned above. Security personnel will be hired on a need basis. For the ground truthing exercise to be undertaken, Mobile Mapper Licenses will be purchased and installed in the Tablets. The use of the mobile mapper stems from the fact that GPS would capture data as is while the mobile mapper will enable taking of coordinates and the ability to transfer the data to the server with the aid of good internet connectivity. The use of tablets will do away with cameras, GPS and batteries reducing the cost. The same tablets used in ground truthing the strata will be used during data collection. The full list of items required during ground truthing is indicated in the budget. Field sample points used in ground truthing will be based on first draft strata. Sample points will be randomly generated to verify the accuracy of the stratification. The duration of the ground truthing exercise for the whole country will take approximately 12days comprising of 10 teams.

PRIMARY SAMPLING UNITS

Shapefiles (Administrative Units, Rivers, Roads, Rail)

The primary sampling units will be required in a digital GIS format i.e. a shapefile. These are vector data sets that will be overlaid with the images for the purpose of analysis. The Kenya National Bureau will provide boundary data at National, County, Sub county, Locational and sub- locational levels. Kenya Agricultural and Livestock Research Organization (KALRO) will provide the Agro-Ecological Zones (AEZ). The above shapefiles will assist in locating both the administrative units and the Agro-Ecological Zones of various crop in the sampled holdings

Creation of PSUs

Primary Sampling Unit refers to the sampling units in the first stage of selection in a multistage sampling process. The output stratified layer in the previous process will form the base layer. Once the natural boundaries have been identified and extracted, the later will be used in the subdivision of the strata to form the PSUs. The PSUs will be developed by strata and a sample of the PSUs obtained through Probability Proportional to Size (PPS) sampling method. These PSUs will be subjected to an area rule whereby the PSU segments will be divided into blocks of 200 to 400 hectares. The sample size will be such that the estimates will be representative at the county level.

SECONDARY SAMPLING UNITS (SSUs)

Creation of SSUs

Secondary Sampling Unit refers to the sampling units in the second stage of selection in a multistage sampling process. The PSUs generated in the previous process will be used in the creation of the SSUs. These PSUs will be subjected to an area rule whereby the PSU segments will be divided into blocks of 10 hectares which are herein referred to as SSUs. Sampling of the SSUs will be based on systematic sampling method. The SSUs will have unique identifiers in the attribute table. The ID will be used in the selection of the samples.

ENUMERATION SURVEY

Map Production

To improve on the stratification accuracy, field maps will be produced for use through RS/GIS approaches. The maps will be used in validation of the stratification products. For every sampled segment, a segment image map will be produced to aid the enumerators in collecting data. A suitable size and scale of the map will be determined and cartographic visualization applied. The number of maps produced will be dependent on the coverage of the segment and crop calendar (seasons).

Ground-truthing

Field verification will be carried out for the selected SSU. The selected SSUs will have IDs identifying their boundaries. During field verification, the selected SSUs will be identified using landmark features such as boreholes, hospitals, schools, rivers or roads as indicated in the field maps.

The following steps will be adopted for undertaking ground-truthing:-

Preparation of field questionnaires (check-list)

The TWG will determine which thematic areas before developing the questionnaires. These questionnaires will be in digital format to enable real-time transmission to the server. Hard copy questionnaires will be used as back up.

All land parcels in the SSU will be measured using tablets. This will be done by tracking of all the plots in the segment.

Data Collection

The team will be expected to collect various types of data to enable them enrich the initial available auxiliary data. Standard procedures will be adopted as follows:-

- Mobilization of a team of experts - The TWG will ensure that a team of experts are in place before the exercise takes off
- Formulation of a check-list - The check-list will ensure that data gaps are eliminated. This will minimize errors
- Mobilization of survey tools and equipment - Acquisition of tablets, vehicles, maps and items mentioned in the budget
- Publicity - The survey exercise has to be publicized before commissioning. This will enable smooth operation at the community level
- Fieldwork - The experts will be dispatched to different regions within the country based on the classes which will require validation.

Data cleaning, Analysis and Storage

Data from the field will be downloaded from the servers at the KNBS. Data from the server will be cleaned and weighted. Thereafter statistical tables will be generated for both seasons. SPSS software will be used in processing the statistical tables. After the analysis and production of the indicators, the output will be linked to their exact location using the unique ID on a GIS platform. The unique ID will be used to link the non-spatial and spatial data to complete the attributes in the spatial files. A Geo-data base will be designed to facilitate the linking and storage of the files. In the geo-database, access protocols are to be defined to allow access, editing and dissemination.

Awareness/publicity

To ensure maximum cooperation and participation from the citizens, publicity of the survey will be done using fliers, print, electronic media, barazas and other suitable channels. To enhance awareness creation and survey publicity, a team will be created comprising of KNBS and MOALF knowledgeable of the subject matter to steer the campaign through sensitization to the chiefs, village elders, sub chiefs and opinion leaders.

Training (TOT, Supervisors and RAs)

Two levels of training will be undertaken for the Pilot and the Main survey. These are:
Training of Trainers (ToT)
Training of supervisors and research assistants
The TWG will mount training of the TOTs who will then train the supervisors and the research assistants. The training will focus on:

- Mapping, ground truthing
- Use of tablets, mobile mapper
- SAS Questionnaire administration

Report Writing and Publication

The following reports will be prepared.

- Pilot / Pretest Report
- The Seasonal Agricultural Survey (SAS) and other Publications

The experiences and lessons learnt from the pilot report will be used to fine tune both the various survey instruments in the main survey as well as the mode of operation. The survey results and indicators will be published and disseminated to the stakeholders.

Dissemination

Dissemination of the results of SAS is important because it provides information for decision making to users such as policy makers, researchers and the general population among others. Some modes of dissemination include:

- Hold a workshop to release the results
- Highlight in the electronic and print media
- Upload in websites
- Distribute hard copies

ABSTRACT

This paper reviews experience of Georgia in building the master sample frame for agricultural and rural statistics. In November 2014 the National Statistics Office of Georgia (Geostat) conducted Agricultural Census together with General Population Census. In particular, census contained the following questionnaires: Questionnaire on Dwelling, Personal Questionnaire, Questionnaire on Emigrants and Questionnaire on Agriculture. Additionally, census identified the holdings that operate aquaculture and greenhouses. The data derived from the census is used for constructing master sample frame.

Census was conducted using the GIS maps, thus, all the data derived from the census will be linked to the GIS data. Geostat also conducted Agricultural Census for legal entities in order to fulfill the agricultural census data (including common land data). This paper describes design process of the questionnaires used in census as a tool for identifying the frame units of different surveys and the main variables subject to be obtained.

As a result, the Master Sample Frame attained from the census is very comprehensive and can be used for many different surveys as it was derived from the integration of population and agricultural censuses. The paper presents benefits of conducting agricultural and population censuses together in building the master sample frame.

The paper will also describe the core set of variables which will be derived from the census and it will provide examples of new surveys which can be conducted using the master sample frame.

Keywords: Master sample frame, census, agricultural statistics, sample survey

1. Introduction

Statistical system in Georgia is centralized. The Law of Georgia on Official Statistics creates a general framework for statistical system in the country and sets coordination principles for all institutions responsible for producing official statistics in Georgia. According to the law, production and dissemination of statistics shall be based on the 10 basic UN principles of official statistics. Geostat is a coordinating body of Georgia's statistical system and the only producer of official agricultural statistics in the country[1]. Geostat is the agency responsible for conducting censuses on population, housing and agriculture.

Georgia has substantial agricultural potential, The government places great emphasis on the need for investment in increasing output and productivity of Agricultural Sector. Demand for agricultural data is increasing daily and Geostat has to respond to user needs.

Agriculture has always been one of the important sectors of Georgian economy. Despite the fact that share of agriculture, hunting, forestry and fishing in GDP was only 9.2% in 2015, 48.6% of employees in Georgia were employed in this sector. The share of rural population is 42.8% according to the Population Census 2014.

Almost every household living in villages is an agricultural holding and even in small towns 2/3 of households are engaged in agriculture. Overall, 3 out of 5 household are engaged in agriculture and they are scattered through every region of the country. According to the Census of Agriculture 2014, total number of agricultural holdings is around 642 thousand, out of them only 2 thousand is legal entity while other 640 thousand is household. Majority of agricultural holdings are small and they produce agricultural products for their own consumption.

Due to favorable geographical location and climate, Georgia produces more than 25 kinds of permanent and more than 20 kinds of annual crops. Also animal husbandry is quite common in the agriculture of Georgia. One of the specificities of the country is that the agricultural sector is not well-specialized and majority of holdings produce many different kinds of agricultural products.

The main source of current agricultural statistics is the Sample Survey of Agricultural Holdings which dates back to 2007 and its methodology was elaborated with the support of Food and Agriculture Organization (FAO) and the United States Department of Agriculture (USDA). Sample frame of the survey was based on the Agricultural Census 2004 which was the first in the history of independent Georgia. In 2014 Geostat conducted the second Agricultural Census of the country together with the Population Census. Based on the census database, in 2015-2016 Geostat prepared Master Sample Frame for agricultural surveys.

[1] The Georgian statistical system covers the whole area of the country, except the occupied territories.

2. Building Master Sample Frame in Georgia

In November 2014 the National Statistics Office of Georgia conducted Census of Agriculture together with the Population Census. In fact, there were 4 different censuses conducted together: Housing Census, Population Census, Census of Emigrants and Agricultural Census. Additionally, census identified holdings operating aquaculture and greenhouses. The census was conducted using GIS maps.

Geostat started preparatory works for the General Population Census in 2006. One of the principal parts of these works was implementing GIS in order to create digital cartographic material and use them in census data collection and dissemination process. At the first stage, GIS group, which was created at Geostat, developed GIS maps using cartographic material available in the country. A supplementary work was done to cover the territories where cartographic material was missing. In addition to this, a numbering script was prepared in order to give its own code to each parcel and buildings located on it through the country territory. After this, a supplementary work was done for updating existing software and for switching to fully automatized system.

In 2013 Geostat conducted preliminary field works to elaborate list of dwellings and households existing in Georgia. In order to digitalize collected information and integrate with cartographic data, there was developed software which was using coding system created by GIS group. Information received from the preliminary field works was used for correcting and finalizing existing data on buildings and for distributing work among census enumerators effectively. In addition to these, household duplication and missing risks were minimized.

By implementing GIS, Geostat managed to significantly decrease time needed for preparing cartographic materials, use financial means in more effective way and prepare high-quality maps.

Register of legal entities engaged in agriculture was prepared separately, due to the fact that General Population Census has only covered household sector. For completing the list of agricultural enterprises, all existing reliable sources were used: existing sample frame of the regular quarterly survey on agriculture, Statistical Business Register, Public register, Information available at the Ministry of Agriculture, at local governments, at the Ministry of Education and at the Patriarchate of Georgia. After the General Population Census Agricultural Census for Legal Entities was conducted separately.

Preparation process of the census questionnaires was held under the international guidelines and recommendations, taking into the consideration the needs of local users. The census questionnaire consisted of four separate parts, respectively to four different censuses: Questionnaire on Dwelling (Q1), Personal Questionnaire (Q2), Questionnaire on Emigrants (Q3) and Questionnaire on Agriculture (Q4). Each questionnaire had unique ID number that was linking them to each other. In total, census questionnaire had 9 pages: 2 for Q1, 2 for Q2, 1 for Q3 and 4 for Q4.

Q1 contained questions on dwelling conditions, as well as the full list of households and persons living in the dwelling with status of the persons - usual resident, temporary absent, temporary present, emigrant. According to the status of the person, appropriate questionnaire was filled (Q2 or Q3).

Since the population and agricultural censuses were conducted together, it was agreed to use the same reporting unit, thus a household was considered as one agricultural holding. In case of two or more holders in the household one of them was selected as a holder and their operated lands and livestock were summed up and assigned to the holder. In case of one or more households in a holding, each household was considered as a separate holding and land and livestock were assigned proportionally according to the share of households in the holding.

There were main identification questions in the Q1 for agricultural holdings. According to them, if household was identified as a holding, Q4 was filled by the enumerators. Besides, Q1 was identifying the holder. Additionally, Q1 contained identification question on holdings operating aquaculture.

Questionnaire on Agriculture (Q4) did not contain any question about the holder rather than holder's unique number indicated in Q1 and Q2, since all relevant information was covered by Q1 and

Q2. Q4 covered all core indicators recommended by the Food and Agriculture Organization and local user's needs were taking into account. [2]

For the Agricultural Census for Legal Entities an electronic questionnaire was prepared, which was also used for the census of municipalities (common land data). The content of the electronic questionnaire was the same as of Q4. In addition to the questions similar to Q4, there were additional questions regarding personal characteristics of the company director/holder.

As a result the census database contains information on dwelling conditions, personal information of the population, personal information of emigrants, agricultural data on holdings, personal information of holders, data on households operating aquaculture and greenhouses and geographic data. The database is a comprehensive source for analysts and researchers to cross-analyze social-economic and agricultural data.

The coding system included in the census database easily links all obtained data and creates Master Sample Frame for Agriculture. The existed MSF is used and can be used for various surveys: integrated agricultural surveys, specific agricultural surveys, aquaculture surveys, greenhouse surveys, social-economic surveys, etc.

In 2015 Geostat prepared Strategic Plan for Agricultural, Environmental and Rural Statistics in Georgia 2016-2020 (SPAERS). It determines the planned activities for improving agricultural, environmental and rural statistics, including new surveys to be conducted in coming years. MSF will be main tool for the agricultural surveys and it will be used as a frame for making samples.

MSF facilitates identification and monitoring process in the field works, since it contains detailed personal data of the holder and her/his household members, as well as GPS coordinates of the household location. It also gives great possibility to prepare maps indicating sampled units for enumerators to be used during the field works.

Georgian MSF covers various variables regarding Family holdings, Agricultural enterprises, Households, Emigrants, Housing conditions, Aquaculture holdings, Greenhouse holdings, municipal (common) land, etc.

3. Conclusions

By conducting population and housing censuses and agricultural census together, the National Statistics office of Georgia has created the first Master Sample Frame for Agriculture. The identification codes system embedded in the questionnaires easily linked the population and agricultural censuses and hence linked the agricultural holdings data to the households data. Use of GIS maps during the census fulfilled MSF with the detailed geographic data.

The Master Sample Frame is used for regular agricultural surveys and will be used for new regular surveys as well as for one-time surveys which are planned to be conducted in the coming years. Merging different surveys using MSF decreases survey costs and respondent burden which is crucial for statistical system. MSF facilitates to meet planned activities determined by SPAERS in more efficient way. It is also good tool for the surveys studying agricultural activities for specific social groups. MSF can be widely used for identification and monitoring process during the field works that will decrease the time needed for data collection and improve data quality.

It is important that MSF will be updated regularly by the data obtained from all agricultural and social-economic surveys based on Master Sample Frame as well as by the reliable administrative sources available in the country in order to keep MSF up-to-date.

ABSTRACT

Swedish official statistics in the agricultural area has since 1995 been based upon the extensive use of administrative data. However, in most cases it is not advisable to produce statistics direct from administrative registers. This paper reviews the methodologies and techniques used in order to ensure sufficient statistical quality when using administrative sources together with the Farm Structure Survey for the creation of the statistical farm register. The Farm register (FR) is used as a sampling frame for all agricultural statistics based on holdings.

In the paper we will show how the frame can be updated regarding the holdings constituting the frame as well as regarding the characteristics for example area of different crops, rented land and number of animals needed to stratify samples. The results show that integrating administrative registers with surveys is a cost-effective way of updating the frame while reducing the burden on respondents. Various aspects of the quality dimensions "accuracy", "comparability" and "coherence" are the key issues for development in order to improve the quality when integrating registers and surveys.However if extensive, systematic work is integrating registers and surveys, the quality in these dimensions can be high. It is shown that there is at least as much need for work with improving quality, methodological studies and quality assurance for statistics based on administrative registers as for statistics based on sample surveys. When using administrative registers, the integration phase where data from several sources are integrated into a new statistical register is central for improving quality.

Keywords: register-based statistics, administrative registers,

1. Background and aim

At least from 1965 and onwards agricultural statistics in Sweden has been dependent on an updated Farm register (FR). The FR consists of all agricultural holdings in Sweden as well as variables needed for creating a typology consisting of type of farm, size of farmand region. The variables includedifferent kinds of animals and crops, rented land and some general information about type of holding and the holder. The typology is used to stratify effectively and thus minimise the sample in almost all agricultural sample surveys. Up until 1996the FR was updated by a yearly census where farmers were asked about all crops and animals.

When Sweden joined the EU in 1995 administrative registers of all farms applying for EU-subsidies where made available for statistical purposes. Subsequently several studies were made to see how the registers best could be used for agricultural statistics.Selander et al. (1998) and Wallgren& Wallgren (1999) for example compared IACS (the register for area-based subsidies) from 1996 with the objects in the FR from 1995. The results showed that 88 per cent of the objects matched, 4.9 per cent of the objects had multiple links between the registers and 6.9 per cent could not be found in IACS. Of the objects in the IACS register on the other hand, 2.9 per cent could not be found in the FR.As a result of the studies work the following years were focused on integrating the registers and FR. Several questionnaires were sent to subgroups of farmers asking them about keys in IACS.

In recent years Dias et al.(2016) has shown,with the example of Portugal, how alternative methodologies to a traditional population-census could be evaluated. They conclude that since there are advantages and disadvantages to all methods, it is important to make a systematic evaluation so that the trade-offs between options could be taken into account in the decision making process. It is stressed that registers might not have all the content needed; instead the registers may need to be combined with traditional surveys. The findings in the studies of Wallgren & Wallgren (1999) also showed that it is not possible to produce the FR directly from administrative registers. However they showed that administrative registers could be used for updating the objects in the FR as well as give information on some variables, for example crops.

As a result,starting in the year 2000 the FR was no longer updated with an annual full census, instead itwasupdated with an integrated use of registers and surveys in the years for which EU require the member states to conduct a Farm structure survey (FSS) according to regulation (EC) 1166/2008.In the years in-between, the FR is updated mainly from registers, together with information from a sample survey on animals. In recent years additional registers have been used,for example administrative registers on cattle, sheep, poultry and pigs.

When using an administrative register there is at least as much need for methodological studies and quality assurance as for statistics based on statistical surveys. However, the quality deficiencies and the approaches to investigate and resolve them differ.Several studies, for example Wahlgren & Wahlgren (2014),Laitila et al. (2011), Daas et al. (2009, 2010) and Agafitei et al.(2015) have discussed quality frameworks for using administrative registers for statistical purposes. This includes the quality of the register itself, the possibilities of integrating administrative registers into statistical registers and how to document the quality of the statistics produced. There is also a discussion about which part of the process to focus on. Holmberg (2015) summarises that there is an ongoing theoretical development on how to assess the quality of administrative data, but that more work is needed for example regarding linkage errors and cowerage errors.

The framework by Daas et al. (2010) is recommended by EU (2016) for assessing the quality of administrative registers. In 2016 the framework was used for evaluating registers for FSS 2016 (SJV, 2016)

1.1 Aim of the paper

This paper will describe how the FR in Sweden is updated using administrative registers in combination with some census data. The quality achieved by using theadministrative registers in combination with a statistical survey will be compared towhat quality could be achieved by updating FR using only a census and using only administrative registers.The framework recommended by Eurostat (2016) presented by Daas et al. (2010) will be used to highlight the quality in the administrative registers.

The quality will be described according to the quality criterias stipulated in regulation (EC) No 223/2009 on European statistics. Furthermore aspects of cost-effectiveness, privacy and response burden will be addressed.

2. Updating the Farm register (FR)

Figure 1 showsthat the overall method for creating the FR is to make a maximal sampling frame (2) withcombining the objects in the FR from the latest FSS year (1a)by all new possible objects that can be found in registers (1b). Next a questionnaireis sent out to the maximal sampling frame(3), and a current FR is made (5)by combining the information in the maximal sampling frame with information from the questionnaire(4). In the end the variables needed for thetypologyare added.

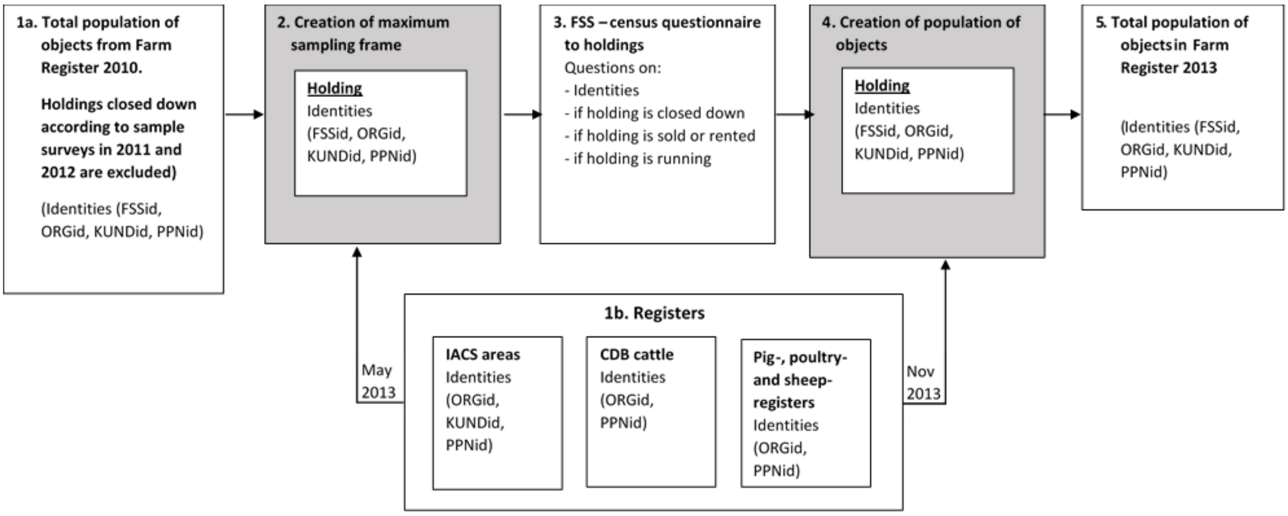

Figure 1:*Creation of the Farm register 2013.*

The target population of the farm register is the same as the target population of FSS. The variables of animals and crops in FR are also defined in the same way as the variables for animals and crops in FSS. I.e. producing the FR means doing a large part of the work needed for FSS.

2.1 Creating the maximal sampling frame

In the beginning of 2013 the total population was taken from the 2010 Farm Register.The indicators related to the source as described in the hyper-dimensions of (Daas et al., 2010) are used to describe the quality of the registers. The Swedish Board of Agriculture is the supplier of the data sources for all registers except the Business register (BR), where the supplier is Statistics Sweden. The Board is also the responsible NSO for agricultural statistics, so privacy and security rules are in place. Historically the registers have always been delivered in time. All persons and organisations in the registers as well as in the FR have a unique organisational number (ORGid). The ORGid is therefore always a linkable auxiliary key between registers.

The IACS register is highly relevant. It consists of all holdings applying for area based subsidies in May each year. In IACS about 60 codes for crops are included. It has unique keys (KUNDid) and the linkability is high. It has clear definitions and the information is well checked. However there is an under-coverage since about 10 per cent of the holdings do not apply for or are eligible for area based subsidies. Following the definition in FR a holding might contain several KUNDid. IACS could be used both for updating the register and for a large proportion of the variables.

The registers for poultry, pigs and sheepas well as the cattle database are aimed at tracing animals in case of an outbreak of a contagious animal's disease. Each production-place with these animals have a unique key (PPNid). The production-place is related to a person or legal entity with an organisational number (ORGid). One holding can relate to several production-places. The information in the registers differs. The poultry-and pig- registers mainly holds information on the number of animals that could be held at the production-place.

In the sheep-register additional information on the number of sheep in December are added by a questionnaire. There is a unit non-response of about 24 per cent. This register also has an over-coverage of about 20 per cent. It can be assumed that the over-coverage of the poultry- and pig-registersis the same. The under-coverage is small since the PPNid needs to be reported when animals are slaughtered. These registers could be used to update the objects in the maximal sampling frame but the quality is not sufficient for the variable values.

In the cattle-databaseeach head of cattle has an identifier thatis related to a production place (PPNid). There is, however, no distinction in the register between dairy-cows and cows for meat-production. Information from a second auxiliary register of milk deliveries is used to obtain the required information. It is assumed that if the holding delivers milk in the month of the reference day, the cows on the holding are all dairy cows. This approach will resultin a small over-estimation of dairy cows and subsequently an underestimation of cows for meat-production. However a sample survey conducted in 2002 showed that the error was less than 1per cent. The cattle database is therefore used both for updating the objects and for the variables needed for cattle.

The use of registers means that thepostal questionnaire sent to the farmers did nothave to include questions on crops and cattle since this information is available from registers. Only questions on the number of horses, poultry, pigs-, and sheep were included.Since there could be multiple to multiple objects in the different registers, the order of merging is decided by specific rules. Each holding in FSS has a set of related keys (for example Orgid and KUNDid). The keys are ordered by their quality. If there are multiple possibilities of linking, the key ordered the highest i.e. with the best quality is used first.

The linkages made in the spring 2013 showed that 64 036 objects could be linked to the registers while11 689 holdings in the FR 2010 could not be found in registers. 3 004 of them had not been found in registers 2010 either and 8 685 are holdings that existed in registers 2010 but not 2013. Information from sample surveys done in 2011 and 2012 indicate that 800 holdings had closed down during the period. 868 additional holdings were found in the cattle register, IACS or the pig-, poultry-, and sheep registers. 934horticultural enterprises in the business register were added to find horticultural holdings that might fit into the frame. In the end the maximal sampling frame amounted to 77 527 holdings. By creating the sampling frame this way there will be an over-coverage in the frame. The under-coverage is assumed to be small as long as the holdings were present in 2010.

When the questionnaire was created it included questions regarding whatkeys (ORGid, KUNDid, PPNid) that were related to the holding and whether it was sold, rented out, closed down or still running. If the holding was sold or rented out it was askedwho was now running the farm. It is assumed that most of the 8 685 holdings that could no longer be found in the registers are no longer farmers, but some of them are likely to be the same as the 868 holdings that were found in registers but not in the register from 2010. This together with the linkage process could mean that the same holding might get more than one questionnaire. Whether this has occurred is therefore a question in the questionnaire. The questionnaire also includes questions on animals and rented land, variables that could not be found in the registers. The variables grazing land and arable land are included as a reference to the area of rented land.

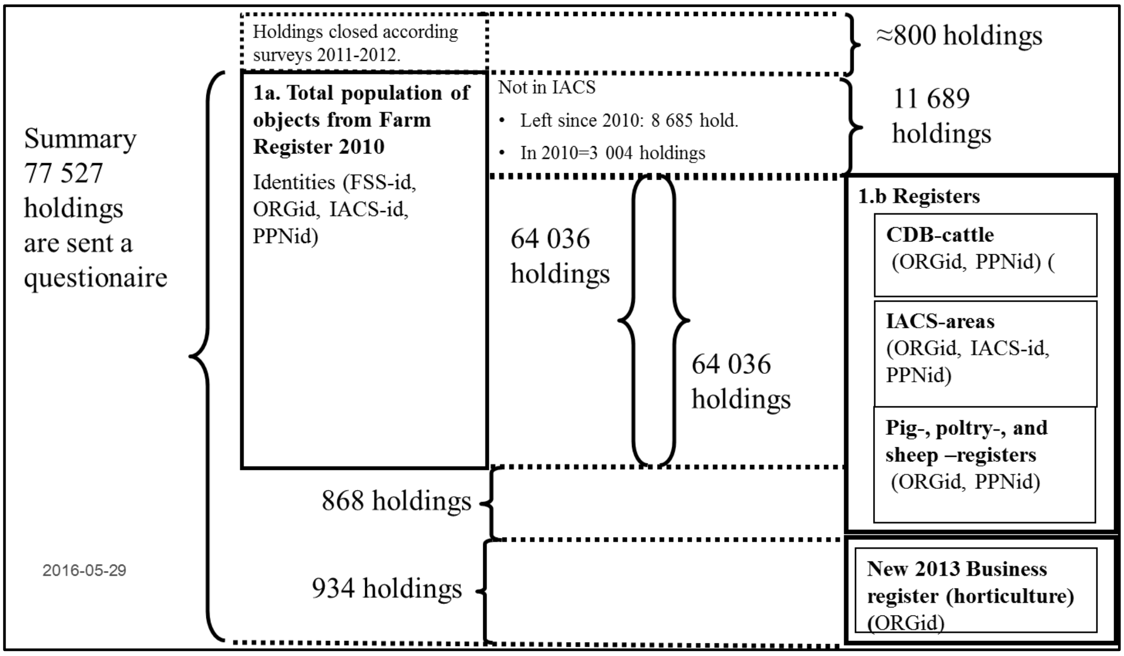

Figure 2.*Creation of the maximal sampling frame.*

2.2 Results from 2013

In November when the answers from the questionnaire were processed, updated data was gathered from the registers and related to the reference time. The information from the questionnaire and the registers wasmatched and the population of objects for 2013was created. In the questionnaire the set of keys and the quality of the keys related to the holding were updated. The linkage was then made using the same principles as when creating the sampling frame. The linkage resulted in 67 126 holdings in the FR for 2013.

613 duplicates were found. The duplicates were mostly holdings in FR 2010 that were not found in registers included in the group “left since 2010”. The duplicates were due to linkage errors.

The holdings in the group “left since 2010” were mainly growing crops. Out of the 8 684 holdings 3 125 had been closed down and 3 626 had been taken over by another holder. I.e. only 16 per cent were still farmers so there is a large over-coverage in this group. Out of the 3 004 holdings in the group “In 2010” 989 holdings had closed down and 541 had sold the farm to someone else. I.e. 58 per cent were still running the holding. It could be concluded that those holdings that for several years are running their business without applying for subsidies continue to do so.

The results regarding the horticultural register showed that 30 per centwere still running their holdings.574 holdings had closed down and 77 had sold it to someone else. For the holdings in this group it is more common to close down the business than letting someone else continue it. Out of the holdings in the pig-, poultry-, and sheep groups about half were still running their holdings and out of the large group that matched with IACS 98 per centwere still running their holding.

When the population was created, the variables were connected to the objects using the established links of keys. The information on areas and crops given in IACS as well as information about cattle given in the cattle register are considered to have high quality since the information is subject to extensive controls. For example, the holding is requested to give information about the total area of arable land in hectares as well as the total area of rented arable land in hectares. If the total area of arable land differs from the summarised areas of arable land used for different crops in IACS, the IACS figure will be used. As a result, the answers in the questionnaire wereonly used to calculate the share of rented arable land at the holding. The divergent answers could also be a sign that the creation of objects had not been fully successful. Consequently the information was used to improve the creation of objects.

3. Comparing quality between registers, census and multiple source

Every 10:th year a full census needs to be made meeting the target-population of FSS according to regulation (EC) 1166/2008. The census includes the variables in the FR. The alternatives which are interesting to compare are different methods for updating the FR in the two times during the 10 year period when the FSS is stipulated to be made as a sample survey. The three alternatives compared are a:

1. combination of census and registers i.e. the current method described in section 2,
2. register based approach, using registers in combination with the FSS-sample survey,
3. full census based method using a census and not any of the registers available.

3.1 Cost-effectiveness, privacy and response burden

Privacy and the principle that information given for statistical purposes should not be used for administrative purposes are fundamental when producing statistics (Eurostat 2016). On the other hand, administrative registers may be used for producing statistics. In Sweden, the Official Statistics Act (2001:99) addresses data disclosure and the Secrecy Act (1980:100) addresses the confidentiality of individual information. In the case of the FR, individual data from administrative registers are protected by the Secrecy Act (1980:100) when used for statistical purposes, regardless of whether the data would be public or not from the body responsible for the administrative register.

Using administrative registers is also a way of reducing the burden on respondents. At our user-meetings the Union of Swedish Farmers states that it is favourable to share information between governmental bodies in order to make it possible for farmers to only provide the same information once. The hours spent filling out the present set of questionnaires are calculated to 5 800 hours. If no administrative registers where used the questionnaire would also need to have information on all animals and all crops and the total number of hours spent could be calculated to 9 600 hours. If only administrative registers were used the time would be 0. However compared both to the current method used and the full census the quality of the register would be lower. The samples for surveys in the years 2014-2020 would need to be larger. We have calculated those extra hours to 9 500 hours. This includes larger samples for the sample surveys of crops, rented land, fertilisers and the census 2020.Over the 10 year period the difference between register-based statistics and the current method regarding response-burden is low.

The total cost for the current method used in 2013 was 750 000 euro. The cost for a full census through postal questionnaires could be estimated to 1 100 000euro and for producing the statistics solely from registers to 450 000 euro. However there would be an additional cost for the larger samples in the years 2014-2020. Producing statistics from administrative registers is cost-effective in relation to postal questionnaires. From a cost-effectiveness point of view it can be seen that a large proportion of the cost is due to handling paper questionnaires. In 2013 only 20per cent answered using the web service. I.e. the most obvious way of saving money would be to persuade farmers to answer through the web.

3.2. Quality criteria

Relevance refers to the degree to which statistics meetcurrent and potential needs of the users. The updated FR is harmonised with the target population and some of the variables in FSS. I.e. the needs from EU-legislations are met. The FR also can be used to disseminate statistics for small regions or groups as well as combining data in new ways without restrictions. It could be assumed that a full census would meet the same quality criteria. If the FR were updated only by registers itwould still fulfil the needs from EU-legislation regarding FSS. However since animals would be sampled it could only be used for producing statistics on NUTS3 sometimes NUTS2 level.

Accuracy refers to the closeness of estimates to theunknown true values.For register-based surveys, key issues are integration errors as well as how well the definition of objects and variables in the registers correspond with the required definitions in the statistics. The problems of matching different sources should not be underestimated. There is a risk for over-coverage in the FR. Parts of the same holding or the same areas could be counted several times. It is possible that a landowner, who is no longer cultivating his land and who belongs to the 8 685 holdings that could not be found in the register, answers the questionnaire on the basis of the land that he owns without cultivation. At the same time, the tenant of the same land who has applied for subsidies also states that he uses the land. Using only a census would lead to an under-coverage of the FR since the holdings not applying for subsides might be lost and new holdings more difficult to find. Using only registers for creating objects might also lead to an under-coverage since holdings not in the subsidy systems would be excluded.

For *timeliness* i.e. the period between the availability ofthe information and the event or phenomenon it describes there are no differences between approaches.Wallgren & Wallgren (2014) stress that timeliness is often a problem when using administrative registers. However in the case of IACS and the cattle-database this is not a problem. IACS data are available in May the reference year and the cattle-database is updated constantly.

Punctuality which means if release dates are kept,*accessibility and clarity* that has to do with the user's possibilities to access and compare data and *coherence* i.e. if the information is put together and presented in a logical way present no differences between alternatives.

Concerning *comparability*, or the possibility to compare results over time, problems might occur. Statistics based on administrative registers are dependent on changes that the statistical bodies may not be able to predict. For example, the change in the CAP in 2005 meant that the holders applying for subsidies in 2005 would be eligible for subsidies in subsequent years. The changes in the CAP affected the statistics in several ways, for example the number of holdings increased. Two explanations to this increase could be found. Firstly it was thought that small farms that had not been eligible for subsidies now applied for subsidies and were consequently incorporated into the population of holdings. The change in administrative rules thus improved the quality of the FR, correcting a previous under-coverage. Secondly, it could be assumed that some landowners applied for subsidies although the land in practice was cultivated by a neighbouringholder, leading therefore to over-coverage in comparison with the definitions in the FR.This problem would be the same for the register based approach but would not occur for the alternative based on full census.

The quality in terms of comparing results from registers and surveys are high because of the wide-ranging work done to merge different registers. In this sense the quality would be lower in the two other alternatives.

1. Conclusion

To conclude the use of registers is cost-effective and reduces the response burden for the holdings. Regarding the quality criteria of relevance, there are advantages to integrating registers with surveys and censuses when collecting data for the FSS. On one hand, in solely register-based surveys, the register may not cover the requested variables. On the other hand, in solely statistical surveys, the questionnaire would be expensive and cause a high response burden.Regarding the dimension of timeliness, the registers used for the FSS are updated and available earlier than results from a survey or census would be. When comparing the accuracy of the results, there are several aspects to consider.However, integrating registers and surveys as well as only using a statistical survey is considered to give accurate results. The coherence and comparability is assumed to be the highest when registers and surveys are integrated because of the wide-ranging work done to merge different registers. The availability is good in all three alternatives.

The paper shows that different aspects of accuracy are the key issues to consider in order to improve the quality when integrating registers and surveys in the FSS.

ABSTRACT

Methodological and practical problems have to be faced when building a master sampling frame for agricultural, rural and agri-environmental statistics. This paper addresses some of them, focusing on quality and coverage issues and on the impact of increasing computational ability to handle massive data sets on the generation and updating of master sampling frames. Advantages, disadvantages and requirements of the combination of different kinds of frames and the main methods for linking frames at the design stage and at the estimation stage are analysed. A proposal for increasing the efficiency of the allocation of the sample units to the different combined frames is also discussed.

Keywords: Master sampling frame, Multiple frames, Single and two-stage estimators

1. Introduction

In this paper, we present an analysis of methodological and practical problems to be faced when building a master sampling frame for agricultural, rural and agri-environmental statistics. We start from the traditional approach for generating a master sampling frame for agricultural statistics and analyse the effect of incomplete or out of date sampling frames. In section 3, the impact of increasing computational ability to handle massive data sets on the generation and updating of master sampling frames is discussed. Then, other kinds of master sampling frames are taken into consideration (section 4). Section 5, presents a review of the main methods for linking frames at the design stage and at the estimation stage, focusing both on single-stage and two-stage estimators. In section 6, we talk about the use of area sampling frames for collecting crop and agri-environmental data, the advantages, disadvantages and requirements when list frames are combined with area frames, with single-stage, as well as with two-stage estimators, and the difficulties in the identification of the farms selected through the area frame, according to the kind of area frame and adopted technological tools. Section 7 focuses on a method for improving the efficiency of the allocation of the sample units to the different combined frames. Finally, some conclusions are drawn.

2. The traditional approach for generating a master sampling frame

A master sampling frame is a sampling frame that provides the basis for all data collections through sample surveys and censuses in a certain sector, allowing to select samples for several different surveys or different rounds of the same survey, as opposed to building an ad-hoc sampling frame for each survey. The aims of the development of a master sampling frame are: avoiding duplication of efforts, reducing statistics discrepancies, connecting various aspects of the sector, allowing the analysis of the sampling units from the different viewpoints, and having a better understanding of the sector. The traditional approach for producing agricultural statistics adopted in most developed countries is the following (see Benedetti et al. eds. 2010): a complete enumeration census is carried out every 5-10 years. Data are collected through mail, email, personal interviews, computer assisted personal interviews, computer assisted telephone interviews, or the web. The census allows generating the list frame that is updated on the basis of administrative data, in the period between two successive censuses and is used for all kinds of sample surveys of farms; thus, it could be considered as a master sampling frame for agricultural statistics. An assessment of the quality of the data collected allows deciding if and how to use this list as a master sampling frame. For example, at the end of the data collection of the Italian agricultural census, a sample survey for assessing the quality of collected data was designed (Mazziotta, 2013). A stratified random sample of about 50,000 farms was selected and the farmers were interviewed through computer assisted telephone interviews in the period from 20 May 2011 to January 2013. This assessment showed that the complete enumeration census systematically underestimates the main structural variables that are generally used for stratification, when annual sample surveys are designed. In addition, the level of the bias varies in the different regions of the country, reducing the efficiency of the stratification.

3. Impact of increasing computational ability on the generation and updating of master sampling frames

The unbiasedness of this kind of list frame depends on the level of under-coverage and over-coverage of the list at the census date and on the quality of data and the process used for updating the list after the census date. This updating process has become easier, due to great improvements in data base management, including geographic databases (GIS). Moreover, methodological developments for deterministic as well as for probabilistic record linkage have considerably increased the capacity to identify the same record in different lists. For the Italian agricultural census, a very accurate assessment of the coverage was carried out (Mazziotta, 2013) on the basis of an area sample. Around 1,500 sheets of cadastral maps (areal units in which each municipality is subdivided – secondary sampling units) were selected from a sample of municipalities (primary sampling units). The owners of the parcels in the selected sheets of cadastral maps were identified, on the basis of the cadastral archive, and interviewed. 21,588 farmers were interviewed (1.620.884 active farms and 34.070 temporary inactive farms were identified by the agricultural census). The estimates were computed in the framework of the indirect sampling (Lavallée, 2007), and the weights (Lavallée and Rivest, 2012) were assigned based on the selection probability of each sheet of cadastral map and the number of sheets in which a farm has parcels (derived from the interview). A sophisticated record linkage procedure was implemented in three successive steps: deterministic, probabilistic and manual, involving various kinds of administrative registers. 81.4 % of farms in the area frame were included in the census list; 5.2 % of farms in the area frame were present in the census list with different characteristics, 1.7 % of the farms in the area frame had multiple links with census list, and 11.7 % of the farms in the area frame had no link with the census list. Of course, the percentage of farms in the area and in the census list decreased for small farms: 71% and 78.2 % for farms with utilized agricultural area in the range (0.01 - 0.99 hectares) and in the range (1 -1.99 hectares) respectively. This level of coverage is in line with most developed countries. These results of the quality assessment of the census data stimulates a reflection, if the main aims of the agricultural census are creating the list of all farms (including small ones) to be used as master sampling frame, with accurate structural information for stratification and producing estimates for very small administrative domains, at least once every 5-10 years.

Various kinds of administrative registers are generally used for updating the census list. The quality of the result depends on the administrative data that can be used and on the consistency of the identifiers of the units in the different registers. The over and under coverage can be high even if good administrative data, very sophisticated record linkage procedures and geo-location of administrative information are used, as showed by the following experiment. Several kinds of administrative data were taken into consideration for updating the Italian census list in 2008 (8 years after the census). Main registers used were the lists related to farms that apply for subsidies, livestock farms, agrarian income, cadastre, taxes, social security and specific lists created by regional authorities. A sample of 15,682 units was selected out of a subset of 80 municipalities. Enumerators used a web-based data collection system developed on purpose, in order to ensure accurate data collection. The result was that only 39.15% of the farms included in the integrated list were considered existing and active by the test. 44.74% of the farms in the integrated list were not active and 16.11% of them were not identified through the test (Berntsen and Viviano, 2011). This level of over-coverage implies that, if such a list is used for a sample survey, the enumerators waste much time trying to identify farmers, which then prove to be inactive. Moreover, distinguishing inactive farmers from total non-responses is difficult. Finally, the risk of producing biased estimates is high, unless an accurate estimate of the over-coverage is available. These considerations suggest adopting this approach only where the reliability of administrative data used for updating the census list is very high and the definitions adopted by administrative registers are compatible with the ones of the census.

4. Other kinds of master sampling frame

Other approaches have been developed for creating master sampling frames. In several countries, the population census is conducted using an administrative structure in which cartographic or other mapping materials are used to divide the country into enumeration areas. The sampling frame is the list of enumeration areas. In agricultural sample censuses and surveys, a sample of enumeration areas is selected, the list of households in selected enumeration areas is created and a sample is extracted from each of these lists, following a two stages sample design. In many countries, a sample agricultural census is conducted: some enumeration areas are randomly selected and screened for farms. The resulting sampling frame consists of the agricultural census enumeration areas. These approaches present coverage problems at least of the entity of the complete enumeration agricultural census described before. A proposal by FAO and UNFPA aims at avoiding to face the cost of the agricultural census: the list of farms or agricultural households is identified on the basis of specific agricultural questions included in the population census questionnaire. This approach is promising for countries where agriculture is not an important economic sector, like small islands. More work is needed for testing the quality of data collected using long questionnaires and the coverage of the list of farms generated from the population census; particularly, the entity of under and over coverage in different categories of countries should be assessed. Finally, the list frame of farms generated through the module on agriculture submitted to the households presents very few auxiliary variables; thus, the efficiency of the sample designs for annual sample surveys is very low, and this may have a strong impact on annual survey costs. For more details and an analysis of advantages, disadvantages and requirements see Keita and Gennari (2013) and Carfagna *et at.* (2013). In some countries, the list of the farms is based on administrative sources, such as business registrations or tax collections. A big disadvantage of the administrative sources is that they may not include the total population, especially units below a threshold required to be registered or pay taxes. In other words, while they will be inclusive of commercial farms, are not likely to include small-scale farms and subsistence farming units (see Carfagna and Carfagna, 2010).

5. Linking frames at the design stage and at the estimation stage

When the coverage and the accuracy of the structural characteristics are not high, alternative approaches can be followed: creating a sampling frame integrating different lists (design level), combining estimates from different lists (estimator level), using an area frame, combining an area frame with one or more list frames. The first option foresees that different lists concerning the same population are used for creating the sampling frame. In such a case, one single frame is created on the basis of two or more lists. In order to get one list combining more than one, records have to be matched. This is not an easy task because farms can appear with different pieces of information in the different lists, and sometimes only partial or wrong information is available. A wide literature has been developed on record linkage, focusing on deterministic and probabilistic rules for matching; moreover, the capacity of storing and managing databases is increased impressively. However, the coverage of the sampling frame is strongly influenced by the quality of the combined lists. Lists with limited coverage or out of date information can create difficulties in the record linkage process, increase the over-coverage and give little contribution to reduce the under-coverage of the sampling frame. Unless the different lists contribute with essential information to complete the frame and the record matching gives extremely reliable results, the frame will be still incomplete and with many duplications (see Carfagna and Ferraz, 2015).

Another option is treating the different lists separately and selecting samples from each list. All observations can be treated as though they had been sampled from a single frame, with modified weights for observations in the intersection of the lists (single-stage estimation). The basic idea is that a multiple frame sample can be viewed as a special case of selecting two or more samples independently from the same frame. As stated by Kalton and Anderson (1986), when a sample is drawn from two or more overlapping frames, the chance of an element being selected depends on the number of frames on which it appears. Compensation for the varying inclusion probabilities of different population elements may be made, by means of a weighting adjustment in the analysis, such as assigning sample element weights made inversely proportional to their inclusion probabilities. Kalton and Anderson (1986) and Skinner (1991) proposed an unbiased estimator that does not require determining the common units of samples from the different frames. Mecatti (2007) and Mecatti and Singh (2014) also gave a contribution to the development of single-stage estimators proposing their multiplicity estimator. Like the other single-stage estimators developed previously, the Mecatti and Singh estimator has two crucial requirements: the multiplicity of each sample unit is known and the union of the collection of frames covers the target population. Mecatti and Singh (2014) assume that the information on the multiplicity can be given by the interviewed sample units. For agricultural statistics, this assumption implies that each of the selected farmers knows which frames include his farm. The assumption that the union of the collection of frames covers the target population is seldom realistic, even in developed countries. Indeed, if the aim is providing a rough estimate of main agricultural items, the bias introduced by a limited under-coverage tends to be not particularly high, since generally it concerns mainly small farms, whose contribution to the total of main items is limited. However, the bias can be higher and difficult to remove for minor and special agricultural items. Moreover, small farms are important if we want to have an overview of the trends in rural areas. Another way of taking advantage of various frames at the estimator level is adopting an estimator that combines estimates calculated on non-overlapping sample units belonging to the different frames with estimates calculated on overlapping sample units (two-stage estimation). Two-stage estimators do not require the knowledge of the multiplicity for selected units, but assume that the union of the collection of frames covers the target population. Some two-stage estimators need the identification of identical units only in the overlap samples and some others have been developed for cases in which these units cannot be identified (see Fuller and Burmeister 1972). Both single-stage and two-stage estimators do not require record matching of listing units of the different frames (a process that is notoriously error prone when large lists are used). Generally, complex designs are adopted in the different frames to improve the efficiency and this affects the estimators. Lohr and Rao (2006) proposed optimal estimators and pseudo maximum likelihood estimators when two or more frames are used. Ferraz and Coelho (2007) investigated the estimation of population totals incorporating available auxiliary information from one of the frames at the estimation stage, for the case of a stratified dual frame survey; for a review of multiple frame estimators see Carfagna (2001) and Carfagna and Carfagna (2010).

6. Combining lists and area frames, advantages, disadvantages and requirements

Combining a list and an area frame is a special case of multiple frame sample surveys in which sample units belonging to the lists and not to the area frame do not exist. This approach is very convenient when the list contains units with large (thus probably more variable) values of some variables of interest and the survey cost of units in the list is much lower than in the area frame.

Ground data collection through an area frames is the most reliable way for collecting crop data and some agri-environmental data linked to the land, like the ones included in the field data collection form 2015 of the European land use and cover area frame survey (LUCAS). These data allow computing the following indicators: land cover/land use/change, parcel size, cropping system/land management, irrigation, landscape elements, associated trees and shrubs, soil erosion/soil quality. Ground positioning systems (GPS), aerial images, aerial photos (also photo-interpreted and stored on a PDA, Google Earth, Geographic information Systems (GIS) have considerably modified the data collection process and increased the quality of data.

If economic and rural characteristics and/or agri-environmental indicators related to the farm management are relevant for a country, the ground observation through an area frame is not sufficient and the farmers have to be selected and interviewed. Moreover, when the area frame is combined with one or more list frames, the presence on the lists of the farms selected through the area frame has to be assessed for most estimators.

The main typologies of area frames are segments, with or without physical boundaries, and clustered and un-clustered points. When segments are adopted, the fields totally or partially included in the segments can be used for identifying the corresponding farms; then, from the estimation viewpoint, the traditional open, closed and weighted estimators can be taken into consideration. The number of farms indirectly selected through a segment depends on the number of parts of farms included in the segment; thus, it changes from segment to segment and only an expected number of farms can be prefixed by selecting the segment size. If clustered or un-clustered points are selected, the field corresponding to the point identifies the farm.

The challenging part is collecting the data of the farm corresponding to the field. This task is difficult when the farmers live in villages far from the land. When un-clustered point sampling is adopted, the identification of the farmer is more cumbersome because the next farmer to be identified is far away. Close farmers are easier to identify, since one of them can give some information on the others. Sometimes, point sampling of farms in a segment is carried out, in order to select only a subset of the farms totally or partially included in the segment. This approach is appropriate where the optimum segment size for collecting area and yield information in the fields is larger than the optimum segment size for farmers' interviews. This happens where the farm size is small. Point sampling in the segments also allows prefixing the number of farms selected in each segment, in case point sampling with replacement is adopted (the same farm can be selected by more than one point). This is a big advantage for the sample allocation to the frames.

7. Sample allocation

Under a linear cost function, the optimum share of the total sample to be allocated to each frame can be determined, in order to optimize the precision of the total estimate. However, the optimum sample allocation depends on the variances of domains, which are generally unknown before the survey. An adaptive sequential approach could be adopted for determining the allocation during the survey. Consider that adaptive sequential sample designs are very efficient because the sample selection depends on previously selected units and the stopping rule is based on the estimate. Unfortunately, sequential sample designs are biased, for the same reasons. Thompson and Seber (1996, pages 189-191) faced the problem of sample allocation without previous information on the variability inside strata suggesting a stratified random survey in two phases or, more generally, in k phases. In our case, the strata represent the strata in the different sampling frames. At the k-th phase, a complete stratified random sample is selected, with sample sizes depending on data from previous phases. Then the conventional stratified estimator, based on the data from the k-th phase, is unbiased for the population total Y. The key to design unbiasedness of such an estimator is that each of the estimators is design unbiased and that the weights are fixed in advance and do not depend on observations made during the survey, which implies that, at whatever k-th phase, each of the strata needs to be sampled. These elements guarantee unbiased but not very efficient estimates. Carfagna and Marzialetti (2009), proposed the adoption of an adaptive sequential sample selection with permanent random numbers, which allows optimizing the sample allocation to the different strata and the use of optimum weights for estimating the population total. This procedure foresees that one sample unit is selected at each step, the standard deviations of the domains are computed and the next sample unit is assigned to the stratum where the sample size is farthest below the size assigned by Neyman's allocation. In the case of the sample allocation to two or more sampling frames, a less cumbersome k-step procedure with permanent random numbers, where k is equal to a small (2 or 3) number of steps is more appropriate. A permanent random number is assigned to all sampling unit in each domain (each stratum of each sampling frame). Then, a first random sample of sampling units is selected. The main aim of this first sample is generating a first estimate of the standard deviations in the domains, which are used for determining the optimum allocation of the second step sample and the optimum weights for combining the estimates from the various lists, then the process can be repeated.

8. Concluding remarks

The quality of the data collected by a complete enumeration census of agriculture should be checked before using the list of farms generated by the census as a master sampling frame, since the under-coverage is about 20% in developed countries. The impressive progress in managing big amount of data and the use of georeferenced data have considerably improved the quality of the updated list; however, this kind of update does not eliminate the under-coverage and can increase the over-coverage, creating several data collection problems. Creating a muster sampling frame integrating different kinds of lists, taking advantage of the improvements in record linkage can be an alternative. However, unless the different lists contribute with essential information to complete the frame and the record matching gives extremely reliable results, the frame will be still incomplete and with many duplications. Another option is treating the different lists separately and selecting samples from each list, using a single-stage or a two-stage estimator. The single-stage estimators have crucial requirements which are seldom satisfied, whiles two-stage estimators facilitate the use of different and complex sample designs in the different lists, increasing the efficiency of the estimators. Ground data collection through an area frame is the most reliable way for collecting crop data and some agri-environmental data linked to the land; however, if all economic characteristics and/or agri-environmental indicators related to the farm management have to be estimated, the ground observation through an area frame is not sufficient and the farmers have to be selected and interviewed. When un-clustered point sampling is adopted, the identification of the farmer is cumbersome because the next farmer to be identified is far away. The optimum sample allocation to different strata of the sampling frames depends on their variances, which are generally unknown before the survey. An adaptive sequential approach for determining the allocation during the survey increases the efficiency of the estimates.

ABSTRACT

To improve agricultural and rural official statistics, FAO designs and carries out action plans. The World Plans with specific focus have a long history: they began in 1930 and the last focuses on integrating agricultural censuses and agricultural surveys within the National Statistical System (NSS). The most recent Global Strategy [FAO (2011, 2012)] focuses on developing master sampling frames that are integrated with the NSS and allow the linkage of the farm as an economic unit to the household as a social unit and both to the land as an environmental unit [FAO (2015)]. Two keywords in this last plan are 'integration' and 'linkage'. 'Integration' refers to the use of the same sampling frame and related materials in multiple surveys, as well as the same concepts, survey personnel, and facilities. 'Linkage' is the basis for analysing the relationships among the economic, the social and the environmental dimensions of sustainable development.

FAO (1996, 1998, 2015) and the United Nations Statistical Division (UNSD,1986, 2008) have elaborated guidelines to assist countries in planning and implementing agricultural and household surveys, respectively. The central topic of these guidelines is the development and maintenance of master sampling frames. In this paper we focus on the integration of a dual sampling frame for agriculture with a sampling frame for households to build a multiple sampling frame that allows the required linkage among reporting units. We apply this strategy in three Latin America countries. We consider multiple frame regression estimators, highlighting its usefulness to integrate register and survey data and for combining data from independent surveys.

Keywords: Multiple overlapping frames, regression estimators, integrating register and survey data, combining data from independent surveys.

1. Introduction

There is consensus in the scientific community about the multidimensional (economical, social, and environmental) nature of sustainable development, and the Global Strategy to improve agricultural and rural official statistics [FAO (2011, 2012)] lays great stress on using a sampling frame that allows for the linkage of the farm as an economic unit, to the household as a social unit, and both to the land as an environmental unit. Multiple sampling frames meet this requirement and are cost-efficient.

Sampling strategies based on multiple overlapping frames have deserved a notable attention in last years, as a tool to deal with nonsampling errors: undercoverage, nonresponse, and measurement errors [Lohr (2011)]. In this paper we follow this sampling strategy for integrating agricultural and household surveys. Focus is on the linkage among farms, households and parcels. We structure the paper as follow. In section 2 we present the sampling strategy and its application in three Latin America countries. In section 3 we consider the multiple overlapping frame estimators proposed in the literature. In section 4 we consider multiple frame regression estimators, highlighting its usefulness to integrate survey and register data. Section 5 is about concluding remarks.

2. Integration of agricultural and household sampling frames

The sampling frames recommended by FAO and UNSD guidelines are dual frames, with an area component and a list component. The area frame ensures completeness, accuracy and up-to-datedness of the master frame: it is well established in the literature [Fecso et al. (1986), Faulkenberry and Garoui (1991), Vogel (1995), Ambrosio and Iglesias (2014)]. In agricultural surveys, the list contains the largest farms and contributes to improve the area sample accuracy. Census enumeration areas are used in household surveys as Primary Sampling Units (PSUs) and a list is elaborated within selected PSUs and is used to select the household sample.

We integrate the agricultural sampling frame and the household sampling frame in a unique multiple sampling frame. This multiple frame provides farms to observe economic variables: acreage and crop yields, livestock production, aquaculture and forestry. It provides also households to observe social variables: household composition, living conditions, employment, income, food and hunger, poverty, or inequality. And it provides parcels to observe environmental variables: soil degradation, water consumption for irrigation, or the quantity used of chemical fertilizers, herbicides, pesticides and fungicides.

Sampling a population with multiple overlapping frames

We use P to refer either the farms population, $F=\{f \mid f=1,2,\cdots,F\}$, the parcels population, $L=\{l \mid l=1,2,\cdots,L\}$, or the households population, $H=\{h \mid h=1,2,\cdots,H\}$. We assume that each population unit, $jj \in \mathrm{P}$ $(jj \equiv f,h,l)$, is associated to at least one sampling unit in the multiple frame

$\mathrm{I} = \{i = 1, 2, \cdots, A^q; q = 1, 2, \cdots, Q\}$, where A^q denotes both, the generic single frame q and the number of sampling units, and Q is the number of single frames. We define the indicator variable $I_{ij}^q = 1$ if the population unit $jj \in \mathrm{P}$ is associated to the sampling unit $i \in A^q$, and $I_{ij}^q = 0$ otherwise $(jj \equiv f, h, l)$.

The sample

We select a set of samples $\{\mathsf{S}^q; q = 1, 2, \cdots, Q\}$ independently from each frame A^q, using a sampling scheme that associates to sampling unit $i = 1, 2, \cdots, A^q$ an inclusion probability π_i^q. From the standard dual frame for agricultural surveys, where A^1 is an area frame with $i = 1, 2, \cdots, A^1$ segments and A^2 is a list frame with $i = 1, 2, \cdots, A^2$ names of farms, we select independently a sample S^1 of segments and a sample S^2 of names. From the standard frame for household surveys, A^3, we select a sample S^3 of names, independent of S^1 and S^2.

As a result, we have: (i) a sample of parcels, $\mathrm{S}_L^1 = \{l \in L | i \in \mathrm{S}^1 \wedge I_{il}^1 = 1\}$, where $I_{il}^1 = 1$ when the area, a_{il}, of parcel l within the segment $i \in \mathrm{S}^1$ is $a_{il} > 0$, (ii) and a set of two partially overlapping samples of farms, $\{\mathrm{S}_F^q; q = 1, 2\}$, where $\mathrm{S}_F^q = \{f \in F | i \in \mathrm{S}^q \wedge I_{if}^q = 1\}$, where $I_{if}^1 = 1$ when the area, a_{if}, of the farm f within the segment $i \in \mathrm{S}^1$ is $a_{fi} > 0$, and $I_{if}^2 = 1$ when the name $i \in \mathrm{S}^2$ is associated to the farm f, (iii) and a sample of households $S_H^3 = \{h \in H | i \in \mathrm{S}^3 \wedge I_{ih}^3 = 1\}$, where $I_{ih}^3 = 1$ when the name $i \in \mathrm{S}^3$ is associated to the household h.

Country examples

We study the case of three Latin American countries: Guatemala, Costa Rica and Ecuador. In these countries, there is a dual sampling frame for agricultural surveys. The kind of limits used to define sampling units differs among countries: limits are geometrics in Guatemala and Ecuador, while identifiable physical boundaries are used in Costa Rica. The area frame, A^1, has 190100 segments in Guatemala [Ambrosio (2013), FAO (2015)], 352254 segments in Ecuador (Ambrosio, 2014) and 120326 segments in Costa Rica (Ambrosio, 2015).

The area frame is stratified into four strata, using the percentage of cultivated surface as stratification variable. The data source for stratification is a land use map in Guatemala and Ecuador and a geo-referenced agricultural census in Costa Rica. A target segment size is defined that varies among strata: in Guatemala it ranges from 6.25 hectares (cultivated surface bigger than 60% and small fields) to 100 hectares (cultivated surface lower than 20%), in Ecuador the range is from 9 to 576 hectares, and in Costa Rica the range is from 10 to 100 hectares. In Guatemala and Costa Rica S^1 has 1500 segments, and in Ecuador 5520 segments. The sample is allocated to strata according to Neyman's criterion, and five replicated samples are selected in each stratum.

The list frame, A^2, differs among countries according to available resources. In Costa Rica, there is a recent agricultural census and a list frame for each one of the main crops and animal' species is available (the bovine list frame has 31171 farms, and the porcine list frame has 14355 farms). In

Guatemala and Ecuador, the agricultural censuses are obsoletes and the number of list frames is reduced to the biggest farms in Ecuador and to the main animals' species in Guatemala.

An area sampling frame of enumeration areas (EA) with mapped, well-delineated boundaries is available for household surveys. In Guatemala the frame has 15511 EA with an average of 140 households by EA. The EA are stratified using available population figures, and a two-stage

sampling scheme is used to select the household sample, S^3. In the first stage, a sample of EA is selected with probabilities proportional to size (in Ecuador the sample size is 2586 EA for labour surveys, 1128 EA for surveys on living standard and 3411 EA for income surveys). In the second-stage, a list of household is updated within each EA in the first-stage sample and a sample of households (12 by EA) is selected with equal probabilities.

3. Multiple frame estimators

Typically, a population unit (e.g. a farm) is covered by two or more single frames (e.g., area and list frames) and, as a result, the weight estimator, $\hat{Y}_{\mathrm{P}} = \sum_{q=1}^{Q}\sum_{i=1}^{S^q} w_i^q y_i$, where $w_i^q = \frac{1}{\pi_i^q}$, is a biased estimator of the population total, Y_{P}. To see this, consider the population partitioned into $D = 2^Q - 1$ non-overlapping domains and $Y_{\mathrm{P}} = \sum_{d=1}^{D} Y_d$, where Y_d is the domain total, $d = 1, 2, \cdots, D$.

For dual frames, $Q = 2$, $\hat{Y}_{\mathrm{P}} = \sum_{q=1}^{2}\sum_{i=1}^{S^q} w_i^q y_i = \sum_{i=1}^{S^1} w_i^1 y_i + \sum_{i=1}^{S^2} w_i^2 y_i$, and $D = 2^2 - 1 = 3$. Domain $d = 1$ is the set of units covered only by A^1, domain $d = 2$ is covered only by A^2 and domain $d = 3$ is covered by both, A^1 and A^2. The population total is $Y_{\mathrm{P}} = \sum_{d=1}^{3} Y_d = Y_1 + Y_2 + Y_3$. Now, $\sum_{i=1}^{S^1} w_i^1 y_i$ is a unbiased estimator of A^1 total, which is domain $d = 1$ total plus $d = 3$ total, $Y_1 + Y_3$, and $\sum_{i=1}^{S^2} w_i^2 y_i$ is a unbiased estimator of A^2 total, which is $d = 2$ total plus domain $d = 3$ total, $Y_2 + Y_3$. Thus,

$E\hat{Y}_{\mathrm{P}} = E\sum_{i=1}^{S^1} w_i^1 y_i + E\sum_{i=1}^{S^2} w_i^2 y_i = Y_1 + Y_2 + 2Y_3$ and the bias of $\hat{Y}_{\mathrm{P}}$ is $B\hat{Y}_{\mathrm{P}} = E\hat{Y}_{\mathrm{P}} - Y_{\mathrm{P}} = Y_3$.

A screening approach is followed in FAO (1996, 1998), where the single frames are pre-screened to remove overlap, so that domains with two o more frames are empty and, as a result, the weight estimator is unbiased: for dual frames, $d = 3$ is empty, $Y_3 = 0$, and hence $B\hat{Y} = 0$. However, screening operations are resource-consuming and a number of more cost-efficient alternatives can be found in the literature (Lohr, 2011). Cost-efficiency was the motivation of Hartley (1962, 1974) to propose first multiple frame estimators. Skinner and Rao (1996) and Lohr and Rao (2000, 2006) proposed pseudo-maximum likelihood multiple frame estimators. Bankier (1986) and Kalton and Anderson (1986) proposed standard single-frame estimators for multiple frame survey.

Adjusted-weight estimators

Most of these alternatives look for an adjustment, m_i^q, of the sampling weight w_i^q in such a way that using $\tilde{w}_i^q = m_i^q w_i^q$ instead of w_i^q, the adjusted-weight estimator $\hat{Y}_{\mathrm{P}} = \sum_{q=1}^{Q} \sum_{i=1}^{S^q} \tilde{w}_i^q y_i$ is unbiased. This can be achieved using for each frame and domain a fixed set of adjustment such as $\forall i \in d$, $m_i^q = m^{(q,d)}$, with the restrictions $m^{(q,d)} > 0$ (if domain d is not part of A^q, then $m^{(q,d)} = 0$) and $\sum_{q=1}^{Q} m^{(q,d)} = 1$ for $d = 1, 2, \cdots, D$. The adjusted-weight estimator $\hat{Y}_{\mathrm{P}} = \sum_{d=1}^{D} \hat{Y}_d$, where $\hat{Y}_d = \sum_{q=1}^{Q} \sum_{i=1}^{S^q} \tilde{w}_i^q \delta_i(d) y_i = \sum_{q=1}^{Q} m^{(q,d)} \sum_{i=1}^{S^q} w_i^q \delta_i(d) y_i$ and $\delta_i(d) = 1$ if $i \in d$ and $\delta_i(d) = 0$ otherwise, is unbiased .

For dual frames, a fixed weight adjustment is: if $i \in (d = 1)$ then $m_i^1 = m^{(1,1)} = 1$ and $m_i^2 = m^{(2,1)} = 0$, if $i \in (d = 2)$ then $m_i^1 = m^{(1,2)} = 0$ and $m_i^2 = m^{(2,2)} = 1$ and if $i \in (d = 3)$ then $m_i^1 + m_i^2 = m^{(1,3)} + m^{(2,3)} = 1$. The adjusted-weight estimator is $\hat{Y}_{\mathrm{P}} = \sum_{d=1}^{3} \hat{Y}_d$, where $\hat{Y}_1 = \sum_{q=1}^{2} \sum_{i=1}^{S^q} \tilde{w}_i^q \delta_i(1) y_i = \sum_{q=1}^{2} m^{(q,1)} \sum_{i=1}^{S^q} w_i^q \delta_i(1) y_i = m^{(1,1)} \sum_{i=1}^{S^1} w_i^1 \delta_i(1) y_i + m^{(2,1)} \sum_{i=1}^{S^2} w_i^2 \delta_i(1) y_i = \sum_{i=1}^{S^1} w_i^1 \delta_i(1) y_i$, $\hat{Y}_2 = \sum_{i=1}^{S^2} w_i^2 \delta_i(2) y_i$ and $\hat{Y}_3 = m^{(1,3)} \hat{Y}_3^1 + m^{(2,3)} \hat{Y}_3^2$, where $\hat{Y}_3^1 = \sum_{i=1}^{S^1} w_i^1 \delta_i(3) y_i$ and $\hat{Y}_3^2 = \sum_{i=1}^{S^2} w_i^2 \delta_i(3) y_i$. Often, it is taken $m^{(1,3)} = m^{(2,3)} = \frac{1}{2}$ and, as a result, $\hat{Y}_3 = \frac{1}{2} \hat{Y}_3^1 + \frac{1}{2} \hat{Y}_3^2$.

Optimal estimators

Hartley (1962) proposes this other fixed set of adjustments: if $i \in (d = 1)$ then $m_i^1 = m^{(1,1)} = 1$ and $m_i^2 = m^{(2,1)} = 0$, if $i \in (d = 2)$ then $m_i^1 = m^{(1,2)} = 0$ and $m_i^2 = m^{(2,2)} = 1$ and if $i \in (d = 3)$ then $m_{i,\theta}^1 = m_\theta^{(1,3)} = \theta$ and $m_{i,\theta}^2 = m_\theta^{(2,3)} = 1 - \theta$, where $0 \le \theta \le 1$. The adjusted-weight estimator is $\hat{Y} = \sum_{d=1}^{3} \hat{Y}_d$, where $\hat{Y}_1 = \sum_{i=1}^{S^1} w_i^1 \delta_i(1) y_i$, $\hat{Y}_2 = \sum_{i=1}^{S^2} w_i^2 \delta_i(2) y_i$ and $\hat{Y}_3 = \theta \hat{Y}_3^1 + (1-\theta) \hat{Y}_3^2$, so that $\hat{Y}_{\mathrm{P}} = \hat{Y}_1 + \hat{Y}_2 + \theta \hat{Y}_3^1 + (1-\theta) \hat{Y}_3^2$. The value $\theta = \frac{1}{2}$ is often used and the estimator is internally consistent. However, the optimal value is $\theta_H = \dfrac{V\hat{Y}_3^2 + Cov\left(\hat{Y}_3^2, \hat{Y}_2\right) - Cov\left(\hat{Y}_3^1, \hat{Y}_1\right)}{V\hat{Y}_3^1 + V\hat{Y}_3^2}$ and changes with the survey variable, so that it is internally inconsistent. In practice, internal consistency requires that one set of weights be used to estimate all survey variables: Pseudo-maximum likelihood estimators are internally consistent (Lohr, 2011).

Single frame estimator

Kalton and Anderson (1986) propose an adjustment weight, which treats all observations as though they had been sampled from one frame: if $i \in (d=1)$, then $m_{i,S}^1 = 1$, if $i \in (d=2)$ then $m_{i,S}^2 = 1$ and if $i \in (d=3)$ then $m_{i,s}^1 = \frac{w_i^2}{w_i^1 + w_i^2}$ and $m_{i,s}^2 = \frac{w_i^1}{w_i^1 + w_i^2}$. If $i \in (d=3)$ then $\tilde{w}_i^1 = \tilde{w}_i^2 = \frac{1}{\pi_i^1 + \pi_i^2}$. This estimator is internally consistent.

Multiplicity-adjusted estimators.

Singh and Mecatti (2011) and Mecatti and Singh (2014) propose to adjust for multiplicity the survey variable value, instead of the sampling weight. The multiplicity of a population unit, $j \in \mathrm{P}$ ($j = f,h,l$ and $\mathrm{P} = F,H,L$), is the number of sampling units, $m_j = \sum_{q=1}^{Q} m_j^q$, to which it is associated, $jj \in \mathrm{P}$ where $m_j^q = \sum_{i=1}^{A^q} I_{ij}^q$ is the multiplicity within A^q, where $I_{ij}^q = 1$ if the population unit is associated to the sampling unit $i \in A^q$, and $I_{ij}^q = 0$ otherwise. The population total is $Y_{\mathrm{P}} = \sum_{q=1}^{Q} \sum_{i=1}^{A^q} \tilde{y}_i^q$, where $\tilde{y}_i^q = \sum_{j=1}^{\mathrm{P}} \alpha_{ij}^q y_j$ is the multiplicity-adjusted value of the survey variable in the i^{th} sampling unit, where $\alpha_{ij}^q = \frac{I_{ij}^q}{m_j}$.

The weight multiplicity-adjusted estimator, $\hat{Y}_{\mathrm{P}} = \sum_{q=1}^{Q} \sum_{i=1}^{S^q} w_i^q \tilde{y}_i^q$, is unbiased and internally consistent.

Note that the adjustment, $\frac{1}{m_j}$, applies to the survey variable value, y_j, instead to the sampling weight, w_i^q, and it consists in sharing y_j among the number of sampling units to which $j \in \mathrm{P}$ is associated.

In terms of the population units, the multiplicity-adjusted estimator can be written as an adjusted-weight estimator, $\hat{Y}_{\mathrm{P}} = \sum_{q=1}^{Q} \sum_{j=1}^{S_{\mathrm{P}}^q} \tilde{w}_j^q y_j$ where $\mathrm{S}_{\mathrm{P}}^q = \left\{ j \in \mathrm{P} \middle| i \in \mathrm{S}^q \wedge I_{ij}^q = 1 \right\}$ is the set of population units associated to S^q and $\tilde{w}_j^q = \frac{1}{m_j} \sum_{i=1}^{S^q} w_i^q$. The size of $\mathrm{S}_{\mathrm{P}}^q$ is $\mathrm{n}_{\mathrm{P}}^q$.

Linkage

To ensure the required linkage between farms and households, we define the link $I_{fh} = 1$ if at least one person from the household $h \in H$ works for the farm $f \in F$ and $I_{fh} = 0$ otherwise. A parcel is linked to the farm which it belong and to the households through the linkage between farms and households: $I_{lf} = 1$ if l belongs to f and $I_{lf} = 0$ otherwise. If f is included in S_F^1 (see section 2), then the set of households $\mathrm{S}_H^1 = \left\{ h \in H \middle| f \in S_F^1 \wedge I_{fh} = 1 \right\}$ linked with f are included in the household sample. If f is included in S_F^2, then the set of households $S_H^2 = \{h \in H | f \in S_F^2 \wedge I_{fh} = 1\}$ linked with f are included in the household sample.

If the household h is included in S_H^3, then the set of farms $S_F^3 = \{f \in F | h \in S_H^3 \wedge I_{fh} = 1\}$ linked with h are included in the farm sample. If f is in $\{S_F^q; q = 1,2,3\}$, then the set of parcels $L_f = \{l \in L | I_{fl} = 1\}$ are included in the sample. This sampling procedure is related with both, network sampling and indirect sampling [Falorsi (2014), Singh and Mecatti (2011), Mecatti and Singh (2014)].

The parameter to be estimated is the population total, $P = \{L, F, H\}$: over land, $Y_L = \sum_{l=1}^{L} Y_l$, over farms, $Y_F = \sum_{f=1}^{F} Y_f$, and over households, $Y_H = \sum_{h=1}^{H} Y_h$. Given the links (I_{lf}, I_{fh}) between (l, f, h), (i) the multiplicity of the parcel l is $m_l = \sum_{q=1}^{Q} m_l^q$, where $m_l^1 = \sum_{i=1}^{A^1} I_{il}^1$, $m_l^2 = \sum_{i=1}^{A^2} I_{if}^2 I_{lf} = m_f^2 I_{lf}$ and $m_l^3 = \left(\sum_{h=1}^{H} m_h^3 I_{fh}\right) I_{lf}$; (ii) the multiplicity of the farm f is $m_f = \sum_{q=1}^{Q} m_f^q$, where $m_f^1 = \sum_{i=1}^{A^1} I_{if}^1$, $m_f^2 = \sum_{i=1}^{A^2} I_{if}^2$ and $m_f^3 = \sum_{h=1}^{H} m_h^3 I_{fh}$; and the multiplicity of the household h is $m_h = \sum_{q=1}^{Q} m_h^q$, where $m_h^1 = \sum_{f=1}^{F} m_f^1 I_{fh}$, $m_h^2 = \sum_{f=1}^{F} m_f^2 I_{fh}$ and $m_h^3 = \sum_{i=1}^{A^3} I_{ih}^3$.

The total over land is $Y_L = \sum_{q=1}^{Q} \tilde{Y}_{Lq}$, where $\tilde{Y}_{Lq} = \sum_{i=1}^{A^q} \tilde{y}_{Li}^q$, where $\tilde{y}_{Li}^1 = \sum_{l=1}^{L} I_{il}^1 \frac{y_l}{m_l}$, $\tilde{y}_{Li}^2 = \sum_{f=1}^{F} I_{if}^2 \sum_{l=1}^{L} I_{lf} \frac{y_l}{m_l}$ and $\tilde{y}_{Li}^3 = \sum_{f=1}^{F} \left(\sum_{h=1}^{H} I_{ih}^3 I_{fh} \right) \sum_{l=1}^{L} I_{lf} \frac{y_l}{m_l}$ are the multiplicity-adjusted values of the survey variable associated to the i^{th} sampling unit in each frame. The total over farms is $Y_F = \sum_{q=1}^{Q} \tilde{Y}_{Fq}$, where $\tilde{Y}_{Fq} = \sum_{i=1}^{A^q} \tilde{y}_{Fi}^q$, where $\tilde{y}_{Fi}^1 = \sum_{f=1}^{F} I_{if}^1 \frac{y_f}{m_f}$, $\tilde{y}_{Fi}^2 = \sum_{f=1}^{F} I_{if}^2 \frac{y_f}{m_f}$ and $\tilde{y}_{Fi}^3 = \sum_{f=1}^{F} \left(\sum_{h=1}^{H} I_{ih}^3 I_{fh} \right) \frac{y_f}{m_f}$. The total over households is $Y_H = \sum_{q=1}^{Q} \tilde{Y}_{Hq}$, where $\tilde{Y}_{Hq} = \sum_{i=1}^{A^q} \tilde{y}_{Hi}^q$ and $\tilde{y}_{Hi}^1 = \sum_{f=1}^{F} I_{if}^1 \sum_{h=1}^{H} I_{fh} \frac{y_h}{m_h}$, $\tilde{y}_{Hi}^2 = \sum_{f=1}^{F} I_{if}^2 \sum_{h=1}^{H} I_{fh} \frac{y_h}{m_h}$, and $\tilde{y}_{Hi}^3 = \sum_{h=1}^{H} I_{ih}^3 \frac{y_h}{m_h}$.

The multiplicity-adjusted estimator, $\hat{Y}_P = \sum_{q=1}^{Q} \sum_{i=1}^{S^q} w_i^q \tilde{y}_{Pi}^q$, is unbiased and its variance is $V\hat{Y}_P = \sum_{q=1}^{Q} \sum_{i=1}^{A^q} \sum_{i'=1}^{A^q} \left(\pi_{ii'}^q - \pi_i^q \pi_{i'}^q \right) \frac{\tilde{y}_{Pi}^q}{\pi_i^q} \frac{\tilde{y}_{Pi'}^q}{\pi_{i'}^q}$. The variance estimator is $\hat{V}\hat{Y}_P = \sum_{q=1}^{Q} \sum_{i=1}^{S^q} \sum_{i'=1}^{S^q} \frac{\pi_{ii'}^q - \pi_i^q \pi_{i'}^q}{\pi_{ii'}^q} \frac{\tilde{y}_{Pi}^q}{\pi_i^q} \frac{\tilde{y}_{Pi'}^q}{\pi_{i'}^q}$.

The multiplicity-adjusted estimator can be written in terms of population units as an adjusted-weight estimator, $\hat{Y}_{\mathrm{P}} = \sum_{q=1}^{Q}\sum_{j=1}^{S_{\mathrm{P}}^{q}} \tilde{w}_j^q y_j$, where $\tilde{w}_j^q = \frac{1}{m_j}\sum_{i=1}^{S^q} w_i^q$.

4. Multiple frame regression estimators

To use auxiliary information, we specify a regression model in terms of population units, $y_j = \mathbf{x}_j\boldsymbol{\beta}+\varepsilon_j$, where $\mathbf{x}_j$ is the $(1\times p)$ vector of auxiliary variables, including the constant 1, $\boldsymbol{\beta}$ is a $(p\times 1)$ vector of regression parameters, $E\varepsilon_j = 0$, and $V\varepsilon_j = \sigma^2$. The model in terms of sampling units is, $\tilde{y}_i^q = \tilde{\mathbf{x}}_i^q\boldsymbol{\beta} + \tilde{\varepsilon}_i^q$, where $\tilde{\mathbf{x}}_i^q = \sum_{j=1}^{S_{\mathrm{P}}^q}\alpha_{ij}^q\mathbf{x}_j$, $\tilde{\varepsilon}_i^q = \sum_{j=1}^{S_{\mathrm{P}}^q}\alpha_{ij}^q\varepsilon_j$, $E\tilde{\varepsilon}_i^q = 0$, $V\tilde{\varepsilon}_i^q = \sigma^2\sum_{j=1}^{S_{\mathrm{P}}^q}\left(\alpha_{ij}^q\right)^2$.
Lu (2014) proposes four methods to estimate $\boldsymbol{\beta}$. We consider the probability weighted least square estimator, $\hat{\boldsymbol{\beta}}_{\tilde{w}} = \min_{\boldsymbol{\beta}}\sum_{q=1}^{Q}\sum_{i=1}^{S^q}\tilde{w}_i^q\left(\tilde{y}_i^q - \tilde{\mathbf{x}}_i^q\boldsymbol{\beta}\right)^2$, where $\tilde{w}_i^q = w_i^q\tilde{\alpha}_i^q$ and $\tilde{\alpha}_i^q = \frac{1}{\sum_{j=1}^{S_P^q}\left(\alpha_{ij}^q\right)^2}$: it is

$\hat{\boldsymbol{\beta}}_{\tilde{w}} = \left(\tilde{\mathbf{X}}^{\mathrm{T}}\mathbf{D}_{\tilde{w}}\tilde{\mathbf{X}}\right)^{-1}\tilde{\mathbf{X}}^{\mathrm{T}}\mathbf{D}_{\tilde{w}}\tilde{\mathbf{y}}$, where $\tilde{\mathbf{X}}$ is the $\left(\sum_{q=1}^{Q}S^q\times p\right)$ multiplicity-adjusted auxiliary data matrix,

$\tilde{\mathbf{y}}$ is the $\left(\sum_{q=1}^{Q}S^q\times 1\right)$ vector of multiplicity-adjusted survey variable data,

and $\mathbf{D}_{\tilde{w}} = diag\left\{\tilde{w}_i^q; i=1,2,\cdots,S^q; q=1,2,\cdots,Q\right\}$.

$\hat{\boldsymbol{\beta}}_{\tilde{w}}$ is a design-consistent estimator of the regression parameter values in the finite population, $\boldsymbol{\beta}_N = \left(\tilde{\mathbf{X}}_N^T\tilde{\mathbf{X}}_N\right)^{-1}\tilde{\mathbf{X}}_N^T\tilde{\mathbf{y}}_N$, where $N = \sum_{q=1}^{Q}A^q$ is the number of sampling units in the multiple frame, $\tilde{\mathbf{X}}_N$ is the $(N\times p)$ matrix of multiplicity-adjusted auxiliary variable values, and $\tilde{\mathbf{y}}_N$ is the $(N\times 1)$ vector of the multiplicity-adjusted survey variable values.

The Multiplicity-adjusted Generalized Regression estimator (MGREG) is $\hat{Y}_{MGREG} = \sum_{q=1}^{Q}\sum_{i=1}^{A^q}\tilde{\mathbf{x}}_i^q\hat{\boldsymbol{\beta}}_{\tilde{w}}$: it is a design-consistent estimator of the population total, Y , and its asymptotic design-variance can be estimated using $\hat{V}\hat{Y}_{MGREG} = \hat{V}\left(\sum_{q=1}^{Q}\sum_{i=1}^{S^q}w_i^q\hat{e}_i^q\right)$g, where $\hat{e}_i^q = \tilde{y}_i^q - \tilde{\mathbf{x}}_i^q\hat{\boldsymbol{\beta}}_{\tilde{w}}$ (Fuller, 2009; Kim and Rao, 2012).
Ranalli et al (2014) propose calibration estimators. Deville and Särdal (1992) and (Fuller, 2009) show how calibration estimators can be approximated by regression estimators.

Integrating survey and register data

The MGREG estimator is useful to integrate survey and register data. To see this, we assume that there is a set of values $\left(y_j, \mathbf{x}_j\right)$ associated with each population unit: y_j is the survey variable value and $\mathbf{x}_j$ are register values. We assume that the choice of $\mathbf{x}_j^q$ differs among single frames (registers) and we use a different working model in each register, $\tilde{y}_i^q = \tilde{\mathbf{x}}_i^q \boldsymbol{\beta}^q + \tilde{\varepsilon}_i^q$, where $\tilde{\mathbf{x}}_i^q = \sum_{j=1}^{S_P^q} \alpha_{ij}^q \mathbf{x}_j^q$, $\tilde{\varepsilon}_i^q = \sum_{j=1}^{S_P^q} \alpha_{ij}^q \varepsilon_j$, $E\tilde{\varepsilon}_i^q = 0$, $V\tilde{\varepsilon}_i^q = \sigma^{2,q} \sum_{j=1}^{S_P^q} \left(\alpha_{ij}^q\right)^2$. To observe data on $\left(y_j, \mathbf{x}_j^q\right)$, we consider Q^1 frames of the target population, , and we select independently from each one a sample, $\left\{S^q; q = 1, 2, \cdots, Q^1\right\}$. We consider Q^2 registers as independent large samples, $\left\{S^q; q = 1, 2, \cdots, Q^2\right\}$, selected from , where we observe only data on $\mathbf{x}_j^q$.

To estimate regression parameters, $\boldsymbol{\beta}^q$, we use data from Q^1 and the probability weighted least square estimator, $\hat{\boldsymbol{\beta}}_{\tilde{w}}^q = \min_{\boldsymbol{\beta}^q} \sum_{i=1}^{S^q} \tilde{w}_i^q \left(\tilde{y}_i^q - \tilde{\mathbf{x}}_i^q \boldsymbol{\beta}^q\right)^2$, which is $\hat{\boldsymbol{\beta}}_{\tilde{w}}^q = \left(\tilde{\mathbf{X}}^{qT} \mathbf{D}_{\tilde{w}}^q \tilde{\mathbf{X}}^q\right)^{-1} \tilde{\mathbf{X}}^{qT} \mathbf{D}_{\tilde{w}}^q \tilde{\mathbf{y}}^q$, where $\tilde{\mathbf{X}}^q$ is the $\left(S^q \times p^q\right)$ multiplicity-adjusted auxiliary data matrix, $\tilde{\mathbf{y}}^q$ is the $\left(S^q \times 1\right)$ vector of multiplicity-adjusted survey variable data, and $\mathbf{D}_{\tilde{w}}^q = diag\left\{\tilde{w}_i^q; i = 1, 2, \cdots, S^q\right\}$.

We use data from Q^2 to estimate $\sum_{i=1}^{A^q} \tilde{\mathbf{x}}_i^q$, using $\sum_{i=1}^{S^q} w_i^q \tilde{\mathbf{x}}_i^q$. The MGREG estimator is

$\hat{\hat{Y}}_{MGREG} = \sum_{q=1}^{Q^2} \sum_{i=1}^{S^q} w_i^q \tilde{\mathbf{x}}_i^q \hat{\boldsymbol{\beta}}_{\tilde{w}}^q$, and its error is

$$\hat{\hat{Y}}_{MGREG} - Y = \hat{\hat{Y}}_{MGREG} - \sum_{q=1}^{Q^2} \tilde{\mathbf{x}}_{N^q}^q \boldsymbol{\beta}_{N^q}^q = \sum_{q=1}^{Q^1} \sum_{i=1}^{S^q} \left(\tilde{y}_i^q - \tilde{\mathbf{x}}_i^q \boldsymbol{\beta}_{A^q}^q\right) + \sum_{q=1}^{Q^2} \left(\sum_{i=1}^{S^q} w_i^q \tilde{\mathbf{x}}_i^q - \tilde{\mathbf{x}}_{A^q}^q\right) \hat{\boldsymbol{\beta}}_{\tilde{w}}^q + \left(\tilde{\mathbf{x}}_N - \sum_{q=1}^{Q^1} \sum_{i=1}^{S^q} w_i^q \tilde{\mathbf{x}}_i^q\right) \left(\hat{\boldsymbol{\beta}}_{\tilde{w}}^q - \boldsymbol{\beta}_{A^q}^q\right)$$

, where $\tilde{\mathbf{x}}_{A^q}^q = \sum_{i=1}^{A^q} \tilde{\mathbf{x}}_i^q$, $\tilde{\mathbf{x}}_N = \sum_{q=1}^{Q^2} \tilde{\mathbf{x}}_{A^q}^q$, $\boldsymbol{\beta}_{A^q}^q = \left(\tilde{\mathbf{X}}_{A^q}^{qT} \tilde{\mathbf{X}}_{A^q}^q\right)^{-1} \tilde{\mathbf{X}}_{A^q}^{qT} \tilde{\mathbf{y}}_{A^q}^q$, $\tilde{\mathbf{X}}_{N^q}^q$ is the $\left(A^q \times p^q\right)$ matrix of multiplicity-adjusted auxiliary variable values, and $\tilde{\mathbf{y}}_{A^q}$ is the $\left(A^q \times 1\right)$ vector of the multiplicity-adjusted survey variable values.

$\hat{\hat{Y}}_{MGREG}$ is design-consistent and its asymptotic design-variance can be estimated using $\hat{V}\hat{\hat{Y}}_{MGREG} = \hat{V} \sum_{q=1}^{Q^1} \sum_{i=1}^{S^q} w_i^q \hat{\tilde{e}}_i^q + \sum_{q=1}^{Q^2} \hat{\boldsymbol{\beta}}_{\tilde{w}}^{qT} \left(\hat{\mathbf{V}} \sum_{i=1}^{S^q} w_i^q \tilde{\mathbf{x}}_i^q\right) \hat{\boldsymbol{\beta}}_{\tilde{w}}^q$, where $\hat{\tilde{e}}_i^q = \tilde{y}_i^q - \tilde{\mathbf{x}}_i^q \hat{\boldsymbol{\beta}}_{\tilde{w}}^q$. The elements of the covariance matrix, $\hat{\mathbf{V}} \sum_{i=1}^{S^q} w_i^q \tilde{\mathbf{x}}_i^q$, can be estimated using the HT variance estimator. If $A^q \in Q^2$ is complete, then $\sum_{i=1}^{A^q} \tilde{\mathbf{x}}_i^q$ is known and all terms in the covariance matrix related with A^q are nulls.

Analysis of complex surveys: sampling design informativeness

Linear (regression) and generalized linear models are useful tools for analyzing survey data. Deaton (1997) shows how they can be used with household surveys and with linked farm-household surveys (Singh et al., 1986). Most land use models are generalized linear models (Ambrosio et al., 2008), useful for analysing linked farm-parcel surveys. Relative little work has been done on 'sustainometrics' models (Todorov and Marinova, 2010), for analysing linked farm-household-parcel surveys.

Typically, the analysts fit these models assuming that the sampling design is 'non informative'. However, complex sampling design leads usually to informative samples and, as a result, model parameters estimator are inconsistent (Binder et al, 2005). The weighted estimator is consistent and its asymptotic distribution is normal, and can be used for hypothesis testing and prediction [Fuller (2009)].

5. Concluding remarks

To collect data for designing sustainable policies, we integrate agricultural and household sampling frames in a multiple overlapping frame. This sampling frame provides the required reporting units: the farm as economic unit, the household as social unit, and the parcel as environmental unit. We apply this strategy in three Latin America countries.

Due to overlapping, the sum of the usual single frame weight estimator over the multiple frames is biased. The multiple frame estimators proposed in the literature consist in an adjustment of the single frame weight estimator by adjusting either the sampling weight (adjusted-weight estimators) or the survey variable (multiplicity-adjusted estimators). We focus on multiplicity-adjusted estimators because they are internally consistent and take into account the linkage among sampling units in a simple way.

Regression estimators have received considerable attention in the literature, but mainly for single frames. We extend this single frame estimator to the multiple frame case, highlighting the usefulness of multiple frame regression estimators to integrate register and survey data.

Linear (regression) and generalized linear models are useful tools for analysing survey data, and we suggest using weighted estimators to estimate model parameters, in order to take into account the sampling design informativeness. Hypothesis testing and prediction can be carried out using the asymptotic normal distribution of these estimators.

METHODOLOGICAL CHALLENGES AND PROPOSALS FOR THE NEXT AGRICULTURE CENSUS ROUND

Session Organizer
J. Castano | FAO | Rome | Italy
M. Greco | Istat | Rome | Italy

ABSTRACT

The FAO World Programme on the Census of Agriculture 2020 (WCA 2020), that will be published in 2015, will be the tenth decennial census programme. It is an international standard that is expected to drive the implementation of agricultural censuses in all countries in the period between 2016 and 2025. The WCA 2020 is occurring at a time when demand increases for integrated, synergetic and cost-- efficient national agriculture statistical systems. Some of the main features of the new WCA 2020 are: • Close linkages to the Global Strategy to Improve Agricultural and Rural Statistics and the emphasis on the integration of the census of agriculture within the overall framework of the system of integrated agricultural censuses and surveys. • Two methodological approaches are recognised namely the classical (a single one-- off complete enumeration) and the modular approach (combining complete and sample enumeration) while noting the increased use of registers and administrative records as a source of census data. • The distinction between 'essential', 'frame' and 'additional' census items. Essential items are recommended to be collected by all countries, frame items are used for the construction of sampling frames while additional items are for more in-- depth data. • An increased emphasis on the use of information technology in the collection, processing and dissemination of census data. The objective of the session is to discuss the efforts that countries are making to conduct censuses within a more integrated, synergetic and cost-- efficient agriculture statistical system. Possible topics for papers in this session include: 1. Integration of agricultural census with other major statistical operation such as population census and economic census 2. Combined approaches that use statistical and administrative sources to meet the data needs of the census of agriculture 3. Frames for the agricultural census and dealing with outdated frames 4. The use of information technology to reduce the time lag between census data collection and analysis and to facilitate user-- friendly dissemination to support informed-- decision making. 5. Types of census enumeration: complete enumeration, sample--based enumeration, combination of approaches, rolling enumeration. 6. Innovative research uses of census data, e.g. for agri-- economic and environmental estimates: water consumption for agriculture, sustainable agriculture, farm typologies.

ABSTRACT

The first Agricultural Census in Armenia was conducted in 2014. The legal basis to conduct the Agricultural Census was RA Law "On State Statistics" (2000), Three-year state statistical work program, RA Law "On Agricultural Census» (2008), RA Government Decree on 25 April 2013 "On implementation of Armenia Agricultural Census in 2014 and Pilot Agricultural Census in 2013". Totally 107 documents (55 Resolutions of the State Council on Statistics of RA) have been adopted.
The methodology of Agricultural Census includes the selection of time period for the census implementation, objectives and coverage of indicators, general population (census units) and methods (exhaustive and sampling), accounting period and census phases.
The Agricultural Census units were all legal persons dealing with agricultural production, individual entrepreneurs, group farms (correctional institutions, military units, orphanages, organizations of social services for the elderly and disabled, education, research and experimental units), individual households in rural and urban areas, and in horticultural companies, communities. Preparatory work has been done through the development of lists of farms in communities and organization plans, recruitment, staff training and publicity campaign.
The Census has been implemented by preliminary visit, control visit and publicity campaign. These activities have been followed by the acceptance of documents by checking/coding of questionnaires responses, questionnaires data entry and obtaining of output tables.

Legislation, methodology and standards have been developed by recommendations of international experts: UN FAO, US Department of Agriculture, EU/Eurostat (Denmark and Sweden) within the EU Twinning Project “Forwarding Armenian Statistics through Twinning” (2011-2013), as well as studying Agricultural Census experience in USA, Denmark, Sweden, Russia, Moldova, Georgia, and other countries. The funds have been provided by the World Bank, Austrian Development Agency/UNDP, EU/budget support, USAID.
Agricultural Census will enable to improve agricultural statistics, form complete statistical data system on agriculture, establish statistical registers for units engaged in agricultural activities, and ensure data international comparability.

Keywords: Agriculture, statistical data, households, questionnaire.

1. Introduction

Since the establishment of the United Nations (UN) in the second half of 20th century, humanity started worldwide the development of accounting systems and maintenance of statistics in accordance with unified and comparable definitions, classifications and methodology. This refers to all spheres of human activities, including agriculture, which is considered as one of the most important fields.
Many countries, including Armenia compile agricultural statistics based on reports from local authorities, because of lack of resources. This method of data collection affects on data quality and that is why an agricultural census is an irreplaceable tool to provide valuable information for agriculture statistics.
According to the World Programme for the Census of Agriculture 2020 (WCA 2020), “A census of agriculture is a statistical operation for collecting, processing and disseminating data on the structure of agriculture, covering the whole or a significant part of a country. Typical structural data collected in a census of agriculture are size of holding, land tenure, land use, crop area, irrigation, livestock numbers, labour and other agricultural inputs. In an agricultural census, data are collected at the holding level, but some community-level data may also be collected”.
UN Member States are required to conduct an Agricultural Census at least every 10 years in accordance with the guidelines defined by the FAO.

2. Need to conduct Agriculture Census in the Republic of Armenia

Statistical data on agriculture in the Republic of Armenia are collected, summarized and published by the National Statistical Service of the Republic of Armenia (NSS RA). Agriculture statistics is guided by the annual state statistical work program, according to the main strategic directions of statistics development that are stated in three-year state statistical work programs. Statistical data are collected directly (sampling) by direct enumeration of agricultural holdings and commercial enterprises engaged in agricultural activities, as well as from administrative registers (Ministry of Agriculture of RA, Ministry of Nature Protection of RA, Cadastre Committee), communities (866 rural and 49 urban). Statistical data on agriculture are presented monthly, quarterly and annually based on the current reports.
Until 2014 an agricultural census has not been conducted in the Republic of Armenia.
According to the existing methodology the Agricultural Census is statistical operation for collecting, processing and disseminating exhaustive data on the structure of agriculture, agricultural lands, livestock, agricultural machinery and buildings, existing resources (human and material) and their utilization.

Meanwhile the Agricultural Census was important for the Republic of Armenia, as the collected statistical data will be used for:

- poverty monitoring,
- food security monitoring,
- planning of agriculture and development of strategy in this area,
- gender statistics,
- improving current agricultural statistics,
- providing users with more comprehensive information and so on.

Conducting Agricultural Census in Armenia was also important because agriculture is considered as one of the most important sectors of economy, and the share of new value in Gross Domestic Product (GDP) during the recent years is 16-20%, and the number of employees in this field is about 37 % of the total employed population.

There are many and various economic entities in the field of agriculture, the majority of them are agricultural holdings (rural households). 90 % of GDP in agriculture belongs to these holdings and they may be described as follows:

- small sizes,
- lack of internal accounting,
- law marketability level (45 % of the products are produced for own consumption, 20 % belongs to in-kind payments and barters and only in average 35 % is monetized),
- low degree of specialization,
- small, limited amounts of investments and incomes,
- high level of changeability of economic activity and intra-sectoral activities (including seasonal).

Implementation of Agricultural Census will give a possibility to create overview of agriculture in Armenia characterized not only by internationally comparable disaggregated indicators, but also it will clarify the detailed structure and composition of agriculture as a field of entrepreneurship (type of economic activity). As a result, it will become possible to form new organizational and legal forms for 340,000 households engaged in agricultural activities, which will be a basis for administrative registration, and thus this field will be no more described as “informal activity”. According to the survey results in 2009 (“The Informal Sector and Informal Employment in Armenia” Country Report), the agriculture sector had the highest rate of informal employment (98.6%). The informal employment rate in agriculture has not been changed and was 99.3 % in 2015 according to the Labour Force Survey.

3. Legal basis for conducting Agricultural Census in the Republic of Armenia

Law on Agricultural Census was adopted in 2008, and that is in line with methodological approaches of the international practice.

This law stipulates the following provisional requirements for the Agricultural Census: objectives, units of the agriculture census and their obligations, bodies conducting Agricultural Census and their obligations, financing, liabilities for violation of the Agricultural Census legislation, etc.

According to the given Law the objectives of Agricultural Census are as follows:

- collection of information on agriculture structure, agricultural land, machinery, constructions, available resources (human, material) and their use at the republican, regional and community level,
- formation of complete statistical data system on agriculture,
- formation of statistical register for agricultural holdings,
- ensuring comparability with international statistical data.

4. Activities necessary for the preparation and organization of Agricultural Census in Armenia

The following activities have been defined to conduct the Agricultural Census in Armenia for the first time:

- to establish commissions (Republican and regional) for the preparation and conducting Agricultural Census,
- to prepare and adopt legal acts and documents (instruction, questionnaire, list, enumerators notebook),
- to develop a publicity campaign program (TV, radio, slogans, posters, booklets, messages, website, social network, etc.),
- to prepare budget estimates,
- to recruit and train staff,
- to prepare and conduct Pilot Agricultural Census (testing),
- to conduct Agricultural Census,
- to code questionnaires, checking, data entry, verification and aggregation,
- to publish and disseminate Agricultural Census data.

5. Preparation and organization of Agricultural Census in Armenia

Agricultural Census Department has been established in May 2013 for the preparation and conduction of the Agricultural Census.

The Pilot Agricultural Census has been conducted on 10 - 30 November 2013 to test the census procedures.

The Main Agricultural Census has been implemented on 11-31 October 2014.

Agricultural Census units were:

- all legal persons dealing with agricultural production,
- individual entrepreneurs,
- group farms (correctional institutions, military units, orphanages, organizations of social services for the elderly and disabled, education, research and experimental units),
- individual households in rural and urban areas, and in horticultural companies,
- communities.

The list of individual households was compiled in the following way:

- in rural communities with the population less than 2000 the lists of units have been formed by the village heads, based on data records of rural communities,
- in urban and rural communities with the population of 2000 or more, by specially hired employees to make a listing, based on the schematic plans of communities.

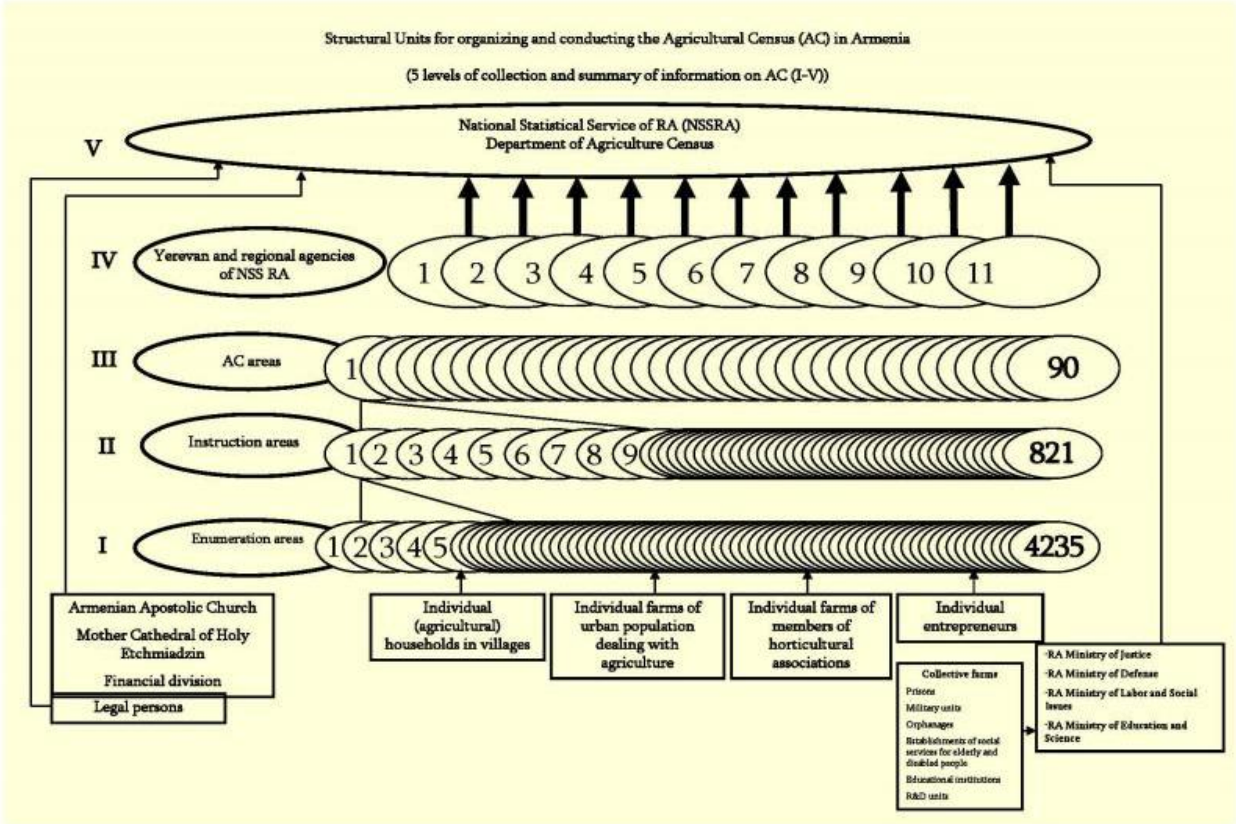
Data collection has been implemented by the completion of relevant questionnaires.

Around 250 characteristics have been included in the questionnaires, in particular the main recommended by FAO are:

- household address,
- household`s head gender, age, education, etc.,
- legal status of the household,
- the main purpose of production,

- land size, sowing areas, perennial areas,
- irrigated land and irrigation methods,
- fisheries,
- the availability and use of agricultural machinery,
- plant protection means and fertilizers,
- labour force,
- agro tourism, etc.

Figure 1: *Management scheme of the Agricultural Census in Armenia*



According to the organizational plan for 2014, 90 census areas, 821 instruction areas and 4235 enumeration areas have been established on the whole territory of the country.
Agricultural Census has been prepared and implemented by the following three stages:

1. Preparatory work
   - compilation of lists of farms in communities,
   - development of organization plans,
   - recruitment and staff training,
   - publicity and awareness campaign.
2. Carrying out of Agricultural Census
   - preliminary visits to households (farms),
   - carrying out of Agricultural Census,
   - conducting of sample control visit,
   - publicity and awareness campaign.
3. Acceptance of documents and information processing
   - acceptance of documents,
   - checking/coding of responses in questionnaires,
   - questionnaires data entry,
   - deriving of output tables.

To ensure the completeness and quality of daily collected data, operational controls of field work were carried out. The data field work was monitored in the following way. Enumerators work was monitored by instructors-supervisors, and their work by heads of census areas and their assistants, whose work in its turn by coordinators. The overall control has been implemented by heads of regional agencies of the NSS RA and the ones responsible for territorial units. International experts also participated in the field work monitoring process.
For data editing and imputation special software was developed using CSPro (Census and Survey Processing System) and SPSS that were localized and improved by international experts, taking into account the peculiarities of Agricultural Census implemented in Armenia.

6. Post- enumeration survey

Highlighting the importance of data quality, after the data collection, the post-enumeration survey has been implemented from 28 November to 14 December 2014 that comprised 3.5% of general population. Random sampling was carried out in 134 urban and rural communities of country's 10 regions.
Data are not yet finalized, and therefore at this stage it is not possible to reveal differences with other available sources.
It is foreseen to publish the Agricultural Census final results in the 4th quarter of 2016.

7. Donors support

The legislation, methodology and standards, questionnaires, publicity campaign materials, deriving of output tables, preliminary data release, etc. for 2014 Agricultural Census have been developed based on the FAO guidelines, recommendations and support of international experts, such as Mr. Michael Steiner, Expert, USDA, Mr. Rolf Selander, Senior Adviser, Statistics Sweden, Mr. Kristian Hulsager, Head, Agricultural Statistics Department, Statistics Denmark, Mr. Karsten Larsen, Head, Agricultural Statistics Division, Statistics Denmark, Mr. Thomas Bie, Resident Twinning Adviser, European Union (EU) Twinning Project “Forwarding Armenian Statistics Through Twinning” and Mr. Giorgi Kvinikadze, Mr. Oleg Cara, Mr. Vasile Petre, Experts, FAO, as well as with the support of staff of the Ministry of Agriculture of RA.
In the course of the Agricultural Census preparation, organization, implementation and data aggregation the NSS RA has studied the experience on Agricultural Census in USA, Denmark, Sweden, Russian Federation, Moldova, Georgia, Italy and Austria, and other countries. A delegation from the NSS RA visited FAO Headquarters in Rome to participate in meetings on the development of the agricultural statistics system in Armenia.
Funds have been provided by the World Bank, Austrian Development Agency/implementing agency UNDP jointly with FAO, EU budget support/ the European Neighborhood Program for Agriculture and Rural Development (ENPARD/ implementing agency FAO, United States Agency for International Development (USAID)/ implementing agency USDA.
The census budget amounted to $ 5.1 million. The number of accounted farms was 418 880. The costs per unit were $ 12.1.

8. Conclusion

Agricultural Census in the Republic of Armenia will improve current statistics, form complete statistical data system on agriculture, establish statistical registers for entities engaged in

agricultural activities, improve sample statistical tools and ensure their comparability with existing international standards, identify trends of changes in agricultural infrastructures throughout the years.
Agricultural Census will provide a wealth of new and reliable information to the Ministry of Agriculture for strategy formulation, policy making and focused action plans.
Challenges of Agricultural Census:

- lack of funds to conduct regular censuses
- lack of administrative registers
- lack of legal definition of farm, criteria for determining the farm (land size, heads of livestock, etc)
- difficulties on recruitment of large number of qualified enumerators and supervisors.

Recommendations:

- to create Farm Register
- to introduce agricultural statistics system based on Farm Register
- to introduce new methods of data collection.

DOI: 10.1481/icasVII.2016.f37b

ABSTRACT

In Sweden and in the EU there are two main sources for statistics about number of agricultural holdings and their type of farming. One is the Farm register (FR) and one is the Business register (BR). The aim of this paper is to examine and compare these two sources to find out if there is a possibility to use the BR as a source in the next agricultural census and as a consequence reduce the response-burden for some agricultural holdings and lower the total administrative cost of the census.

To achieve the aim of the study, micro level data from the FR and the BR in Sweden have been merged by the social security number or organisation number. All agricultural holdings in the FR were included and all economic activities classified as agriculture were included from the BR.

The resultsshow that the number of agricultural holdings differ between the registers and not all of the holdings in the FRare possible to match with the BR. The Swedish typology for classification of type of farming does not fully harmonize with the NACE codes (Statistical classification of economic activities in the European Community)in the BR, which complicates the comparison.

The main conclusion of the research is that the FR and the BR have different purposes and are regulated in different EU legislations which makes the use of the BR in the agricultural census difficult. However, the results show that it is possible to reduce the response-burden for someagricultural holdings in the FR and also possibilities to improve the quality in both registers.

Keywords: Farm register, Business register, agricultural holdings

1. Introduction

In Sweden and in the EU there are two main sources for statistics about number of agricultural holdings and their type of farming. One is the Farm register (FR) and one is the Business register (BR). Depending on which source is used, the number of agricultural holdings and the characteristics of the holdings differ, which makes statistics on agriculture incoherent and difficult to use.This paper explains the differences between these sources and investigates the possibilities of exchanging information between the registers.

In Sweden, an agricultural holding is seen as an entrepreneurial activityjust like any other entrepreneurial activity. That means for example that they are taxed in the same way. Also both farmers and other businesses have the same type of identifiers (social security- or organisation numbers) that would imply that the possibilities to coordinate the registers are good.According to Wallgren, A., Wallgren, B. (2014) the use of registers will “reduce the costs for both respondents and statistics producers” and also registers have “almost complete coverage of population”. Watt (2010) has studied the possibility to use the New Zealand (NZ) business frame for agricultural statistics. Watt points out that for NZ there are some significant benefits,like cost-efficiency and use of the frequently updated information in the BR, but also some challenges.

Both the FR and the BR are widely used by policymakers in Sweden. Alsofor research, in public debates and in decision making. There is a need for coherent statistics on the number of agricultural holdings and their type of farming. In the agricultural census, the agricultural holding is defined in (EC) No 1166/2008 as “a single unit both technically and economically which has a single management”. The threshold is based on number of hectares of arable land and animals and the type is decided in a typology especially developed for agricultural activities. The concepts of theagricultural census are in line with the guidelines in the World Programme for the Census of Agriculture (WCA) provided by the Food and agriculture organization of the United Nations (FAO).In Sweden the census results are used to form a FR. The BRis regulated in (EC) No 177/2008. The register consists of “all enterprises carrying on economic activities contributing to the gross domestic product (GDP) and their local units”. The agricultural activities are classified in accordance with the NACE classification comparable to other entrepreneurial activities.
In this paper micro level data from the FR and the BR have been merged to examine and compare the differences of the registers. Initially, it was not expected that all agricultural holdings would match between the FR and the BR, nor that the number of agricultural holdings would be equal between the registers.

This paper will discuss if:

- the BR can be used as a source in the next agricultural census round to possibly get faster, cheaper and more complete data
- the information in BRcan improve the quality in the FR and vice versa
- the response-burden can be reduced in the agricultural census.

2. Concepts and definitions

Each member state in the European Union (EU) shall carry out surveys on the structure of agricultural holdings, the Farm Structure Survey (FSS), according to Regulation EC No 1166/2008. The aim of the FSS is to provide statistics on the structure of agricultural holdings and enable the study of trends at the European Community level. Since the results from the FSS are in line with the guidelines in WCA,the statistics are comparable in all FAO member states. WCA has a key role in the system of integrated agricultural statistics. According to EC No 1166/2008 the surveys shall cover all agricultural holdings reaching one of the physical thresholds specified below:

- More than 2.0 hectares of arable land
- More than 5.0 hectares of agricultural land
- At least 200 m² under glass
- At least 2500 m² outdoor horticultural cultivation
- Possessed at least: 10 cattle or 10 sows or 50 pigs or 20 ewes or 1000 poultry (incl. chickens) on the reference day in June

The FSS is the main source to form the Swedish Farm register (FR). The information in the census is collected both through postal questionnaires and administrative registers. In the FR information about the holder, the area of different crops and number of animals is included. Other information is also included in the census regarding other gainful activities directly related to the holding (OGA) and people working on the agricultural holding.

The Business register (BR) is regulated in (EC) 177/2008 aiming at “a common framework for business registers for statistical purposes in the European community”. According to Council Regulation (EEC) No 696/93 the register shall be compiled of “all enterprises carrying on economic activities contributing to the gross domestic product (GDB), and their local units”. In Sweden this means that the register contains all legal persons and natural persons who fulfill at least one of the following criteria, and estates of deceased persons fulfilling at least one of the first two of the following criteria:

- Registered for VAT
- Registered as employer
- Having a registered firm
- Registered for F-tax (business tax)

The Swedish BR is a part of Statistic Sweden's (SCB) business database. It is mainly used as a population register, sample frame and as a co-ordination tool within Statistics Sweden.
The BR is mainly updated with information from the Swedish National Tax Board, other administrative registers, statistical surveys and external users.

2.1.1 Type of farming

In the FR, type of farming and the size of the agricultural holding are defined by the Swedish typology. The typology is based on standard labour requirement. These estimates are based on hectares of different crops and number of animals. The holdings are then differentiated by the scale of production.

In the BR, the economic enterprises are classified in accordance with the Standard for Swedish Classification of Economic Activities (SNI 2007). The classification is in line with NACE and generally with International Standard Industrial Classification of All Economic Activities (ISIC),which makes the register comparable with other EU and UN member states.

2.1.2 Other gainful activity directly related to the holding (OGA)

In the FR, OGA is an economic activity, but not an agricultural activity, in which the resources from the agricultural holding are used. The resources could for example be land, buildings, machines or products. Forestry is not an OGA.

In the BR,each firm can register several economic activities. In this research, activity one through five are included. The first (primary) activity has the most economic importance to the firm. The definition is therefore wider in the BR compared to the FR.

2.1.3 Employment

All persons, 15 years or older, who worked at least one hour onthe agricultural holding during one year are classified as employed in the FR, regardless of economic compensation. They can be either family members, or other permanently or temporarily persons.

In theBR, the number of employees does not have a key role. It is only used to decide the size of the company based on employment. Due to this, the register of Labour statistics based on administrative sources (RAMS) was merged with the FR. RAMS is the main source oflabour statistics in Sweden. It contains all enterprises which have at least one employed person.To be classified as employed at a specific enterprise, the activity at the enterprise must be that person's main employment, i.e. no other employment that generates a higher income for that person in November. It can be either the business owners, such as sole traders that has declared an active firm, or employed persons according to the income statement (KU). Persons between 16 – 74 years old can be classified as employed.This means that the definition is narrower in RAMS than in FR.

3. Method

3.1 Input

In this research all agricultural holdings in the FR were included for year 2010 and 2013. In the BR, all economic activities classified within NACE A1 Crop and animal production, hunting and related service activities, except 1.7 Hunting, trapping and related service activities, are included. A company can register several economic activities and the firstthrough fifth activity are included. The micro level data pertains to year 2010 and 2013.

As mentioned above,RAMSwas used in the matching process. All enterprises classified as agricultural holdings (NACE 1.1–1.6) with at least one employed person are included.

3.2 Data processing

To achieve the aim of the study, micro level data from the FR and the BR have been merged using the social security number or organisation number. This unique identifier is essential in order to link the information successfully. In the FR an agricultural holding can contain several persons, for example several family members. Primarily it is the holder that has been used in the merging and secondarily it is some other person, e.g. wife/husband, family member or other persons. Due to this, there is no one-to-one match between the registers. If several family members are registered as sole traders, this will result in two or more enterprise units in the BR but only one holding in the FR. This challenge also corresponds to the findings of Watt (2010).

4. Result

4.1 Number of units and matching result

The total number of agricultural holdings in the FR was 67 146 in 2013. That is a decrease by 6 % in number of holdings compared with 2010.

The number of agricultural holdings in the BR includes all economic enterprisesclassified within an agricultural activity (NACE 1.1–1.6), first activity through fifth activity. The total number were 130 242 in 2013. That is an increase by 10 % compared with 2010.

Table 1: *Number of agricultural holdings*

Farm register		71 091	67 146	-3 945
Business register		118 599	130 242	11 643
- of which:	active[1]	116 440	128 456	12 016
	primary activity[2]	102 923	109 774	6 851

The number of agricultural holdings in the BR that could be matched with the FRwas 61 370 or 47 % in 2013. In the FR, 79 % of the agricultural holdingscould be matched withthe agricultural holdings in the BR in 2013.

Table 2: *Number of units distributed by matching result*

	Hit against									
	Physical person		Legal person		Wife/ husband		Other persons		Total

FR in BR	47 355	46 702	4 018	4 096	1 483	1 483	1 011	869	53 867	53 150
BR in FR	56 304	57 083	4 196	4 287	.	.	.	.	60 500	61 370

4.2 Type of farming

The agricultural holdings in the FR and BR are divided by type of farming. In the FR,type of farming is based on the Swedish typology which is not fully consistent with the types in the SNI/NACE. In the FR almost 24 500 holdings or 36 % are classified as Small farms in 2013. Small farm means that standard labour requirement is less than 400 hours per year. In the BR about 50 % of the enterprises are classified as Mixed farming which includes a combined production of crops and animals but no specialised production.

Table 3: *Type of farming in the Farm register and in the Business register*

The Farm register				The Business register			
Main-, basic-, Detailed type (Swedish typology)	2010	2013	Diff.	**Division, Group, Class (SNI/NACE)**	2010	2013	Diff.
1. Crop production	20 310	18 668	-1 642	**1.1 Growing of non-perennial crops**	24 174	23 703	-471
- 11 Field crops	18 596	16 753	-1 843	**1.2 Growing of perennial crops**	682	791	109
- 12 Vegetables- ornamental- and nursery plants	741	885	144	**1.3 Plant propagation**	509	534	25
- 13 Fruit and berries	370	403	33	**1.4 Animal production**	27 564	28 103	539
- 14 Mixed crop production	603	627	24	**Including**

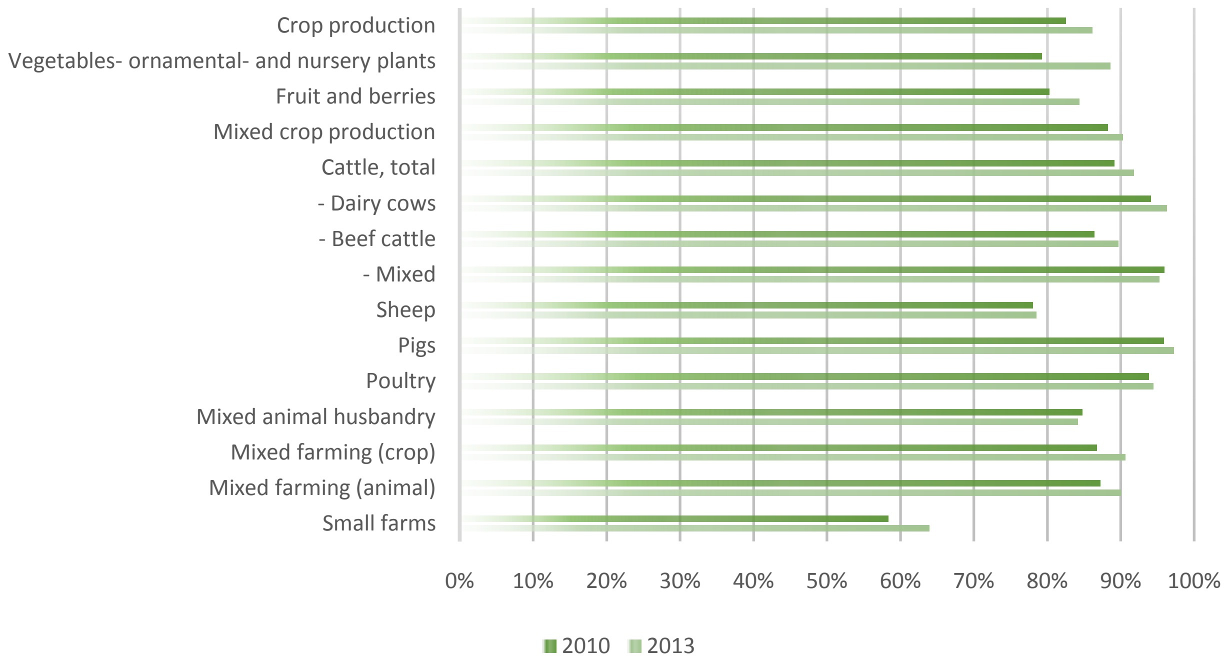
3. Mixed farming	5 048	4 301	-747	**1.6 Support activities to agriculture and post-harvest crop activities**	5 220	7 018	1 798
9. Small farms	25 046	24 498	-548				
Total	71 091	67 146	-3 945	**Total**	118 599	130 242	11 643

Figure 1 presents the share of agricultural holdings, in the FR, in each type of farming that is possible to match against the BR. Among the agricultural holdings with pig production or dairy

[1] In the Business Register an enterprise is regarded as active if it is registered for VAT and/or has employees and/or if it is registered for F-tax (business tax).
[2] The number includes both enterprises classified as active and not active.

cows, 97 % and 96 % respectively could be matched against the BR in 2013. Almost 24 500 agricultural holdings in the FR are classified as Small farms. Among this type of farming only 64 % was found in the BR.

Figure 1:*The share of each type of farming in the FR, obtained by matching FR and BR*

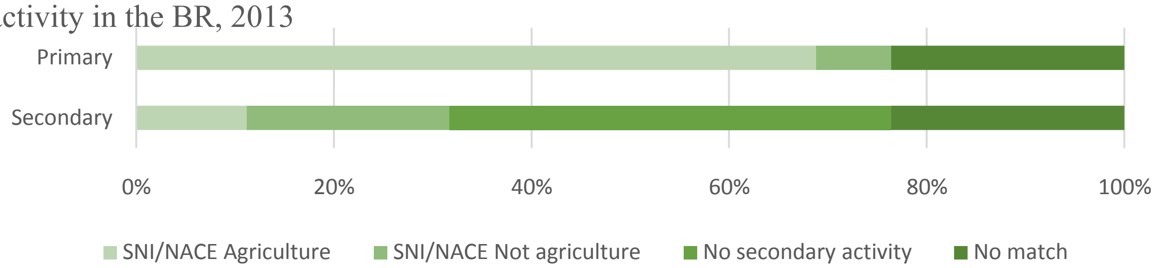


Type of farming may not be the same in the FR and in the BR due to the different classification methods. Among the 97 % holdings with pig production in the FR that could be matched with the BR, 64 % were found in the corresponding economic activity of 1.4.6 Raising of swine/pigs in the BR. 30 % of the holdings with pig production was classified as 1.5.0 Mixed farming. In total, 39 % of the agricultural holdings in the FR thatcould be matched against the BR are found in 1.5.0 Mixed farming in 2013. Bear in mind that the FR has several mixed farming types, see Figure 1. Among the 39 % of the agricultural holdings in the FR that were found in the economic activity of 1.5.0 Mixed farming, about 50 % are classified in some of the mixed farming types.However, the remaining part had a more specified type of farming in the FR compared with the BR.

4.3 Other gainful activities

In the BR, 55 165 agricultural holdings or 42 % had an activity that is not agriculture. The type of farming where the highest share had another activity was Raising of horses, 67 % of the holdings, followed by Support activities for crop production and animal production. In the FR,25 059 or 37 % of the agricultural holdings had registered an OGA in 2013. Mixed crop production and Poultry had the highest share of holdings with OGA, 51 % each. Figure 2 presents the share of agricultural holdings in the FRwithout OGA distributed by primary or secondary activity in the BR. 76 % of the agricultural holdings *without* OGA in the FRcould be matched with the BR. 69 % of the holdings have agriculture as primary activity and the remaining 7,5 % have a primary activity that is not agriculture.

Figure 2: The share of agricultural holdings in the FR without OGA distributed by primary and secondary activity in the BR, 2013



4.4 Employment

In the FR, a total number of 105 543 persons were employedin 2013, not including the business owner.The total number of employees was 57 124 persons in 2013 according to RAMS.

Table 4: *Number of employed in the Farm register and in RAMS*

		Farm register		RAMS	
Number of		2010	2013	2010	2013
Agricultural holdings		71091	67 146	40060	39031
Employment		107837	105543	57487	57124
- of which:	sole traders	92071	88463	41874	41049
	limited company	15766	17079	15613	16075

5. Discussion and conclusion

5.1 Discussion

The results of this paper indicate that the populations in the FR and the BR differ.This is mainly due to the different purposes. The BR is supposed to contain all enterprises witheconomic activities.Meanwhile, in the FR, all agricultural holdings need to be within the specified thresholds to be in the register, regardless of economic impact. In Sweden, the number of agricultural holdings in the BR are significantly higher than in the FR. This indicates that there is a lot of enterprises with relatively small agricultural activities in the BR who are not meeting the minimum thresholds conditions of the FR. Also, a number of enterprises in the BR are, for example, enterprises that have anagricultural income from renting out land. Therefore, contrary to one of the challenges that Watt (2010) struggled with, the thresholds are lower in the BR than in the FR. In the BR, there are also enterprises that raise horses and other animals, including reindeer and pets, included but they are not in the FR. Also, one holding in the FR can be linked to several economic enterprises in the BR.Due to these differences,the number of agricultural holdings is not consistent. Table 1 shows that there is an increase in the number of agricultural holdings in the BRbetween 2010 and 2013. The main reason for this is methodology changes regarding activity status. In 2010 a large number of enterprises were disconnected from their economic activity (NACE).In 2011 the rules changedagain meaning that most of the disconnected enterprises werereconnected to the economic activity, increasing their numbers.Thisindicatesthat a number of the enterprises contributes very little to GDP and that they areone the vergeof beingexcluded from the BR.

Table 3 presents that a large share of the agricultural holdings in the BR are classified as Mixed farming (NACE 1.5). Also, 39 % of the holdings in the FR thatcould be matched against the BR were classified as Mixed farming while at least half of them had a more specified type of farming in the FR. This means that the NACE classification quality in the BR can be improved by using the FR data on type of farming. Table 3 also presents the number of holdings with dairy cows.

In the FR, the number of holdings with dairy cows is collected from administrative registers at the Swedish Board of Agriculture. These are extremely reliable because each head of cattle is labeled and belongs to a given place of production and the cattle register has been merged with registers of agricultural holdings delivering milk. Table 3 indicates that the BR probably overestimatesthe number of holdings with dairy cows, perhaps due to lack of updated NACE codes. Figure 1 presents that almost all of the holdings with milk cows in the FR are found in the BR. This example also indicates that the NACE classification quality in the BR canbe improved by using the FR data.

Comparing the total share of holdings with OGA in the FR to economic activities beyond agriculture in the BR,there are no big differences between the registers.Figure 2 presents that 7.5 % of the agricultural holdings in the FR that did not report an OGA in the agricultural census did have a primary activity which was not agricultural in the BR. This indicates that there is a possibility to improve the OGA variable for some of these agricultural holdings. It also indicates that there is a possibility to reduce the response burden and improve the quality of OGA for each of the agricultural holdings in the FR that can be matched with the BR due to the information on primary and secondary activities.

Table 4 presents thatthe number of employees in limited companies are quite similar in FR and RAMS. This can be explained by the fact that limited companies to a greater extent are registered firms with payed employees. This makes it possible to reduce the response burden and increase the quality of the employment variable in limited companies.

5.2 Conclusion

In order to use information from the BR in the next agricultural census round, the ideal situation would be if the registers where completely harmonised. However, that is not realistic to expect due to:

- the FR and the BR having different purposes,
- different base regulationsand thresholds andtherefore
- the definition of an agricultural holding, type of farming etc. is not identical.

However, the resultsof this paper show that:

- It is possible to improve the quality in NACE classification of enterprises in the BR with the information from the FR and in that way facilitate the merging of the registers
- The information on non-agriculturalactivities in the BR can be used to reduce the response-burden regarding OGA for some agricultural holdings in the agricultural census and possibly reduce the non-response rate
- It is possible to use the number of employees in limited companies from RAMS to reduce the response-burden in the agricultural census

The results also show that users need to be aware of the differences between the registers in order to make evidence-based decisions on agriculture.

Strategy for Agricultural Statistics 2020 and beyond: for the future European Agricultural Statistics System (EASS)

ABSTRACT

Many important policies of the European Union, such as the Common Agricultural Policy, depend on agricultural statistics. These statistics need to be of high quality, coherent, comparable and flexible, and should be produced efficiently based on users' needs in order to best serve evidence-based policy making and monitoring. The current EU agricultural statistics system does not fulfil these requirements well enough. To address this, Eurostat launched the "New legislation on Agricultural Statistics for a strategy towards 2020 and beyond" initiative in 2014. It aims to introduce two new legal frameworks stepwise: an "Integrated Farm Statistics" Regulation which will provide the basis for collecting farm level micro-data, based on a modular approach with core, module and ad hoc surveys; and a "Statistics on Agricultural Input/Output" Regulation which will provide aggregated statistics in tabular form. These frameworks will contain basic elements such as scope, precision and quality requirements and will use common definitions and classifications, while more technical elements will be covered by secondary legislation. EU Member States will be free to choose data sources, including administrative and other new data sources.

This paper presents the Strategy for agricultural statistics 2020 and beyond and shows its suitability to meet technical and methodological requirements as well as to successfully navigate the complex institutional, legal and political context within the European Union and its 28 Member States. It can therefore serve as an instructive example for a cross-border implementation of the United Nations Global Strategy to improve agricultural and rural Statistics.

Keywords: Global Strategy to improve agricultural and rural statistics, modernisation, flexibility, comparability

1. Context of European Union agricultural statistics

The current European Agricultural Statistics System (EASS) has been developed since the early 1950s. Agricultural statistics are the oldest European Union (EU) statistics still being produced, many of them provided under legal obligations. The EASS covers more than 50 data sets sent to Eurostat, the statistical authority of the EU, by National Statistical Institutes (NSIs) or other national statistical authorities (ONAs). It consists of seven statistical domains: structural data, agri-monetary statistics, crop production, organic farming, permanent crops, animal products and livestock, and agri-environmental indicators. The Farm Structure Surveys (FSS) with a decennial agricultural census and regular interim sample surveys form the backbone of the EASS, because they are its biggest individual collections and provide reliable data on the structure of agricultural holdings in the EU. This makes it possible to analyse the state of EU agriculture, monitor changes, trends and policy impacts, and build statistical farm registers.
The main aim of the EASS is to support decision-making, policy design, implementation, monitoring and evaluation in several policy areas related to agriculture, such as the EU Common Agricultural Policy (CAP), climate change and environmental policies. Agriculture accounts for almost 40% of the EU's institutional budget (currently about 59 billion Euro annually), the EU's single highest common expenditure area, and covers 47% of the EU's territory, resulting in a very high environmental impact.

The EASS needs to fulfil a number of **requirements** because it is a part of global, regional (EU) and national agricultural statistics systems. In order from global to national, these are:

- Implement the United Nations **Global Strategy** to improve agricultural and rural statistics. This initiative aims to improve the availability and use of agricultural and rural data necessary for evidence-based decision making by 1) producing a minimum set of core data, 2) better integrating agriculture into national statistical systems and 3) improving governance and statistical capacity building (GSARS 2016).
- Support the monitoring and evaluation of the **United Nations Sustainable Development Goals** (SDG) by providing high-quality, coherent and comparable agricultural data for the SDG indicator framework (ECOSOC 2016).
- Serve **users' information needs** by producing high-quality, coherent, comparable and flexible agricultural data for the effective and efficient design, implementation, monitoring and evaluation of policies, laws and other interventions. These users are mainly policy- and decision makers at EU, national and regional levels, but also scientific researchers, businesses and citizens.

In addition, certain global, regional and national changes are acting as **problem drivers** for the EASS, exerting pressure on it to respond in order to continue fulfilling its main functions. These drivers are:

- **Changes in world agriculture** such as volatility in prices and food safety and security, changing dietary habits, e.g. Asia's growing appetite for dairy and meat, a growing and increasingly less poor world population requiring more food (60% more by 2050, according to the Food and Agriculture Organization of the United Nations (FAO)), increasing urbanisation leading to significant consequences for food consumption and food flows, and increasing agricultural concentration. These phenomena are particularly important for the EU, as agricultural exports from its 28 Member States amounted to 120 billion Euro in 2013 (in particular value-added products), with imports of just over 100 billion Euro (concentrated around animal feed and tropical products). The increasing global interconnectedness of agricultural production structures, prices, yields and supply chains can lead to complex "butterfly effects" and calls for detailed data in this area to make rapid crisis responses and generally more effective policy making possible.

- **Climate change and environmental effects** will impact food security, while more frequent extreme weather events such as droughts, floods and ensuing possible conflicts are expected to lead to food shortages and volatile prices. As agriculture has a strong environmental and climate change impact and is itself strongly affected by climate change, a thorough knowledge of what is produced where by whom and how is needed to target agricultural, environmental and related policy interventions to where they are most needed. Therefore, good data on these aspects of agriculture is needed to enable environmentally sustainable action, such as a low-carbon transition in rural areas. Moreover, the links between agriculture, the environment and the climate are complex and dynamic, and the impact of agricultural practices and products on human and animal health and welfare is strong, but not fully understood yet. Depicting all these interlinkages requires a lot from statistics.
- **The CAP has recently been reformed** and will continue to be reformed in response to changing national, European and global conditions and evolving policy. Some examples are the growing popularity of organic food, the abolition of milk quotas, and the increasing diversity of EU agriculture. The European Commission's recent work on developing the CAP for 2014-2020 demonstrated the central role of statistics in designing, implementing, monitoring and evaluating this policy. Reforms of the CAP and other relevant EU policies should therefore be reflected in agricultural statistics data collection.
- **Official statistics are also changing**. New data sources such as administrative data, various registers, results of research projects and Big Data have become more readily available. Information and communication technology and other new technologies enable modernised data collection. At the same time, national and EU budgets are more constrained, and calls to reduce the burden of data collection and production are becoming more frequent. These changes in the sources and ways of collecting and producing data require changes in the framework for agricultural statistics so they can stay up to date and avoid becoming obsolete, inaccurate or too costly.

All these developments put pressure on adapting the EASS to respond to the important growing and changing requirements and objectives. But despite many integration and modernisation efforts, the **EASS has not changed enough** yet, as a recent ex-post evaluation and problem analysis found:

- New and emerging data needs are not addressed adequately because their provision is not included in the legislative acts, the acts are not flexible and integrated enough to respond to new needs in a timely manner, and changes in official statistics are not accounted for;
- The EASS is not flexible enough and is not reacting quickly enough to emerging needs, partly due to the inherent functioning of statistics, partly due to the way the regulations have been set up, but also because of a lack of budgetary and human resources;
- The data collections are not harmonised and coherent enough because new data needs are emerging, legislation has been developed separately over many years, and there are partly different definitions, concepts and aims in different agricultural domains;
- Agricultural statistics could be produced more efficiently if the legislation is adapted so that various sources of information can be used and if Member States adopt more modern technology, but the burden and cost are appropriate considering the substantial budget of the CAP and its impact on the social, economic and environmental situation in agriculture;
- The burden of providing data is perceived as high because data needs are increasing, data collection is not harmonised, and resources continue to shrink both at EU and national level.

If these problems remain unaddressed, and the requirements detailed above therefore only partly fulfilled, continuing changes in global agriculture, the global climate, the CAP and official statistics will make the current EASS progressively obsolete and less useful. This will have more and more urgent and far-reaching consequences for Eurostat, the EU and Member States' policies, reputations and positions in a highly dynamic global order.

Therefore, the **legal basis of the EASS** needs to be updated to respond to these challenges. This is because European statistics are produced within the European Statistical System (ESS), a partnership between Eurostat and the NSIs for the development, production and dissemination of European statistics. In general, NSIs and/or ONAs collect and produce these statistics according to EU-wide statistical regulations prescribing variables, deadlines, methodologies and other aspects of statistics production in order to achieve harmonisation, comparability and full coverage. The NSIs then disseminate the data and send them to Eurostat, which validates them and disseminates official European statistics on its website. Within this system, new proposals for statistical regulations at EU level are discussed at expert, director and Head of NSIs level before they are adopted by the European Commission, the EU's executive. The draft proposal then enters the "ordinary legislative procedure" of the EU, in which the European Parliament (elected representatives from all EU Member States) and the Council of the European Union (ministers of the concerned departments from all EU Member States) discuss, possibly change and agree on laws so they can enter into force. In addition, assigned committees and the Commission can adopt "implementing acts" specifying implementing rules and details of EU laws, and the Commission is additionally empowered to adopt "delegated acts", i.e. acts that supplement or amend non-essential elements of legislative acts.

2. Strategy for Agricultural Statistics 2020 and beyond

2.1. Objectives

In response to the requirements, problem drivers and problems of the EASS and to benefit its main stakeholders, Eurostat developed the agricultural statistics strategy for 2020 and beyond in 2014, with the following specific objectives:

- Produce high-quality statistics that meet users' needs efficiently and effectively. The EASS needs to deliver the statistical knowledge base needed for the CAP and other important EU policies, while reacting to evolving data needs. The scope of agricultural statistics should be widened to include e.g. land cover, and the data must be validated in a streamlined way.
- Increase the flexibility and reaction speed of the agricultural statistics system. It should be possible to introduce new needs, statistics and methodological approaches in an easier and more responsive way. In line with the subsidiarity principle, the exact form of data collection, e.g. the choice of preferred data sources and survey methods, is up to the Member States.
- Improve the integration between agricultural, forestry, land use and environmental statistics. The EASS needs to interact with and be linked to other statistical domains, for example primary production, environmental, social and economic statistics.
- Develop a responsive and responsible governance structure for agricultural statistics. The EASS needs periodic performance assessments to ensure that it is fit for purpose, delivered within a proactive and efficient governance structure that represents the interests of data users and data providers in the ESS context.
- Improve the harmonisation and coherence of European agricultural statistics. The EASS needs a solid shared basis of common definitions and concepts to link the existing statistical domains. Furthermore, statistical thresholds need to be recalibrated to improve coverage and lower the burden of data collection, and administrative and other data need to be reused.

- Produce more statistics while lowering the burden on respondents by exploring alternative data sources and possibilities to improve efficiency. Data sets that are possibly no longer needed should be deleted, and modern information and communication technology should be used to lower the perceived burden of data collection and production.

2.2. Two-step integration approach

To achieve these objectives, Eurostat developed several possible policy options and formally analysed them based on several criteria such as legal, technical and political feasibility, coherence with other EU policy objectives, and effectiveness and efficiency. In the end, it was determined that a two-step integration process for agricultural statistics would best achieve the stated objectives.

This means that two new framework regulations will be introduced stepwise: an Integrated Farm Statistics regulation (IFS) to be in place before the end of 2018 to ensure the agricultural census scheduled for 2020, and another framework regulation on Statistics on Agricultural Input and Output (SAIO) to be adopted and in place before 2022. Together, both framework regulations will cover all aspects of the new statistical programme for agriculture and replace nine current laws. The basic legal acts include common objectives and definitions (periodicity, scope, precision etc.) and also specify, in general, the required core statistical outputs. Secondary legal acts will define technical elements necessary for a harmonised implementation of the basic acts such as descriptions of characteristics. The European Commission will have the power to amend non-essential elements of the basic act in order to ensure the flexibility needed to respond to changing policy and data needs.

The IFS regulation will provide a legal basis for the structural data on farms, including certain more detailed data on permanent crops. In addition, parts of agri-environmental statistics, for which data are needed at farm level (such as irrigation, manure or nutrient use), will be integrated into this framework regulation, as they are presently not under legislation. All IFS data will be sent to Eurostat as micro-data.
The SAIO regulation will contain aggregated crop and animal production statistics, agri-environmental statistics on fertilisers, nutrient balances and pesticides, and potentially agricultural price statistics. All these data are aggregated statistics, and no micro-data will be sent to Eurostat. They deal with agricultural inputs (prices of feed, pesticides etc.) and outputs (crop and animal production and prices). The data can be collected from farms, administrative sources, intermediaries, wholesale entities, market organisations and other sources, and can include a certain amount of expert estimates.

2.3. Methodology

Following the approach recommended by the FAO's World Programme for the Census of Agriculture 2010 (FAO 2005), both framework regulations will consist of (i) a core set of data (essential structural and production variables, e.g. farm size and land use, crops, livestock), which are to be sent to Eurostat with regular frequency (i.e. every three years), depending on the domain, either resulting from a census or a sample survey, on farms above a minimum threshold; (ii) modules that are subsamples of the core and focus on certain thematic aspects from the current list of variables (such as animal housing, irrigation or vineyards) that are needed either at lower frequency (i.e. every six or every ten years), for smaller samples, or at different thresholds than the core, but which can be directly linked to the core data and shall always be conducted together with the core; and (iii) flexible ad-hoc surveys that focus on special topics which are not traditionally part of the EASS, i.e. surveys which aim to cover the variables that fulfil new and emerging data

needs. Their exact contents will be determined later, prior to their implementation, and they are not planned to be carried out at a fixed frequency, but may be repeated as needed.
An agricultural census is needed because it is still the most appropriate way to update information on the full agricultural population in the EU. The census is the only data collection instrument that produces sufficiently reliable statistical information on farms at the lowest geographical level, and is therefore an essential source of information for governments and decision-makers. The FAO also expects its member countries to follow the standards, concepts and definitions guidelines of its World Programme for the Census of Agriculture 2020 in order to achieve harmonised and internationally comparable results and allow countries to benchmark their performance against other countries, among other advantages (FAO 2015). This and other international obligations detailed above are further reasons explaining the need for an agricultural census. However, in order to reduce the burden on the countries with a high number of very small farms, or rather households, it is planned not to oblige carrying out a census on these small units, but to allow carrying out a sample survey instead. In addition, the core, module and ad-hoc survey structure is expected to lead to a reduction of the burden of data collection on all EU Member States while fulfilling all obligations. For the census carried out under IFS, these actions are expected to lead to a reduction in the number of farms surveyed of around 30% overall (3.5 of 12 million farms), and to a reduction of the total required budget of around 18% (56 of 320 million Euro).
In order to further reduce the burden on the farmers and other respondents, the various elements of agricultural statistics should form a statistical system. i.e. data collected for production statistics, permanent crops statistics and organic farming statistics should also be used for farm structure surveys. Member States are also encouraged to use administrative data sources and to set up farm registers, and efforts are being made to harmonise definitions and reference periods across data sources. For this systematic approach to work, definitions need to be identical, and unique farm identification numbers should be introduced.

3. The future European Agricultural Statistics System

The two-step integration of agricultural statistics serves to create an effective and efficient future EASS by fulfilling the requirements and the objectives detailed above, while navigating various complex contexts and constraints, in the following manner.

Table 1: *Requirements, objectives and responses of the agricultural statistics strategy 2020*

Requirement	Response
Implement the UN Global Strategy to improve agricultural and rural statistics	– Collection of better integrated core data – Improved governance and self-assessment
Support monitoring and evaluation of the UN Sustainable Development Goals	– Collection of new and emerging data needs – Focus on data quality and validation – More legal flexibility, coherence and speed
Serve information needs of EASS users	– Collection of new and emerging data needs – Focus on data quality and validation – More legal flexibility, coherence and speed – Frequent, regular exchanges with stakeholders
Navigate the legal system of the EU	– Two-step instead of single-step integration to achieve needed new FSS legislation faster – Balanced legal architecture respecting concerns

	– Frequent, regular exchanges with stakeholders – Improved governance and self-assessment
Respect subsidiarity and proportionality	– Strategy confined to minimum required – Method of data collection left up to Member States
Objective	**Response**
Produce high-quality statistics that meet users' needs efficiently and effectively	– Collection of new and emerging data needs – Method of data collection left up to Member States – Focus on data quality and validation – More legal flexibility, coherence and speed
Increase the flexibility and reaction speed of the agricultural statistics system	– More legal flexibility, coherence and speed – Method of data collection left up to Member States
Improve ntegration between agricultural, forestry, land use and environmental statistics	– Common definitions and documentation – Unique identifiers and new data sources – Frequent, regular exchanges with stakeholders
Develop a responsive and responsible governance structure for agricultural statistics	– Improved governance and self-assessment – Frequent, regular exchanges with stakeholders – More legal flexibility, coherence and speed
Improve the harmonisation and coherence of European agricultural statistics	– Common definitions and documentation – Unique identifiers and new data sources
Produce more statistics while lowering the burden on respondents by exploring alternative data sources and possibilities of efficiency improvement	– Core, modules and ad-hoc survey system – New thresholds and special sample surveys – More use of IT, new data sources, fewer variables – Frequent, regular exchanges with stakeholders

4. Conclusions

The following general conclusions and recommendations can be drawn from the European Commission's experience in developing and starting to implement the agricultural statistics strategy 2020.

- Bold reform can lead to better outcomes than a more incremental approach, even in a complex political, legal and financial context. This also gives a better opportunity for needed changes and improvements.
- Change is necessary to remain relevant. Agricultural statistics are affected by many important and significant global developments, and the world is becoming much more interconnected and complex. This requires faster and more flexible reactions, tools and procedures from official statistics, or they risk becoming obsolete and not fulfilling their data users' needs.
- Even in statistics, political considerations need to be taken into account when designing new laws and initiatives. For example, EU Member States are sceptical of European Commission powers to adapt elements of the legislation, but these are needed to ensure the required flexibility of the agricultural statistics strategy 2020. Therefore, a compromise was struck to preserve flexibility while ensuring easier legislative passage of the IFS initiative.
- The difficult resource situation of many national governments and NSIs needs to be taken into account from the beginning in designing, implementing and evaluating statistical systems so the best possible performance, flexibility and data quality can be ensured even under heavy constraints. The EASS' Strategy 2020 is meant to accomplish

this with its structure of core, module and ad-hoc surveys and several other actions. A plan not adapted to such conditions, while possibly more attractive on paper, may not be able to deliver as well as a system better adapted to reality.

- Comparable and coherent outputs count for more than homogenous inputs, especially in a highly diverse situation as in the EU with 28 Member States that have very different agricultural, social and economic development levels, survey methods, databases and data sources, statistical traditions etc. Data collection can be conducted with the subsidiarity principle in mind in ways that are best suited to regional or national conditions, while harmonisation and comparability can be achieved by common definitions and validation at supranational or intergovernmental level.
- Cooperation and a good working atmosphere can go a long way towards making even difficult decisions more palatable than if they had been presented as *faits accomplis*.

Harnessing data revolution for cost-effective agricultural censuses in the 21st century with widely accessible and used results

Naman Keita

Senior Agricultural Statistics Consultant FAO/World Bank

Viale Terme di Caracalla, CP 64259

Rome, Italy

Naman.Keita21@gmail.com

DOI: 10.1481/icasVII.2016.f37d

ABSTRACT

Data revolution is defined as *'an explosion in the volume of data, the speed with which data are produced, the number of producers of data, the dissemination of data, and the range of things on which there is data, coming from new technologies such as mobile phones and the 'internet of things' and from other sources such as qualitative data, citizen-generated data and perceptions data'*. The other associated feature is '*a growing demand for data from all parts of society*'[1].

This emerging development will have a growing impact on all major statistical data production activities in coming years, including the Census of Agriculture. The Data Revolution raises challenges but also offers unprecedented opportunities to modernize the process of conducting a Census of Agriculture. In this 21st Century, statisticians have access to a variety of methods and tools that was not available before for conducting a census of agriculture. If used appropriately, they can generate significant efficiency savings and provide timelier and better quality data which can be widely accessed and used by a variety of users.

In a context of growing demand for more diversified and frequent data and at the same time the scarcity of resources for census taking, the new tools and methods can be used to address the new challenges for ensuring that the census is conducted in the most relevant and cost-effective way. This requires taking a fresh look at the concept of census of agriculture, the overall strategy and

[1] The UN Secretary-General's Independent Expert Advisory Group on a Data Revolution for Sustainable Development (IEAG) report A World That Counts: *Mobilising The Data Revolution for Sustainable Development*.

modalities of designing and conducting a census of agriculture in order to use innovative options for more relevant and efficient census operation.

The availability of digital and mobile computing tools for data capture using smartphones or tablets, geo positioning tools such as handheld GPS devices and more precise and cheaper remote sensing images can provide cost-effective alternatives to traditional way of collecting, centralizing and processing data depending on country situation. Also the increasing use of other sources of data such as administrative sources in a growing number of countries can complement (or even partially replace field data collection for a number of items) and reduce census burden and cost.

The FAO World Programme for Census of Agriculture 2020 in its forthcoming Volume 2 on Operational Guidelines on Implementing the Census of Agriculture will provide specific guidance on various modalities for conducting the Census in the next decade as well as the use of new tools and methods.

This paper will discuss the challenges and opportunities of the Data Revolution and its potential impact for designing and implementing a cost effective Census in the 21st Century in a context of growing demand for more complex and inter-linked data particularly for monitoring the newly adopted Sustainable Development Goals by the United Nations. The paper will refer to selected country experiences of agricultural censuses using new and innovative methods that take advantage of the on-going data revolution.

Keywords:

Data revolution, Census of Agriculture, Cost effectiveness, open data

Introduction

Data revolution is defined as ‘an explosion in the volume of data, the speed with which data are produced, the number of producers of data, the dissemination of data, and the range of things on which there is data, coming from new technologies such as mobile phones and the ‘internet of things’ and from other sources such as qualitative data, citizen-generated data and perceptions data’. The other associated feature is ‘a growing demand for data from all parts of society’[2].

However, the (UN report, 2014) indicates that ‘People, economies and societies are adjusting to a world of faster, more networked and more comprehensive data – and all the fears and dangers, as well as opportunities, that it brings’ . To remain relevant and cost effective, the implementation of an Agricultural Census in coming decades must take into account this new data and technological environment. Some of the dimensions and features of the data revolution relevant for census of agriculture include: (i) The availability of multiple data sources and their potential use in agricultural census, (ii) the use of technological innovation for data collection and faster processing (iii) the availability of tools and methods for wider dissemination, faster, easier and safer access to census data (aggregated and microdata) and metadata. The sections below will discuss some aspects of these three features as they relate to the census of agriculture.

[2] The UN Secretary-General’s Independent Expert Advisory Group on a Data Revolution for Sustainable Development (IEAG) report *A World That Counts: Mobilising The Data Revolution for Sustainable Development*.

1. Availability of multiple data sources and census modalities

One of the main features of the ongoing data revolution is the increasing number of data producers and data sources in general. This new data environment has an impact on data production strategies to better respond to the challenge of limited resources for statistical activities and growing demand for more quantity and diversified data to be produced more frequently. This challenging data requirement implies the use of multiple data sources and data collection modalities.

The new 2030 Sustainable Development Agenda (SDA) adopted by the UN in September 2015 defines 17 Sustainable Development Goals (SDGs) and 169 individual targets, including 19 multidimensional agricultural-related SDG targets and 25 global indicators for monitoring the progress towards the goals and targets. Many of these indicators require a diversified data sources for their compilation beyond traditional censuses and surveys. Administrative records for example will be an important source of some data requirement.

The changing environment and data requirements have led some countries to conduct a detailed review of their agriculture statistics programme, including alternative options for conducting the agricultural census. For example, a report by Statistics Canada on agriculture statistics program review (StatCan, 2012) includes a detailed evaluation of several options for conducting the census of agriculture within the agriculture statistics program. The evaluation uses criteria based on the six main dimensions of data quality[3] and other criteria such as respondent burden, cost, operations[4] and acceptability by user community and respondent community. The study concludes that the census of agriculture remains relevant and necessary but, regardless of the option chosen, changes are needed in order to render the program more efficient. The changes proposed include increasing the use of administrative data to gradually replace survey data and increasing utilization of remote sensing applications with a view to replacing survey items or entire surveys over the longer term.

The guidelines for the new World Programme for Census of Agriculture 2020 prepared by FAO also takes into account the new data and technology environment and proposes various modalities and data sources for conducting the census of agriculture in the next decade. The guidelines recommend that the census of agriculture may be carried out using different approaches and in various ways, depending on available resources and national conditions. The following four modalities for conducting a census of agriculture are recommended:

(i) *classical approach* in which a census is conducted as a single one-off operation in which all the census information is recorded;

(ii) *modular approach with a* core module by complete enumeration and supplementary module(s) on sample basis, using information collected in the core module as the frame for the supplementary module(s) and conducted shortly after the core module ;

(iii) *integrated census and survey modality* with a census core module (which could be lighter than in the modular approach) to be carried out on a complete enumeration basis and rotating thematic modules to be conducted annually or periodically on sample basis over a longer period between two censuses (usually ten years) through a permanent agricultural survey programme such as the Agricultural Integrated Survey programme (AGRIS); and

(iv) *combined census with* use of registers and administrative records as a source of part of the census data.

It is considered that regardless of the census modality and way of conducting a census, the crucial principle is to achieve the main objectives[5] of a census of agriculture depending on country

[3] Relevance, accuracy, coherence, timeliness, interpretability, and accessibility

[4] Defined as ability to react quickly to new demand, ability to conduct large occasional surveys, timing and compliance with StatCan Business architecture.

[5] To provide **data on the structure of agriculture, especially for small administrative units**, to provide **data to use as**

statistical capacity, national preferences and the availability of resources and data sources. The increasing use of multiple sources in census programmes is one of the changes that will be adopted by many countries in coming agricultural censuses.

2. Use of technological innovation for more relevant and cost effective census

Another important feature of the data revolution is the explosion of technological innovations. The following tools and emerging technologies are some of the innovations that are directly relevant to the design and conduct of agricultural census. They have the potential to allow faster, better quality data collection and processing during an agricultural census at reduced cost. The upcoming FAO guidelines and many recently published guidelines under the Global Strategy initiative and other sources provide practical guidance on the use of these tools and technology. This section discusses some of the main tools and technology relevant to the conduct of agricultural census.

Remote sensing (RS)

Remote Sensing refers to 'images acquired with a conventional camera or electronic sensors from aircraft or satellites. The techniques applied to process and interpret remote sensing imagery include visual photo-interpretation and a wide range of numeric algorithms' (Global Strategy, MSF, 2015).

According to (Delince, J, 2015), there are five main areas of use of Remote Sensing (RS) and aerial photos for agricultural statistics:

- Monitoring Land cover/Land use
- Frame construction
- Support to field work of censuses/surveys
- Crop area estimation
- Crop yield forecasting/monitoring**.**

The most relevant uses of RS and aerial photos for the census of agriculture are cartography and frame building, supporting field work and crop area estimation.

<u>Census frame construction and updating</u>*:* Many countries use enumeration area (EA) maps derived from the cartography work of the population and housing census (PHC) as basis for building the frame for the agricultural census. One of the main products of the PHC cartography and mapping work is a set of EA maps which are large scale maps delineating accurately the area of work of enumerators and covering the entire country. Also, a listing operation is usually conducted during the cartography of PHC. Recent and high resolution satellite images or aerial photos can provide enough details (population density, infrastructure etc..) to support the preparation and updating of EA maps. They facilitate observance of the usual enumeration area properties such as completeness, non-overlap, respect of administrative divisions, accurate delineation and allocation of attributes (Delince, J. 2015). These EA maps from PHC cartography, together with all other information collected (for example number of households or households practicing agriculture) can be used for building the frame for agricultural census based on list frame when this operation is conducted not too far from the PHC.

Satellite images can be also used to identify and subdivide the agricultural land (stratify) by intensity of land use and other land cover characteristics and therefore help in the construction of area sampling frames when this type of frame is used in the agricultural census.

---

benchmarks and to provide **frames for agricultural sample surveys**.

As indicated in (Global Strategy, MSF, 2015) recent developments have seen the emergence of some companies in the information technology sector that produce public-access images with global coverage **(Google Earth, Bing)**. A major advantage is these images are available and easily accessible, with an efficient interface. Most agricultural areas of the world are covered by Very High Resolution (VHR) images which is a significant advance, especially for countries that could not access such images in the past.

Support to field work*:* Recent advances regarding Satellite images or aerial photos can help the enumerator to optimize his travel and facilitate localization of farmers and fields during the field work of the agricultural census. Aerial photos or very high-resolution imagery can help the enumerators to access the land and/or locate the holder. Used as paper prints or on a tablet, imagery can also be used to check on farmer's declaration and minimise measurement errors.

Crop area estimation**:** The two main methods used to derive crop area statistics from remote sensing (Delince J, 2015) are: Pixel counting which is the more direct way of area estimation and Calibration methods for integration of field surveys data and image classification results. However, todate, the operational use of these methods remain limited.

During the recent census of agriculture of Morocco (2015/2016), an extensive use of orto-photos was made during data collection as these photos were considered precise enough (spatial resolution of 30 cm) to identify boundaries of holdings and their plots[6]. The scale of the orto photos was 1/5000, with photos covering an area of 3 km X 4.5 km (about 1350 ha). Below is an example of orto-photo displaying the delineation of one holding composed of one parcel and plot.

Source: Ministère de l'agriculture et de la pêche du Maroc (2015)

[6] The average farm-size is 1.6 hectares in Morocco, according to (USAID Country profile for Morocco: http://www.usaidlandtenure.net/sites/default/files/country-profiles/full-reports/USAID_Land_Tenure_Morocco_Profile.pdf)

Global Positioning System (GPS)

The global positioning system (GPS) is the oldest and best known global navigation satellite systems (GNSS). A GNSS is a system based on a network of navigation satellites that is controlled by ground stations on Earth which continuously transmit radio signals – captured by receivers – to determine the receiver's geographical location (longitude, latitude, and elevation) on the Earth's surface (Global Strategy, MSF, 2015).

The expanded availability, low cost and improved accuracy of handheld GPS devices provide an opportunity to support field activities during a census of agriculture: geo-referencing plots, household or headquarters of holdings; locating sample units or measuring the area of a plots.

Geo-referencing **:** In addition to its use during the cartographic operations to geo-reference boundaries of EAs, GPS can support enumerators during data collection. For each enumeration area, headquarters of holding units can be identified using GPS coordinates on handheld GPS devices or mobile digital device equipped with GPS. When integrated in EA maps, this information can significantly facilitate the field work of the enumerators. A more extensive elaboration on the use of GPS is available in the (UNSD, 2009).

Measuring plots with GPS: GPS is very useful to measure the area of plots on the field and recent studies (Carletto et al., 2015) suggest that technological advances with moderate-priced GPS have led to significant improvements in accuracy of measurements even for small plots. GPS can also be used as a tool for quality control, for point location control in objective yield surveys when used during the census.

Computer Assisted Personal Interview (CAPI) on laptops or notebooks, tablets and Smartphones:

With increased capacity of mobile electronic devices (such as laptop computers, tablets, Smartphones, etc..), large geographical coverage of internet and mobile phone networks and availability of suitable packages, data collection activities during censuses and surveys does not have to rely only on paper questionnaires. In fact, a comprehensive study conducted by (Caeyers, B. and all, 2010) using a randomized survey experiment among 1840 households, designed to compare pen-and-paper interviewing (PAPI) to computer-assisted personal interviewing (CAPI) found 'that PAPI data contain a large number of errors, which can be avoided in CAPI'. A growing number of countries are now using CAPI in data collection activities. An overview of the use of CAPI for agricultural census is provided below[7].

Data capture: Mobile electronic devices with adequate CAPI software can be used to directly capture data in the field, using electronic questionnaires. The electronic questionnaires usually contain the same questions types like on paper questionnaires, but also some new question types not available with PAPI. Some CAPI applications allow the capture of the geo-coordinates of the statistical units, take photos, and scan and record barcodes of items which are present within the statistical unit.

Field data editing and validation: The use of CAPI facilitates the implementation of skip patterns through 'enablement conditions' which are pre-programmed instructions, activating or deactivating questions based on the answer to a previous question. CAPI also provides census and survey designers with validation conditions which are pre-programmed instructions that anticipate an answer to be in a certain range and showing a message in case the answer does not fall in the range.

[7] The main source of information used for this overview is a technical paper prepared in May 2016 by Michael Rahija, Research Officer at the Global Office of FAO Global Strategy as input to World Programme for Census of Agriculture 2020 Volume 2 (forthcoming).

Data transmission and centralization: The use of CAPI, allows a quick transmission of census data captured to a centralized database for further processing. Data is usually transmitted over cell phone and Wi-Fi networks (available in most tablets) . Some tablet devices offer a slot for a SIM card to access cell phone data networks. Finally, some CAPI applications also offer tools for offline data transmission.

Other use of CAPI include: Geo referencing statistical units using tablet with GPS and use for optimizing logistics and supporting enumerators, using GPS and paradata for monitoring survey progress.

An important benefit of CAPI is the savings in costs related to the use of paper questionnaire: paper and printing cost, logistics and storage cost, cost of computers and personnel for data entry. However, equipment and software costs for CAPI should be considered when comparing to paper questionnaires. This cost may be substantial for a comprehensive operation such as a census of agriculture. Equipments may be also re-used in subsequent surveys resulting in additional savings. Data quality should also be improved thanks to field editing and validation features. Finally, timeliness should be also enhanced with quick transmission and centralization and the absence of any further data entry work.

There may be also some limitations in the use of CAPI for census of agriculture in terms of operational constraints, particularly in developing countries, such as limited field personnel able to operate the electronic devices, poor internet and cellular phone network coverage, poor electricity availability in rural areas for recharging batteries and difficult operating conditions (sun, dust, rain poor light etc.). Other limitations reported include poor visibility of screens, slow processing when volume of data increases. A detailed study and testing is recommended before adopting CAPI in a wide scale operation such as a census of agriculture.

Iran was one of the first countries that have successfully implemented its agricultural census using CAPI on tablets; this was during its fourth Iranian Census of Agriculture carried out from 27 September to 9 November 2014 [SCI, 2014]. In order to collect data from the estimated 4.3 million holdings of Iran, 5550 enumerators were mobilized and 7500 tablets were procured. It is reported that there was substantial cost savings and considerable reduction in time lag between data collection and data availability (preliminary results were available within 6 months). Also, the tablets were to be re-used for several other future surveys (Keita, N. 2015).

Computer Assisted Telephone Interview (CATI) and Computer Assisted Web Interview (CAWI[8])

With the considerable developments in ICT during the past decades, remote data collection methods are increasingly being used in countries where the conditions are favourable, reducing considerably the cost of data collection. CATI and CAWI are two such methods. In CATI, data is collected via telephone interview (respondents are contacted by phone and data is entered into electronic questionnaires) while in CAWI, census notice is sent to respondents with instructions on how to access the web (online) questionnaires with their secure access code, phone number to call for help and how to complete it online. The web questionnaire usually includes navigational help information, drop-down menus and online edits similar to the one based on CATI questionnaires. Skip patterns are built in the web questionnaires so only questions related to the type of farm operations are presented to respondents.

[8] Also known as CASI: Computer Assisted Self Interview

Several countries such as Iceland, Spain, Canada, Poland have used these remote data collection methods in a mixed mode (combined with other data collection methods) during their census of agriculture.

3. Wider access to aggregated data, safe access to micro data and open data

The current environment is characterised by a phenomenal development in computer and software capacity, wider internet connectivity and emergence of standards, protocols, methods and tools for data archiving, safe and on-line access to macro-data and micro data. This new environment has opened a new era for potentially accessing census data both in aggregated form and micro data on an unprecedented scale.

There are now digital preservation standards that make it possible to archive and manage digital data over the long term. More detailed guidance on these standards are available from the International Household Survey Network (IHSN) [9] Principles and Good Practice for Preserving Data.

In addition to the traditional paper publications of aggregated census results, a wide variety of electronic products can be made available and easily accessed as stand alone or via internet to satisfy the needs of a wide range of users.

Macro-data aggregated in statistical tables, in graphical or cartographic forms can be made available to the general public online in databases or on the web pages of the census agencies. Aggregated data may also be disseminated through optical disks (CD-ROM or DVD-ROM) and/or on a pen drives. Data can be visualised (often interactively) using appropriate GIS packages and on cartographic supports such as atlases in printed or electronic format.

There is a growing demand for more open data with possible access to micro-data. For a long time this was not possible in many countries, due to the constraints resulting from the statistical laws (confidentiality of individual information) and lack of standards and technical tool to avoid the risks of statistical disclosure. Nowadays, guidance is available for adopting an adequate legal and policy framework which respects the confidentiality provisions in the statistical law for safe access to micro-data (see see http://www.gsars.org/providing-access-to-agriculture-microdata-a-guide/). Moreover, a lot of progress has been made in terms of technical tools for controlling the risks of statistical disclosure through anonymisation of micro-data to respect confidentiality requirements. Finally a variety of methods for formatting data files for safe access to micro data is available, including Public Use Files, Licensed use files, Remote Access Facilities, Data enclaves, Deemed Employee. Further details on these methods of access can be found at: http://www.icpsr.umich.edu/icpsrweb/content/deposit/guide/chapter5.html

4. Concluding remarks

There are features of the current data revolution that can be an opportunity for conducting cost effectively agricultural censuses in this 21st century to respond to the needs of a wide range of data users. Depending on country conditions, tailored census modality may be considered and technological innovations can facilitate timely data collection and processing. Developments in computer and software capacity, wider internet connectivity and emergence of standards, protocols, methods and tools for data archiving, online access to macro-data and safe access to micro data have created a completely new data and technological environment. This new environment has

[9] International Household Survey Network (IHSN) 2009, Working Paper No 003, Principles and Good Practice for Preserving Data

opened a new era for potentially accessing census data both in aggregated form (macro-data) and micro data on an unprecedented scale. Detailed guidelines are also available on the use of these innovations for agricultural censuses and sample surveys.

ABSTRACT

As the frequency of hydro-climatic natural disasters increases so do the financial, human and economic costs in the agricultural sector. Over the past several decades, billions of dollars of private and public sector flows have been spent to reduce the impact of such disasters on populations exposed to them. There are both domestic and international sources for such flows. Estimating the requirement for these flows, as well as looking at the responsiveness of these different forms of support and their impact in mitigating the impact of disaster and aiding recovery are important areas of study. This session will be concerned with some of the key issues surrounding financial flows to support agricultural livelihoods in natural disaster contexts. Included within the scope of the session be questions concerning the measurement of damage and loss in the agricultural sector due to natural disasters. As such papers are invited which focus on the following topics and areas:

- What is the evidence for the responsiveness of public aid flows to different kinds of disasters affecting agriculture and how can we measure the impact of these flows on recovery?
- With globalization and the rise of the internet, private remittance flows are becoming a moreand more important component of disaster relief. How can remittances be measured systematically? What kinds of support do they provide to people living in rural areas? What are the critical conditions determining the effectiveness of remittances as a way of reducing vulnerability and aiding recovery from disasters in agriculture?
- What role can social insurance play in disaster mitigation and prevention for agriculturalcommunities, particularly in contexts where formal insurance and credit markets do not work well or at all. How can the impact of such forms of insurance be measured?
- The financial implications of disasters in agriculture and the subsequent needs in terms of thedollar value of recovery are commonly estimated using Post Disaster Need Assessment (PDNA) methodology. What are the limitations of this approach and how can post disaster assessment techniques be improved in practical ways?"

ABSTRACT

While animals are an integral component of rural economy, India's disaster management laws and policies magnifies vulnerability of livestock. Every year, India faces hydro-climatic natural disasters such as floods and cyclones which expose the existing vulnerability of livestock. It is expected that the disaster management programme of the government of India will include livestock protection in recognition of their contribution to the agricultural sector. Legal instruments of disaster management hardly take into account the plight or impact of livestock washed away, injured or dead. The anthropogenic neglect of animals is not only an ethical neglect but also increases the vulnerability of the already vulnerable.

A careful review of the Disaster Management Act 2005, Compendium of Laws on Disaster Management 2015, and National Policy on Disaster Management 2009, throws light on the absence of mention of social insurance for livestock. The Disaster Management Act makes no clear legal obligation towards animals during emergencies, and the Compendium of Laws on Disaster Management does not speak of livestock

protection during natural disasters. The National Policy provides for proper and speedy disposal of animal carcasses and recommends planning appropriate measures with the community for livestock protection during and after disasters. In all these, there is a conspicuous lack of social insurance for livestock in post-disaster recovery phase.

Under the 10th and 11th Five Year Plans, the Livestock Insurance Scheme was launched by the Ministry of Agriculture, Government of India, on a pilot basis. In the subsequent years, more districts came to be included under this scheme. The Livestock Insurance Scheme is an illustration of social insurance that offers monetary indemnification to farmers and cattle-rearers in case of livestock death. Since the premium of the Livestock Insurance Scheme is subsidized by the government, it aims to work well for Indian agricultural communities which are often poverty-stricken so that formal insurance and credit markets are no viable for them.

There is a need to integrate social insurance for livestock into disaster management. It indicates mainstreaming livestock protection into disaster management design, planning, and implementation. The Livestock Insurance Scheme employs both “Area approach” and “Individual approach” to determine livestock loss due to natural disasters. These approaches should be extended to cover social insurance for notified livestock. Furthermore, India requires an appropriate database of livestock. The Ministry of Agriculture, in cooperation with different state governments, conducts Livestock Census on a periodic basis. However, it has limitations which make impact assessment problematic.

Impact assessment of the social insurance scheme for livestock may be improved with three innovations. Firstly, mapping notified livestock according to area – the lowest unit of area could be “village” at rural level and “municipality wards” for urban areas. Secondly, costing of social insurance should be estimated based on affected areas for which time-series data of natural calamities need to be used. Thirdly, developing loss function based on various parameters which need to be worked out.

Thus, this paper intends to present a blue print of improved social insurance of livestock in India based on available data.

Keywords: Livestock Insurance Scheme, NGOs, Subsidy, Premium

1. Introduction

During disaster management, it has been observed that animals are generally marginalised. Animals need as much protection as human beings in disaster situations. In India, natural disasters like floods and cyclones are common. Abandoned animals display a natural tendency to instinctively move away from flash flood waters. They move to higher grounds wherever available. In doing so, they are exposed to risks of drowning, injury, and death. Evacuation, rescue and rehabilitation of animals will depend on the extent of commitment and human-animal bond. In this paper, animals refer mainly to livestock.

Even as animals are integral to rural economy, India’s disaster management laws and policies magnifies vulnerability of livestock. The disaster management programme hardly takes into account plight or impact of livestock washed away, injured or dead. This anthropogenic neglect of animals increases vulnerability of the already vulnerable. The Ministry of Agriculture (MoA), Government of India (GoI), had flagged of the

Livestock Insurance Scheme wherein half of the premium was subsidized by the Central Government. This scheme offered monetary indemnification to farmers and cattle-rearers in case of livestock death. This paper intends to present a blue print of improved social insurance of livestock viable in rural India. To this extent, the paper has been divided into five sections- Place for animals in Disaster Management Laws and National Policy, Livestock Insurance Scheme, Critical Evaluation of Livestock Insurance Scheme, Strategy for Improvement of Social Insurance for Livestock Safety from Natural Disasters, and Conclusion.

2. Place for animals in Indian Disaster Management Laws and National Policy

2.1 Disaster Management Act 2005

Enacted by the Parliament in 2005, the Disaster Management Act does not deal with animal protection. There is no mention of the word 'animal' so that Central and State Governments have no explicit legal obligation towards animals during disasters. **This anthropogenic neglect of animals is an ethical neglect.** Take the case of Himalayan Tsunami in 2013. Though the disaster affected human beings *and* animals, search and rescue teams were mainly dispatched for people as the death toll reached triple digits. It became difficult to count the number of animals which perished or struggled to survive. Non-governmental organizations (NGOs) such as People for Animals (PFA) and Humane Society took the responsibility to rescue and provide relief to trapped and injured mules and livestock (Lobo 2013). Even then, the role of NGOs seemed peripheral to that of the Central and State Governments and the National Disaster Response Force (NDRF). Since the Disaster Management Act does not mention "animals" and makes the provisions very general that these animals get marginalised, their agony ignored, and their rescue, relief, and treatment side-lined. Hence, the Act is embedded in a parochial bias that legitimises survival of the highest (and fittest) form of life.

2.2 Compendium of Laws on Disaster Management 2015

Interestingly, the Compendium hinted at animal safety in case of biological disasters. The Ministry of Health and Family Welfare (MoH&FW) was declared as the nodal ministry for the management of biological disaster. The MoH&FW would cooperate and coordinate with the Ministry of Agriculture (MoA) if animals and crops were affected. Compared to the Disaster Management Act 2005, the Compendium may be seen as an improvement that takes animals into account. Nevertheless, it came as a surprise that the Compendium did not have laws that would cater to animal protection during natural disasters as well as other kinds of man-made disasters. Post Phailin in 2013, NGOs like Action for Protection of Wild Animal (APOWA) found "The unspeakable misery of animals cannot be described in words" (Ranjan 2013). The International Fund for Animal Welfare – Wildlife Trust of India (IFAW-WTI) initiated its Rapid Action Projects and Emergency Relief Networks (ERN) to bring together over 400 animal rehabilitators from across the country.

2.3 National Policy on Disaster Management 2009

In two chapters, the National Policy cites animals in disasters. In chapter 5 entitled "Disaster Prevention, Mitigation and Preparedness" and chapter 7 entitled "Response".

In the former, under Section 5.2.9 it states "Proper and speedy disposal of dead bodies and animal carcasses deserves due weightage" (National Policy on Disaster Management 2009: 20). Except for reference to animal carcasses, this chapter has no other reference to animals. Instead of animal protection, efficient disposal of animal carcasses receives "due weightage". In doing so, it prioritises animal carcasses over animal lives. In the latter chapter, section 7.10.1 caters to "Animal Care". This section fares better than its predecessor. It takes cognizance of animals, domestic and wild, that vulnerable to the effects of natural and man-made disasters. It recommends planning appropriate measures to protect, shelter, and feed them during and after disasters. It suggests community effort as much as possible for the above because communities have demonstrated compassion to animals during disasters.

3. Livestock Insurance Scheme

One of the popular ways to tackle risks is by way of insurance. Insurance can become an effective tool to brave the risks posed to livestock by natural disasters. In India, the Department of Animal Husbandry, Dairying & Fisheries, Ministry of Agriculture, Government of India implemented the Livestock Insurance Scheme (LIS) first as a as a pilot study in 100 selected districts for two years from 2005 to 2007 (10th Five Year Plan and 11th Five Year Plan) and then on a regular basis in 100 newly selected districts of the country from 2008 to 2013. Thereafter, LIS was extended to 300 selected districts in the states. India has a total of 675 districts of which LIS covered 500- a remarkable achievement indeed! This Centrally Sponsored Scheme (CSS) would be carried out by the State Implementing Agencies (SIAs). States without SIAs would depend on the State Animal Husbandry Departments for implementation of LIS.

LIS has twin objectives that cater to farmers and cattle rearers and the insurance sector. It intends to provide protection mechanism to the former in the event of animal loss due to death and popularize livestock insurance in order to attain qualitative improvement in livestock and their products. Initially, it covered only crossbred and high yielding cattle and buffaloes but later aimed to include indigenous cattle, yak & mithun. The insurance amounts to maximum of the current market price of the insured animal. The insurance premium is subsidized whereby 50% is borne by the Central Government for a maximum of 2 animals per beneficiary for a policy of maximum of 3 years. The broad guidelines of LIS may be found in
http://uldb.org/pdf/Guidelines_for_Livestock_Insurance_Scheme.pdf,
http://dahd.nic.in/sites/default/files/Advisory%20LIS%20%202_0.pdf.

4. Critical Evaluation of Livestock Insurance Scheme

Despite the benefits and scale of coverage of LIS, there are concerns which require attention. Firstly, the insurance scheme does not consider cases of missing livestock in times of natural disasters. Secondly, there is no subsidy on premium against disability of livestock due to natural calamities. As the subsidy on premium is restricted only against death of livestock, the entire cost of premium against disability will have to be borne by beneficiaries. Thirdly, LIS is meant for high yielding cattle and buffaloes which directly pertain to commodification of animals and exclusive of cultural and ethical dimensions. Livestock may not be high-yielding due to nutritional deficiencies in poor households or arid regions in the country or both. They may not be productive for the market but their yield may be enough for daily household consumption. In addition to being a form of wealth, animals also become part of the household. Humans develop an emotional bond with animals that is part of everyday culture. It is quite common to see animal worship in India, particularly *Gau-Mata*. Their lives are revered as much as the lives of human beings which explain why it is unethical to neglect them during natural catastrophes. The emphasis on high yielding milch animals indicates the worth of livestock is measured in terms of market value. Those which are not market-worthy are not eligible for protection at all. For India, this is a very problematic stance that entirely omits cultural and ethical value of livestock. Lastly, this scheme does not address issues that contribute to incidents of moral hazard or fraud often complained by insurance companies.

The Livestock Insurance Scheme employs both “Area approach” and “Individual approach” to determine livestock loss due to natural disasters. Better known as homogeneous area approach, here homogeneous livestock area is assumed as the unit for estimation of yield and payment of compensation. The area is homogeneous in terms of livestock and annual variability in livestock yield. The unit area of insurance, that is, the aforementioned selected districts is decided by the Central Government. The Central Government permits only one insurance company to handle livestock insurance in a state normally, however, in case two or more companies bid the same premium rate then the area is equally divided in terms of Revenue Divisions or in absence of Revenue Divisions, region wise (Livestock Insurance Scheme 2013). This approach has the provision of data on yield variations (Singh 2010). In the individual approach, the farmer or cattle rearer is compensated fully for the losses suffered. The LIS mandates that the method of settlement of claim should be very simple and prompt to preclude unnecessary obstacles to the insured. It clearly states that only four documents would be required by insurance companies for settling claims- First Information Report with the Insurance Company, Insurance Policy, Claim Form and Postmortem Report. All insurance claims must be settled within 15 days positively after submission of requisite documents. Documents or forms for insuring and settling claims must be made available by the insurance agency in local language and English language. It is highly recommended that these approaches be extended to cover social insurance for notified livestock.

Finally, India requires an appropriate database of livestock. The Ministry of Agriculture, in cooperation with different state governments, conducts Livestock Census on a periodic basis. However, it has limitations which make impact assessment problematic. The recent 19th livestock census report do not match with the National Sample Survey Office (NSSO) survey report. The former pegged the number of sheep and goats at 200 million in 2012-13 while the 70th round of National Sample Survey represented a steep fall in their numbers to 99 million. The former also showed the number of poultry at 729 million in 2012-13 while the latter survey reported a huge decline to 255 million. The discrepancy in figures is unsettling since the livestock sector contributes almost 25.6 per cent (at current prices) of total value of output in agriculture, fishing and forestry sector while the overall contribution remained at 4.11 per cent of total Gross Domestic Product at current prices during 2012-13. The trends also differed between livestock census and the NSSO report. Agro-experts were of the opinion that mismatch of data on livestock was nothing new. The mismatch happened even in 1982, 1992, 1997 but the concerned ministry never rectified it (Choube 2015).

5. Strategy for Improvement of Social Insurance for Livestock Safety from Natural Disasters

To begin with, impact assessment of LIS needs to be improved. This may be done in three ways. Firstly, mapping notified livestock according to area – the lowest unit of area could be "village" at rural level and "municipality wards" for urban areas. Secondly, costing of social insurance should be estimated based on affected areas for which time-series data of natural calamities need to be used. Thirdly, developing loss function based on various parameters that need to be worked out.

A holistic strategy to enhance livestock safety from natural disasters requires active participation of civil society in addition to LIS. As discussed earlier, NGOs play a very crucial role in post-disaster animal recovery, rehabilitation and treatment. Livestock safety can be delegated to dedicated NGOs at the pre-disaster stage itself. Coordinating with the respective State Disaster Management Authority (SDMAs), State Animal Husbandry Departments, and SIAs, the NGOs can be deployed to evacuate livestock to animal shelters that are specially built keeping in mind their needs. General trends in evacuation show that owners are compelled to leave their animals behind. NGOs can prevent death, disability or missing of animals and, thereby, they can reduce overall loss of animal wealth.

The package called LIS should include safety net against disability or missing of animals. It is rightly argued that the number of claims per time period, will rise as the range of claims which the scheme is authorised to handle is increased (Mosley 1989: 7). However, the number of claims will not increase drastically with livestock safety planning and active intervention of NGOs at the pre-disaster stage itself. This helps to thwart fears of insurance companies and expand current protection mechanisms.

Insurance companies often complain of moral hazards or frauds in livestock insurance claims. Frauds arise when it becomes difficult to determine whether the animal in the claim is the insured cattle (Dalal et al. 2012: 5). The cause has been attributed to identification problems of the correct animal. The real problem lies elsewhere. Based on the amount of premium paid by the farmer and cattle rearer, they wish to maximize the returns from it. Since the subsidized premium is valid only for two animals, insurance for more than two animals will entail full payment of premium by them. Poverty makes it unaffordable to insure more animals. Little wonder, economic rationality appropriates loopholes in identification of insured animals to claim compensation for uninsured assets. Thus, frauds emerge not because rural poor are malicious but out of constraints of poverty and subsidy limitations in LIS.

A way out may be modeled on the logic of donor-funded "food for work" programme. Here, it may be re-designed to a donor-funded "insurance for risk reduction work" programme (Linnerooth-Bayer 2009: 391). Such a programme has the potential to become a significant source of insurance for farmers and cattle rearers with more than two animals. Income from this source will assist to finance premium on more animals. LIS is valid for a maximum period of three years. In case of no death of livestock in three years, farmers and cattle rearers do not get either the insurance amount or a refund of the premium amount. This factor can lead to reluctance towards LIS or contribute to negligence of animals during disasters. This challenge can be grappled in this way- the insurance company can reduce the amount of premium based on the accumulated insurance amount which will act as incentive for farmers and cattle rearers to insure more livestock. Along with the "insurance for risk reduction work" programme, farmers and cattle rearers will be in a position to afford further insurance. In return, insurance companies get more business as well as lower cases of fraud. Given the role of NGOs in livestock safety, it will help to lower cases of real claim too.

6. Conclusion

Different beings experience disasters and vulnerabilities differently. Compared to human beings, animals including livestock are greatly vulnerable so much so the number of injured, missing, and dead may exceed that of human beings in disasters. This study shed light on the disaster laws and national policy to mitigate disaster risks to livestock. The need of the hour requires a direct approach to livestock emergency preparedness and response. It is strongly recommended mainstreaming livestock protection into disaster management at central and state levels. Mainstreaming would transform their marginality and induce greater sensitivity into disaster management design, planning, and implementation. Simultaneously, the government should train animal owners to be self-reliant with respect to livestock safety and evacuation (Heath 2001: 1904).

The Central Government sponsored LIS addresses death of livestock due to natural calamities like floods and droughts. However, this scheme is not foolproof which restricts impact assessment and a holistic conception of livestock safety during natural disasters. It was suggested that the role of NGOs be recognized and encouraged at pre-, during, and post-disaster stages. Additionally, it was proposed to introduce donor-funded "insurance for risk reduction work" programme and trim down premium on accumulated insurance amount which will act as incentive for farmers and cattle rearers to insure more livestock. These measures would decrease incidents of fraud and expedite the growth of insurance sector in rural India.

Macro-scale assessment and response to natural disasters An ODA approach[1]

Maria Caterina BRAMATI[2] Neil MARSLAND[3]
DOI: 10.1481/icasVII.2016.f38b

Abstract. Climate driven disasters are increasing in frequency and intensity due to climate change. These events affect countries causing severe damages and injuries. In rural areas, climate related disasters cause signmificant disruption to lives and livelihoods. A recent FAO study estimated that 25% of all damage and loss due to natural disasters was absorbed by the agriculture sector. In relation to drought, this figure rises to a staggering 84% . Humanitarian aid and other financial flows are mobilised to support those affected by disasters, such flows are intended to reduce the effects of disasters on households. But how responseive are these flows to the occurrence of disasters and what effect or impact do they have on recovery? In order to examine this, we have analysed time series data on significant flooding events, as provided by the Dartmouth Observatory repositories, the FAO land-cover database, and the ODA yearly data. Other demographic and economic variables are also included in the analysis. The responsiveness of donors to floods is measured by looking at the volume of aid comitted and disbursed following a major flood event from 1985 onwards. In addition, the effectiveness of the response in recovery from these shocks is evaluated using outcome variables related to sources of rural livelihood, of thse the most important is the change in land cover and land under different types of crops.

Keywords: Natural disaster, Vulnerability, Land cover, Panel data

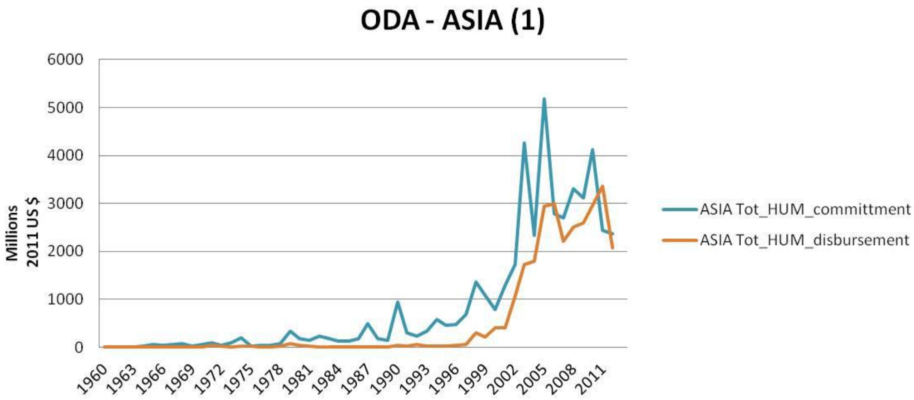
1 Introduction

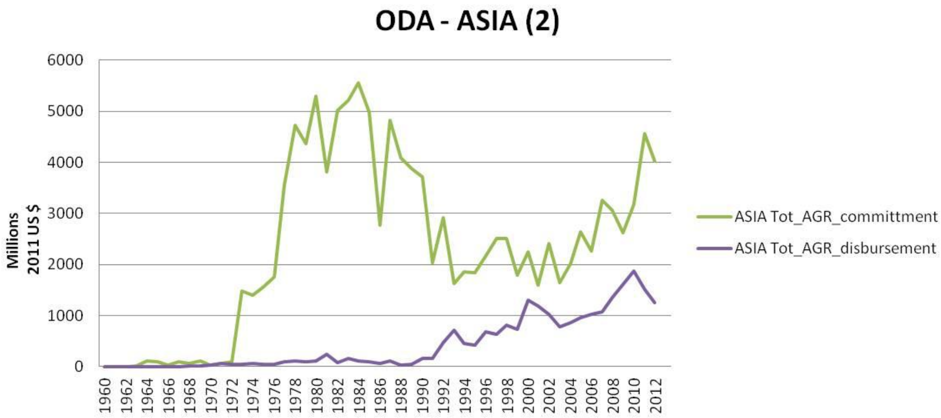
The relationship between humanitarian aid and need has been the subject of much debate in the past decade and has been one of the main motivating factors behind the so-called *Transformative Agenda* of the Inter-Agency Stranding Committee[4]. The lack of a clear relationship between aid and need was a clear conclusion of a seminal paper by Darcy and Hoffman in 2003 who concluded that *international humanitarian financing is not equitable, and amounts allocated across various contexts do not reflect comparative levels of need*.

Charting the relationship between aid flows and severity and magnitude of disasters is an important tool to inform policy in this field.

In a similar vein, there has been considerable sceptiscism regarding the impact of humanitarian aid flows on the populations whom they are intended to assist. This is partly due to the inherent difficulties in attributing changes in income and food security after a disaster with particular aid flows. It is also, however, partly due to the absence of commonly accepted measures of impact.

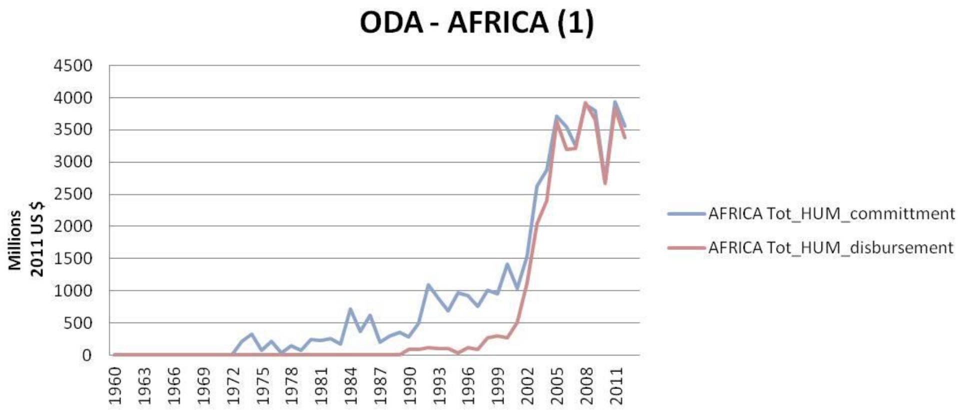
ODA deflated disbursements in Asia

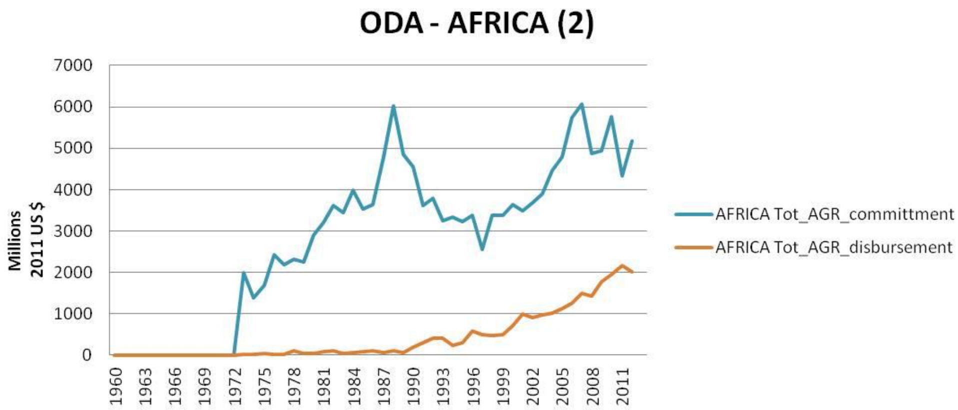




4 The Inter-Agency Standing Committee (IASC) is the primary mechanism for inter-agency coordination of humanitarian assistance.

ODA deflated disbursements in Africa





Recent studies present a mixed picture of the relationship between aid flows and disasters. Focusing specifically on hurricane responses, Yang (2008) concludes that foreign aid and foreign remittance flows seem to increase, whereas private flows turn negative (“capital flight”). Looking at a broader set of disasters, Stromberg (2007) finds that over a 10 year period (1995 – 2004) DAC donors were more likely to give relief the larger the disaster and the poorer the potential recipient country and if the disaster is in the news. Conversely, David (2010) finds that whilst international aid to low-income countries increases following geological disaster shock, in more general circumstances, the responses of aid flows to natural disaster shocks are not statistically significant. In particular, no relationship was found between aid flows and climatic natural disasters. The lack of aid response to climatic shocks is supported by evidence from Raddatz (2007 and 2009).

As a field of research, the economics of disasters can be best described as nascent. The 1969 book entitled “The Economics of Natural Disasters: Implications for Federal Policy” by Dacy and Kunreuther is often regarded as the fields pioneering work, though there have been relatively few subsequent studies. Cavallo and Noy (2009) state that *compared to the vast amount of research done in natural sciences and other social sciences, economic research on natural disasters and their consequences is fairly limited*.

Whilst the field is limited, a few important strands can be identified.

One strand looks at the effects of disasters on economic growth. Within this some studies consider the short-run effects on GDP while the second examines the long-run effects of disasters on economic growth. The short-run studies include: Albala-Bertrand (1993), Kahn (2005), Anbarci et al. (2005), Bluedorn (2005), Raddatz (2007), Strobl (2008), Loayza et al. (2009), Noy (2009), Rodriguez-Oreggia et al. (2009), Leiter et al. (2009), Mechler (2009) and Hochrainer (2009); while long-run studies include: Skidmore and Toya (2002), Noy and Nualsri (2007), Cuaresma et al. (2008), Jaramillo (2009), Raddatz (2009) and Hallegatte and Dumas (2009). Compared to the many short-run studies there have been fewer long-run studies conducted in the literature.

The conclusions of these different studies are variable depending on the data sets and the methodology used, however most studies conclude that disasters have negative consequences on both short and long term growth prospects. Exceptions are Skidmore and Toya (2002) and Kim (2010).

Another strand looks at the responsiveness of different types of capital flows to disasters. Within this group, the most widely cited paper is that of Yang (2008) who uses the incidence of hurricanes to examine the consumption smoothing role of international financial flows and concludes that foreign aid and foreign remittance flows seem to increase following hurricanes, whereas private flows turn negative ("capital flight"). Raddatz (2007) using a panel VAR methodology, finds that aid flows do not respond significantly to the occurrence of natural disasters. Mohapatra, Joseph and Ratha (2009) present micro evidence from household surveys and some macroeconomic results indicating that remittances have a positive role in preparing households against natural disasters and in mitigating economics losses afterwards. These authors find that remittances increase in the aftermath of natural disasters in countries that have a large number of migrants abroad. Of this strand of the literature, the paper with the widest scope is probably that of David (2010) who looks at a range of international financial flows and examines the relationship between these and different types of disasters over the period 1970 – 2005 for a large panel of developing countries. The results show that remittance inflows increase significantly in response to shocks to both climatic and geological disasters. The models suggest a nuanced role for foreign aid. While the responses of aid flows to natural disaster shocks in general tend not to be statistically significant, international assistance to low income countries increases following geological disaster shocks does increase. Furthermore, the results show that typically, other private capital flows (bank lending and equity) do not attenuate the effects of disasters and in some specifications, even amplify the negative economic effects of these events.

The overall conclusion from the literature is that appears to be a large degree of disagreement over (a) whether aid flows respond in a statistically significant way to the incidence of disasters and (b) whether the effects of aid flows on post disaster recovery are statistically significant (positive) or negligible. At one level, our work represents a further study which examines these two questions. What appears to us to be new about our approach is the following

- Greater disaggregation of types of ODA: We distinguish not only between humanitarian aid and non –humanitarian aid, but disaggregate both categories of aid to search for differential responsiveness and impact . Within humanitarian we look at food aid vs general humanitarian aid and within overall development ODA we focus on aid to the agricultural sector.
- Greater disaggregation in terms of impact: We go beyond looking at impacts on GDP growth to focus on the agricultural sector using different measures of impact.
- Temporal disaggregation: We look at the differences between pre – 2005 and post 2005 responsiveness and impact. The choice of 2005 is important as this was the year of major reform in both humanitarian sector (the transformative agenda) and the development sector (the Paris declaration).

This current paper examines similar questions to earlier work, however due to access to extensive and specific data sets, the paper is able to focus explicitly on emergency related aid flows following major flooding events and agriculture. In this sense it allows, for the first time, a very detailed analysis to be undertaken of relationships between a particular type of international aid a particular type of disaster (floods) and a particular productive sector: agriculture.

The study investigates two key questions:

• (a) Is there a statistically robust relationship between the scale and severity of disaster and emergency aid flows to agriculture?

• (b) Is there a relationship between disbursed aid and recovery in the agriculture sector following a disaster?

The paper is organized as follows: after the Introduction containing a short review of the literature, data are illustrated in Section 2. Section 3 contains the model setup and the results. The main conclusions of the research carried out, with strengths and limitations of the approach are briefly discussed in Section 4, which concludes the paper.

2 Data

Several datasets have been merged to build the panel used for the analysis carried out in this paper. Since we focus on flood events, the reference dataset we selected concerns worldwide floods occurred from 1985 on. This repository in made available by the Dartmouth College in the US. The statistics presented in the *Dartmouth Flood Observatory Global Archive of Large Flood Events* are derived from a wide variety of news and governmental sources. The quality and quantity of information available about a particular flood is not always in proportion to its actual magnitude, and the intensity of news coverage varies from nation to nation. In general, news from floods in low-tech countries tend to arrive later and be less detailed than information from 'first world' countries. Here below the list of variables in the dataset.

• DFO# - An archive number is assigned to any flood that appears to be "large", with, for example, significant damage to structures or agriculture, long (decades) reported intervals since the last similar event, and/or fatalities.

• GLIDE# - GLobal IDEntifier Number. A globally common Unique ID code for disasters.

• Country - Primary country of flooding. Other affected countries are listed in three separate fields to the right of the main Country column.

• Locations - Includes names of the states, provinces, counties, towns, and cities.

• Rivers - Names of rivers.

• Begin - Ended - Occasionally there is no specific beginning date mentioned in news reports, only a month; in that case the DFO date will be the middle of that month. Ending dates are often harder to determine - sometimes the news will note when the floods start to recede. An estimate is made on the basis of a qualitative judgment concerning the flood event.

• Duration - Derived from start and end dates.

• Known Dead - News reports are usually specific about this, but occasionally there is only mention of 'hundreds' or 'scores' killed; in this case the estimate is: *hundreds*=300; *scores*=30; *more than a hundred* =110 (number given plus 10%). If there is information on the number of people 'missing', the DFO does not include them in the total of deaths. An exact number is provided for analytical purposes, but those numbers are never more than estimates.

• Number Displaced - This number is sometimes the total number of people left homeless after the incident, and sometimes it is the number evacuated during the flood. News reports will often mention a number of people that are 'affected', but this is not used. If the only information is the number of houses destroyed or damaged, then DFO assumes that 4 people live in each house. If the news report only mentions that "thousands were evacuated", the number is estimated at 3000. If the news reports mention that *more than 10,000* were displaced then the DFO number is 11,000 (number plus 10%). If the only information is the number of families left homeless, then DFO assumes that there are 4 people in each family.

• Damage (US $) - This number is never more than an estimate and no independent criteria are used for determining such. Instead it is retained the latest and apparently most accurate number available in all the relevant sources.

• Main Cause - One of eleven main causes is selected: Heavy rain, Tropical cyclone, Extra-tropical cyclone, Monsoonal rain, Snowmelt, Rain and snowmelt, Ice jam/break-up, Dam/Levy, break or release, Brief torrential rain, Tidal surge, Avalanche related. Information about secondary causes is in the Notes and Comments section of the table.

• Severity Class - Assessment is on 1-2 scale. These floods are then divided into three classes. Class 1: large flood events: significant damage to structures or agriculture; fatalities; and/or 1-2 decades-long reported interval since the last similar event. Class 1.5: very large events: with a greater than 2 decades but less than 100 year estimated recurrence interval, and/or a local recurrence interval of at 1-2 decades and affecting a large geographic region (> 5000 sq. km). Class 2: Extreme events: with an estimated recurrence interval greater than 100 years.

• Geographic Flood Extents (sq km) - This is derived from our global map of news detected floods. Polygons representing the areas affected by flooding are drawn in a GIS program based upon information acquired from news sources. Note: These are not actual flooded areas but rather the extent of geographic regions affected by flooding.

• Magnitude (M) - Flood Magnitude =log(Duration x Severity x Affected Area).

Net Official Development Assistance (ODA) per capita consists of disbursements of loans made on concessional terms (net of repayments of principal) and grants by official agencies of the members of the Development Assistance Committee (DAC), by multilateral institutions, and by non-DAC countries to promote economic development and welfare in countries and territories in the DAC list of ODA recipients; and is calculated by dividing net ODA received by the midyear population estimate. It includes loans with a grant element of at least 25 percent (calculated at a rate of discount of 10%).

The database is entirely based on OECD-CRS Aid Activity database, which is currently the most comprehensive when considering the allocation of assistance to agriculture, as well as other relevant sectors, by recipient country and region at the activity level. CRS database has drastically increased its coverage on multilateral donors in the last decade. It provides a consolidated methodology when more than one donor is involved on the aid delivery process, which avoids double-counting. It includes both ODA and OOF made by bilateral and multilateral donors to developing countries in terms of commitments and disbursements for the period from 1973 to 2011. The ODA database covers agriculture in the broad sense (agriculture, forestry and fishing) and also all the sectors and purposes that are relevant to FAO's strategic objectives like: food and nutrition security, food aid, agro-industries, rural development, water and environment protections. The amounts are expressed in both current and constant USD millions. The embedded DAC deflators are used. Official Development Assistance (ODA) is defined as:

- flows to the DAC list of aid recipients;
- provided to official agencies, including state and local governments, or by their executive agencies;
- administered with the promotion of the economic development and welfare of developing countries; and
- concessional in nature i.e. it contains an element of grant that is at least 25% Other Official Flows (OOF) are transactions by official donors with the list of aid recipients which do not meet the eligibility criteria as ODA either because they are not primarily aimed at development, or because they have a grant element of less than 25%.

Commitment is a firm written obligation by a government or official agency, backed by the appropriation or availability of the necessary funds, to provide resources of a specified amount under specified financial terms, conditions and for specified purposes for the benefit of the recipient country. Disbursement is the placement of resources at the disposal of a recipient country or agency, or in the case of internal development-related expenditures, the outlay of funds by the official sector. It can take several years to disburse a commitment. ODA is further classified in four categories:

1. ODA Grants are transfers in cash or in kind for which no legal debt is incurred by the recipient. For DAC/CRS reporting purposes, it also includes debt forgiveness, which does not entail new transfers; support to non-governmental organizations; and certain costs incurred in the implementation of aid programmes.
2. ODA Grant-like flows comprise a) loans for which the service payments are to be made into an account in the borrowing country and used in the borrowing country for its own benefit, and b) provision of commodities for sale in the recipient's currency the proceeds of which are used in the recipient country for its own benefit.
3. ODA Loans are transfers for which the recipient incurs a legal debt and repayment is required in convertible currencies or in kind. This includes any loans repayable in the borrower's currency where the lender intends to repatriate the repayments or to use them in the borrowing country for the lender's benefit.
4. Equity investment comprises direct financing of enterprises in a developing country which does not (as opposed to direct investment) imply a lasting interest in the enterprise.

The main indicators used from the ODA database are overall disbursement and commitment flows. Commitments on General Programme Assistance and Humanitarian Aid Grouping are also retained

- development food aid and food security assistance, indicated with *committ_foodsec*

- agriculture, indicated with *agr_committ*
- emergency response, indicated with *emerg_committ*
- disaster prevention and preparedness, indicated with *disast_committ*.

Land cover and Food Aid Shipments are also used (FAOSTAT). Variables retained are displayed on Table 6 in the Appendix.

Our final dataset is obtained merging data from the various sources mentioned previously. As a first step of the work, some correlation analysis is carried out for the most relevant variables to our objectives. From pairwise correlations of ODA flows we notice that they are significantly positive correlated with permanent crops and total agriculture land. In particular, commitments for food security are strongly positively associated to arable land. Moreover, some specific sections of commitments related to emergency, agriculture and disaster prevention are mostly associated with higher levels of agricultural arable land. This can be explained not by the fact that commitment flows boost conversion of land for agricultural use, but also by the dramatic level of need of some countries which are depending mostly on agriculture for their livelihood. This is especially true when those countries are subject to extreme natural events, such as floods, which could drastically reduce the agricultural area, destroy crops and thus enhancing food security issues. This in principle should/could stimulate further commitments not only from the side of the country hit by the disaster, but also from DAC donors. Thus, for those reasons, the direction of causality between disbursement and change in land cover for agriculture cannot be clearly identified at this stage. Therefore any conclusions on the effectiveness of international ODA on recovery from flood disasters cannot be drawn. To this aim, more sophisticated models able to take into account feedback effects are needed. To get some insight on time issues related to the effect of past disbursement and commitment on agricultural areas, the correlation analysis is repeated on the same land cover variables observed at time t with disbursements and commitments at time $t-1$ and $t-2$, i.e. one year and two years before, respectively. Interestingly, there is a persistent positive correlation of past ODA flows with agriculture area, in particular with permanent crops area. Similar pattern is noticed for previous year food aid and security commitments against current arable areas. The list of variables used in the next sections is displayed in Table 1. Note, that the number at the end of the variable name indicates the time lag. For example, variables *all7_commitment_defl1* and *all7_commitment_defl2* are the deflated ODA commitments in Humanitarian Aid at 1-year and 2-year lag, respectively.

3 The econometric models

Three models are considered for assessing three main aspects: responsiveness, impact on livelihoods, impact on the economy based on agriculture. EMDAT dataset has been used in the analysis for including the occurrence of a general disasters.

3.1 ODA Response

As already mentioned in the Introduction, our first objective is to investigate if ODA disbursement levels are significantly increased after a flood event and whether the magnitude and severity of disasters have a positive significant impact on those flows. In this model we assess the response of disbursements in humanitarian aid after a general disaster and after a flood. This model is estimated using two dataset. The first is about general disasters (EMDAT) database, and the second about flood only (DARTMOUTH).

The econometric model is a fixed effects with autoregressive errors and takes into account the effects of

- current and past commitment flows (up to 4 years before),
- the severity and magnitude of disasters possibly occurred in the past year,
- food aid shipments (rice and cereals) in previous period,
- changes in land cover.

The response variable is deflated disbursements in section 7, and the explanatory variables are current and past deflated commitments in humanitarian aid, current and past deflated disbursements in agriculture with and without disaster or flood occurrence, variables related to magnitude and severity of disasters or floods. Control variables are current and $1-$lag agriculture and permanent crops area, forest area, previous area food aid shipment in rice and cereals, time dummy related to the period after 2005. The model is estimated after having tested the stationarity of the time series and against the hypothesis of poolability of the data. Moreover, both time and individual effects result significant and the overall variability of the data is quite well explained by the model specification, as confirmed by the overall R squared. From the coefficient estimates displayed in Table 3.1 we observe that commitments in section 7 are persistent (significant up to $4-$lag autocorrelations).

Concerning the response after a general disaster, as displayed in Table 3.1 in the last two columns, current aid grants are positively affected by past commitments in humanitarian aids (up to 2 years before), particularly when commitments are taken at the time of a disaster. Indeed, this has a positive effect of increasing current disbursements. On the other hand, when the disaster is a flood, past commitments in humanitarian aid seem to decrease their positive correlation with current disbursements. This means that the response in case of floods is less dependent on past commitments. This is related to the severity characterizing flood events on people and land. The most severe the flood is at the time commitment, the lowest the correlation with current disbursement (see Table 6 in the Appendix). Moreover, when flood occurs, to lower commitments taken at that time there will correspond higher disbursements in humanitarian aid the year after.

Grants disbursed for humanitarian and agriculture purpose move generally together, i.e. they vary in the same direction in time. This is especially true for Asian countries with high strength of the relation, lower for African ones (see Table 1) and very weak association for South-America and Caribbeans.

Disbursements in aid are responsive to past land cover in agriculture and permanent crops, and forest area. Increasing forest areas in the previous year is associated to higher current disbursements in aid, as well as previous year decrease in agriculture and permanent crops land. On the other hand, current increase in agricultural land is associated to higher disbursement, and lower forest area.

Moreover, there is a general deterministic upward trend in humanitarian aid disbursements in the past 10 years (from 2003 on).

In particular, previous year food aid shipments in rice and cereals increase are associated with increasing current aids. This means that on average, there is a continuity of aids in time under various forms. In general disasters, the variable more affecting the current amount of grants disbursed for aid is previous year number of dead, whereas in case of flood, it is the number of displaced people.

When the model is estimated for the various continents, we observe an higher persistence of past commitments on current aid, and a weak association between the various purposes of disbursements in agriculture and humanitarian aid. Moreover, previous year cereals shipments are highly associated with current humanitarian aids. The opposite is observed for Asian countries (see Table 1), where humanitarian aid is associated with past commitments only in the short run (i.e. 1−year lag), whereas current disbursements in agriculture are associated to humanitarian aid, which are not related to previous year food aid shipments. For Southern and Central America, Oceania and Europe, there are not enough observations to be able to extract robust insights from the analysis.

Flood variables included in the model are related to the previous year. The number of displaced people affects positively current disbursements. Concerning food aid shipments related to rice and cereals occurred the previous year, we observe that they both affect positively disbursement flows.

3.2 ODA Impact on Livelihood

However, errors appear to be strongly correlated with the explanatory variables, which is clearly due to still existing feedback effects. We believe that the endogeneity in our model could be explained by the fact that disbursements at time t, if effective, might give impulse to changes in land cover, especially related to land for agriculture. On the other hand, flood events affect the land cover and stimulate both commitments at time t and thus disbursement flows at time $t+1$. Since endogeneity makes coefficient estimates biased and inconsistent, we use dynamic approach to model the feedback effects of disbursement.

First, we try to model the relationship between ODA and land cover changes in a way which enables for causality reasoning. This is achieved when we 'control' for a set of other relevant variables which affect both ODA and the land cover changes.

Next steps of the analysis involve the estimation of the model using Blundell and Bond (1998) linear dynamic panel-data estimator. Linear dynamic panel-data models include p lags of the dependent variable as covariates and contain unobserved panel-level effects, fixed or random. By construction, the unobserved panel-level effects are correlated with the lagged dependent variables, making standard estimators inconsistent. Arellano and Bond (1991) derived a consistent generalized method of moments (GMM) estimator for this model. The Arellano and Bond estimator can perform poorly if the autoregressive parameters are too large or the ratio of the variance of the panel-level effect to the variance of idiosyncratic error is too large. Building on the work of Arellano and Bover (1995), Blundell and Bond (1998) developed a system estimator that uses additional moment conditions.

This estimator is designed for datasets with many panels and few periods. This method assumes that there is no autocorrelation in the idiosyncratic errors and requires the initial condition that the panel-level effects be uncorrelated with the first difference of the first observation of the dependent variable.

Table 4: IMPACT on LAND : dynamic model for impact of ODA on permanent crops, general disaster vs flood (EMDAT)

In the model for assessing the impact of disaster and ODA disbursements on livelihoods, we use as response variable the change in the land used for agriculture: from the one hand the arable land, and from the other hand areas for permanent crops. The model is estimated using Arellano-Bover linear dynamic panel data estimator, controlling for the economic and demographic size of countries (1-lag GDP at 2005 prices and population in logs), the magnitude and intensity of the disaster or flood (duration, total people affected, estimated damages, etc.) and for the natural trend of agriculture land growth. The explanatory variables are changes in forest area and arable land (when the dependent variable is the rate of change of permanent crop), changes in permanent crops (when the dependent variable is the rate of change of arable land), deflated disbursements in Material relief assistance (section 72010), with and without disaster/flood occurrence, deflated disbursements in Emergency food aid (section 72040), with and without disaster/flood occurrence. Moreover, two different scenarios are considered: general disaster and flood event (dataset EMDAT combined with dataset DARTMOUTH). The main results are summarized here below.

- Changes in permanent crops have natural tendency to increase in time (current growth rate depending from previous year growth rate), approximately at 10% pace, and are positively associated with changes in agriculture arable land.
- When a general disaster occurs, it is very difficult to seize the impact of humanitarian aid disbursements on changes in land for permanent crops and agriculture. This could be explained by the extreme heterogeneity of the impact, magnitude and severity of a disaster which could require multiple interventions, of which humanitarian aid ODA grants are only a small fraction. On the other hand, when a flood occurs, the effect of disbursements in both material relief assistance and emergency food aid is to increase future permanent crop area. This figure is confirmed when only flood data are used (see Table 3.2).

To disentangle the effectiveness of ODA in Agriculture with respect to ODA in humanitarian aid, two further versions of the model are estimated when a flood occurs: the first assess the impact of various ODA grants on permanent crops, distinguishing flood events from general disasters (Table

2). The second evaluates the impact on arable land (Table 3). From the estimates it is clear that

- it is not possible to seize and disentangle the effects on permanent crops of the various ODA in Agriculture. In absence of floods, it seems that higher grants disbursed in the previous year in Agricultural policy and administrative management (section 31110) are accompanied with a decrease in permanent crops (Table 2).
- Interestingly, ODA grants in agriculture seem to be more effective on arable land than on permanent crops. Indeed, when a flood occurs, previous year disbursements in Agricultural Development (section 31120) have positive effect on changes in arable land (Table 2). Moreover, material relief and assistance disbursements in the previous year affect positively the growth rate of arable land, and the positive effect is even higher when a flood occurred in the previous year. Interestingly, growth of forest areas moves in the same direction as arable land growth rate.
- When continents are considered separately, we observe that in Asian countries, disbursements in Material relief is effective when a flood occurs on the future growth of permanent crops. Moreover, material relief assistance is effective also on the growth of arable land. ODA grants in Agricultural policy and administrative management are effective in Asia in case of floods acting on the arable land (Table 3).
- As for Africa, effects of ODA on permanent crops is difficult to see in case of general disaster or flood event. The only exception is a general positive effect of Material relief and assistance, regardless flood events on permanent crops land growth . Same as for Asia, in African countries, arable land is more sensitive to increase in disbursements in Agricultural policy and administrative management in case of flood (Table 3).

3.3 ODA Impact on Agriculture

In this model the impact of disaster and the effectiveness of ODA disbursement s is measured on the economy through the value added from agriculture, as % of the country GDP. Thus, a dynamic panel is estimated using as response variable the value added from Agriculture (% of GDP). The model is estimated using GMM (Arellano-Bond linear dynamic panel estimator), where instruments are variables related to the magnitude and severity of the disaster/flood event occurred in the previous year, 1-lag food aid shipments in cereals and rice. Moreover, we control for the growth rate of agriculture value added, irrespectively of extreme events, the GDP growth, the natural growth of land resources (permanent crops, arable land and forest area) and last decade general trend. The explanatory variables are ODA grants disbursed in the previous year in humanitarian aid and agriculture interacted with land used for permanent crops or with agriculture arable land in the previous year. Moreover, the impact of grants disbursed in the past on current valued added from agriculture through permanent crops and arable land is considered separately in case of disaster/flood event.

The main findings are briefly summarized here below.

• In the last decade there is a general decreasing trend of agriculture value added.

• ODA grants in agriculture and humanitarian aid/material relief contribute to re-boost the economy through agriculture production in permanent crops and arable land, this regardless the presence of disasters/flood events (Table 3.3).

• If a general disaster occurs, ODA humanitarian/relief grants (section 7) increases future agriculture value added through both arable land and permanent crops, whereas grants disbursed in agriculture are effective in case of general disaster through arable land only (Table 3.3).

• When a flood event occurs, ODA grants in aid and agriculture do not generally affect agriculture value added through permanent crops. However, grants disbursed in humanitarian aid and disaster relief is effective on future agriculture value added increase through arable land, with additional positive impact in case of flood (Table 4).

• In Asia the contribution of grants to value added is mainly through arable land, whereas in Africa through permanent crops. For Asiatic countries, the impact of grants in section 3 and 7 on value added is positive in case of general disasters (Table 5), whereas for floods it is mainly grants in agriculture which help (Table 4). As for Africa, grants disbursed in reconstruction and humanitarian aid are mostly effective after a general disaster. There is no evidence for Africa of differential impact when the disaster is a flood, nor through the arable land.

• Positive changes in permanent crops or arable land are accompanied by lower growth rate of forest area and vice-versa.

4 Discussion

The objective of this study are to investigate the effectiveness of ODA flows on disaster recovery related to agricultural land. In particular, this is related to the extent of floods in terms of magnitude and severity across countries from 1985 on. To this aim we build an original panel of world countries merging several data from various sources.

Our research comprises the use of dynamic models to take into account existing feedbacks effects between aid response and changes in land cover. Moreover, a new release of ODA data has been made available by FAO and enables us to use more disaggregated data on commitments related to aid and disaster recovery in agriculture. In addition, we extend the analysis to other disaster types, such as droughts, earthquakes and tsunamis.

From the analysis carried out so far we can conclude that there is a persistent positive correlation of past ODA flows with agriculture land cover, in particular with permanent crops area. Moreover, past year commitments are significantly affecting current disbursements, especially commitments taken the year after a disaster significantly increase current disbursements. The latter usually occur with some delay with respect to the commitment taken, which can be possibly quantified about a 1-year period on average.

Moreover, we observe a differential impact of grants disbursed on agriculture value added through permanent crops and arable land. Interacting with arable land, humanitarian aid and disaster relief help to increase future value added in agriculture when there are floods. This is not true for grants in agriculture development, which help more in case of general disasters mainly through arable area.

ABSTRACT

The great majority of communities affected by disasters in developing countries are directly or indirectly dependent on agriculture for their livelihood. Climate change has been linked to a significant increase in the frequency and severity of disasters in the recent past, leading to natural hazardous events that have had several negative repercussions on the agriculture sector and sub-sectors (i.e. crops, livestock, fishery and aquaculture) and on the life of the people depending on them. The paper will firstly review the commonly used methods of assessing the damages and losses to the agriculture sector and its sub-sectors, with particular emphasis on the strengths and limitations of the Post-Disaster Needs Assessment (PDNA) methodology. After that, it will consider the financial implications of disasters and discuss the necessity of developing follow-up mechanisms to assess the proportion of disbursed funds required to implement response interventions. This will involve an analysis of the extent to which agriculture assistance is usually prioritized in the formal and informal sector, and the typology of targeted and assisted beneficiaries with an emphasis on the gender dimension. The paper concludes with recommendations aiming at improving the current standardized processes of assessing the impacts and effects of disasters, in order to enhance the effectiveness of needs assessment towards resource mobilization and recovery processes.

Keywords: Post-Disaster Needs Assessment (PDNA), Recovery, Livelihood and Gender Sensitivity Analysis, Agriculture Assistance and Disaster Response Mechanisms.

1. Introduction

The agriculture sector remains the backbone of the economy for the majority of developing countries. In Central African Republic, Ethiopia, Tanzania, Malawi, Sierra Leone, Kenya and Cambodia among others, this sector contributes to as much as 30 percent of the national GDP (WB, 2014).
Recurrent and prolonged natural hazardous events and disasters, such as drought, floods, storms, spread of pests and diseases and saltwater intrusion, have severe impacts on agricultural livelihoods. Climate change exacerbates these events and their impacts. According to data from the International Disaster Database – Centre for Research on the Epidemiology of Disasters (EM-DAT CRED), between 2003 and 2013, natural hazards caused USD 1.5 trillion in economic damage worldwide, affecting 2 billion people (FAO, 2015*a*). However, there are no clear indications of how much of this damage affected the agriculture sector.
The increasing complexity and frequency (going from 80 to 420 events recorded per year over the past 20 years; CRED et al., 2015) of these disasters, and the consequent negative impact on vulnerable populations requires post-disaster needs assessments and related monitoring and evaluation studies to enable better assistance for the recovery of affected populations.
Specific methodologies such as Post Disaster Needs Assessment (PDNA) have been developed to estimate the financial implications of natural disasters in order to identify recovery needs defined from a human, socio-cultural, economic, and environmental perspective. Nonetheless, there are no available studies or follow-up mechanisms in place to monitor the magnitude of financial assistance provided to support country recovery, particularly relating to the agriculture sector and sub-sectors (i.e. crops, livestock, fishery and aquaculture).
In order to plan for better assistance and allocate an adequate share of humanitarian and recovery funds to the agricultural sector, as well as to enhance the visibility and accountability of funding provision, it is important to categorize the share of support provided by donor communities *vis-à-vis* the governments of affected countries. This should include the description of mechanisms used to target beneficiaries, the type of assistance received (in-kind vs cash) and the funding gaps, in order to enhance the appeal and recovery processes.
This paper describes the main methodologies used to assess damages and losses in the agriculture sector and sub-sectors, elucidating the financial gaps and implications that need to be addressed in order to better support the recovery of both the formal and informal sectors. Additionally the paper seeks to describe the intended beneficiaries and affected population, with particular attention to gender equality.
The paper concludes by making recommendations to foster the establishment of monitoring and evaluation mechanisms that should be put in place throughout the post-disaster recovery process.

2. Methodologies for assessing agriculture damages and losses

Over the years, assessing the effects and impacts of disasters on the agricultural sector, covering crops, livestock, fisheries and aquaculture,[1] has been mainly done by agronomists or agricultural economists. Institutionally, the ministry or department of agriculture assesses damages and the losses based on the initial reports prepared by first responders, local authorities, or the national disaster or emergency management agencies.
Since the 1990s there have been efforts to agree on a standardized methodology with uniform concepts and means to measure the destruction of agricultural capital and assets and the ensuing production losses, be it through diminishing yields and returns or actual damage to crop and harvest. The best known early

[1] Forest exploitation, be it for logging, collection of plants and animal hunting or the environmental services provided by natural forests, is traditionally not included in the agricultural sector evaluations but dealt with separately, either as lumber industry or forest exploitation. Environmental services are assessed separately as the effects of disasters on the natural or intervened natural habitat.

methodology (called Damage and Loss Assessment - DALA) was developed by the United Nations Economic Commission for Latin America and the Caribbean (UN-ECLAC, see ECLAC, 2003; ECLAC, 2014) with the collaboration of the United Nations Food and Agriculture Organization (FAO).[2] This methodology was used by sector specialists in the Latin American and Caribbean region and others, in order to differentiate the sector production losses (as the production and income flows that have been lost due to the disaster) from the damage to the sector assets and capital (infrastructures such as silos, storage facilities, stables, etc. machinery and implements such as harvesters, tractors, boats, nets and fishing gear, in addition to animal stock such as cattle, bees or fish).

In parallel to this, attention was increasingly given to livelihood losses in the sector and the effect on human capital. This path was followed by FAO alongside the United Nations International Labour Organization (ILO) leading to the jointly FAO/ILO developed Livelihood Assessment Toolkit, LAT (FAO, 2009; FAO and ILO, 2009; ILO, 2011), as a means to approach the micro-impact of disasters on agriculture and rural households.

The DALA methodology was gradually internalized by national governments and international organizations and the sector methodology was incorporated and updated in the current Post-Disaster Needs Assessment (PDNA), following the joint agreement signed by the United Nations (UN), the World Bank (WB) and the European Union (EU) in 2008, to attain a common standard for assessment of and recovery from disasters (IRP, 2013*a*; UNDP, 2013; GFDRR, 2014, 2016). Aside from the purely economic aspects of the DALA, the PDNA aims at also assessing the effects of a disaster on the populations' livelihoods, taking into consideration the human, socio-cultural, economic and environmental perspective. As of today, the PDNA is an internationally accepted methodology, process and tool, used in dozens of specific disasters and has proven its adaptability to specific cases (including a range of types of disaster, economic structures and national characteristics).

The sector analysis of the agricultural related primary sector, i.e. crops, plantations, animal husbandry, bee production, fishing and fish farming, is intended to assess the value chain of the sector, from the farm gate to the market, thus differentiating the loss to actual agriculture farmers and labourers from the intermediate agriculture wholesale trade and the marketing. The latter two must be seen in the context of the commerce and trade sector and require a cross cutting and interconnected analysis that goes from the local market to the international export and import trade. The differentiated impact in terms of types of agricultural producers, gender and use of non-paid labour of family members is to be specifically analysed (IRP, 2013*b*; UN, 2014).

A cross cutting, integrated, holistic approach is part of the sector analysis in so far as food production and income losses in the sector may lead to malnutrition and food insecurity, with economic, social and health implications.

3. Financial Implication of disasters

When considering only climate-related disasters – i.e. floods, droughts, hurricanes, typhoons and cyclones (excluding geological hazards such as earthquakes, tsunamis and volcanic eruptions) – damages and losses recorded in the agriculture sector represent 25 percent of the overall economic impact (FAO, 2015*a*). In most cases of post-disaster recovery and reconstruction, international aid agencies provide technical and financial assistance for the disaster affected populations (Chang *et al.*, 2010). Hence, disbursement of funds and prioritization of resource allocation among the sectors affected by disasters is an important precondition to ensure a well targeted and sustainable reconstruction phase. Between 2003 and 2013, according to a FAO study (FAO, 2015*b*), about USD 4 billion was spent on humanitarian assistance to the agriculture sector, averaging nearly USD 375 million annually as indicated in Figure 1 below.

[2] At the time there was a joint ECLAC / FAO Agriculture Division that linked the ECLAC headquarters with the FAO Regional Office for Latin America, both located in Santiago, Chile.

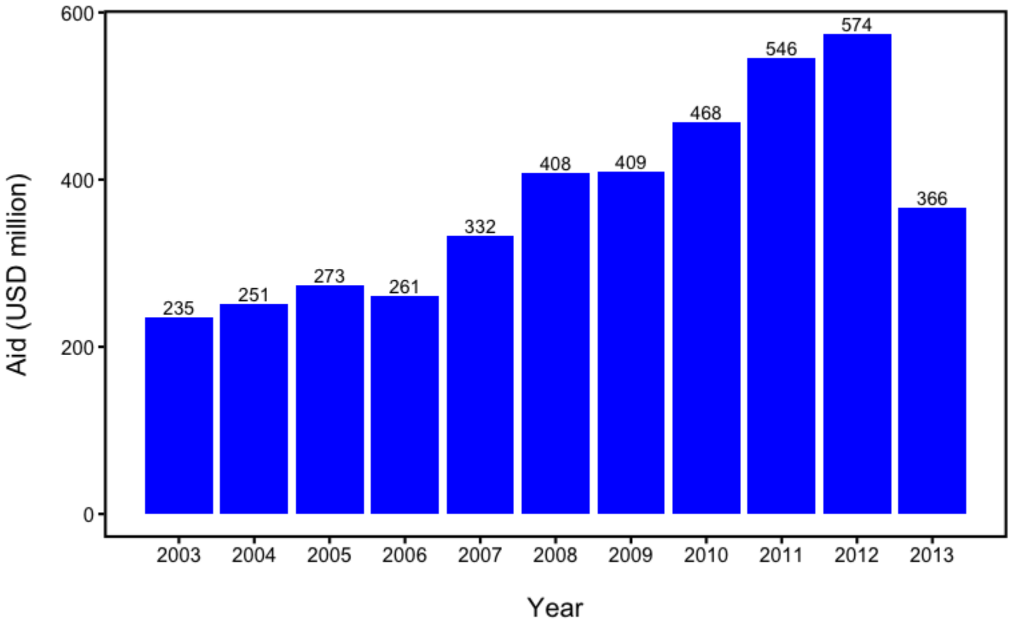

Figure 1: *Total humanitarian aid to the agriculture sector, by year (USD million)*

Considering that during this decade (2003-2013), roughly USD 121 billion was spent on humanitarian assistance for all types of disasters and crises, the proportion of funds allocated to the agriculture sector corresponds to only 3.4 percent of the total humanitarian funds (FAO, 2015a).
Despite this available data, there is no official and disaggregated information reporting allocation of rehabilitation / reconstruction funds to each of the agriculture sub-sectors usually affected by disasters. In fact, most of the available literature focuses on information related to the agriculture sector as whole. Besides, there are no mechanisms in place to assess the proportion of disbursed funds required to implement response interventions, against emergency appeals and pledges. For example, most of the PDNA processes are nowadays ending with the preparation of the Disaster Recovery Framework (DRF), which helps in articulating the recovery vision, defining the recovery strategy, prioritizing actions, fine-tuning planning, and providing guidance on financing, implementing and monitoring the recovery (GFDRR, 2016). However, it is very important to establish follow-up mechanisms that will allow monitoring, evaluating and recording the size and type of investments made to support the recovery of the agriculture sector and sub-sectors. This will enhance the availability of information necessary to communicate the results of the joint efforts and thus ensure a successful and transparent recovery process after the implementation of post-disaster assessments such as PDNA. Establishing monitoring mechanisms should also help in indicating and recording how financial resources were allocated, from which sources and disbursement mechanisms they were obtained (i.e. emergency funds from national budget, grant / credits from financial institution or donors, bi- or multilateral funds, etc.), in addition to type of beneficiaries assisted (i.e. gender groups), with possible identification of financial shortfalls required to provide the entire appealed support.

4. The implication of disasters on the formal and informal sector

Commercial agriculture, or the formal agricultural sector, is the main contributor to the agriculture GDP of a country; going from almost 100 percent in the industrialized nations, to 73 percent in Botswana, 46 percent in Sri Lanka, 20 percent in Iran and none in Burkina Faso (UN, 2004). This sector mainly consists of large scale farms or plantations, with a high level of mechanization, having access to credit and insurance schemes, often in line with and / or supported by agriculture policies of the country. Production is mainly directed to internal markets or to export.
On the other hand, the informal agriculture sector consists mainly of smallholding farmers that include agriculture casual labourers or kind of multiple job holders in rural areas. Farmers are producing mainly for their own consumption, and surplus is sold on the local markets. There are an estimated 500 million smallholder farmers in the world, supporting almost 2 billion people (IFAD, 2013). Even when smallholding

farmers represent a significant share – even the majority – of the rural population, they are still considered part of the informal sector, since they are not fully included into the national accounts system through paying taxes. As a result they are not comprised into the GDP calculations.
For example, in Mali the entire agriculture sector is considered informal, whereas in Kazakhstan, Belarus and Chile, informal agriculture represents 75, 56 and 37 percent of the agricultural sector respectively. On the other hand, the informal sector is almost absent in the industrialized countries (UN, 2004).
Disasters have negative implications in both the formal and informal sectors. In the formal sector, and to less extent in the informal one, disasters decrease national revenues to the GDP, leading to reduced internal food production levels and increased prices of food commodities, in addition to lowering countries' capacity of exporting agriculture products. Whilst in the informal sector, the effects of a disaster on the livelihoods of subsistence or smallholding farmers are usually devastating. In fact, they contribute to loss of and damage to agricultural production, in addition to losses of animals and stocks or damages to assets and infrastructures. Aside from the material losses, disasters increase the level of food insecurity and malnutrition, and diminish the casual and wage labour opportunities to generate income.
Indeed, the capacity to recover from disasters differs in the two sectors. The high level of mechanization, and the possibility to access savings and credits, makes the formal sector more resilient and enables a quicker recovery. In contrast, in the informal sector, the situation is completely the opposite since the people affected, mainly smallholders, are less resilient to disasters and usually require more time and efforts to reconstitute their livelihoods.
In addition, after a disaster, governments are generally more keen to assist in a rapid recovery of the formal agriculture sector in order to restore production and re-establish the contribution to the GDP and national food security, leaving the recovery of the informal sector in the hands of international humanitarian actors (NGOs and UN agencies) as well as faith-based or civil organizations, especially during the relief phase.
Despite this, the type of support provided by international donors or funding institutions depends mainly on their institutional mandate or political interest towards the affected countries. For example, the WB usually focuses in funding the rehabilitation of infrastructures and assets of the commercial agriculture sector (NDRRMC, 2015), whereas the EU plays a major role as a donor when the countries affected are in Europe or where the EU is supporting the implementation of large programmes such as the African Caribbean Pacific – European Union Disaster Risk Reduction Program (ACP *et al.*, 2016).
Overall, in the formal sector, the labour force is mostly provided by casual labourers, which are also largely constituting the informal sector (ILO, 1994; ILO *et al.*, 2007), with the share of female casual labourers ranging from 20 – 30 percent and child labour up to 30 percent (ILO, 1996). In contrast, in the informal economy, women play a much bigger role, together with the working poor and most low-income households (ILO, 2002). In general, rural women are the main producers of the world's staple crops - maize, rice, and wheat - which provide up to 90 percent of the rural poor's food intake. Studies have shown that rural women in particular are responsible for half of the world's food production and produce between 60 and 80 percent of the food in most developing countries (FAO-WB-IFAD, 2009).
Nonetheless, both men and women in the informal agriculture sector suffer increased vulnerability to disasters because they typically lack legal, land or labour rights. However, women suffer more from this deficiency, mainly due to cultural, social, religious or political / economic reasons. For example, women rarely have the same land tenure rights as men or access to the same resources. Animal ownership and use of animal products also differ, alongside cultural gender differences between women and men, including roles, capacities, responsibilities and freedom of speech (FAO, 2010).
Due to this situation, a main focus should be given to the integration of gender equality aspects in the formal and informal sector during the implementation of needs assessments and the response framework process after a disaster. For example, the Philippines' government under the Republic Act 10121 Section 9, item (m) emphases the need of institutionalizing gender analysis during the processes of post-disaster needs assessment and early recovery (NDRRMC, 2015).

5. Intended Beneficiaries and affected population.

The intended beneficiaries of the post-disaster recovery processes in the agricultural sector are usually the people relying on the sub-sectors of crops, livestock, fishery and aquaculture, as their main source of livelihood. They are generally included in the needs assessments through Household Surveys and Focus Group Discussions although not uniformly in different assessment methods. Livelihood-focused assessments engage beneficiaries more effectively both in the implementation and recovery processes compared to more macro-economic level assessment conducted through PDNA. Table 1 illustrates some typical groups of intended beneficiaries and the kinds of support that is usually required for each group.

Table 1: *Type of support and intended beneficiaries in livelihood-based needs assessment*

Beneficiaries	Immediate Relief	Early Recovery Support	Sustainable Livelihood Interventions
Crop farmers	- Provide seeds, fertilizers, pesticides, as well as tools and temporary storage facilities (in-kind or cash or voucher). - Construct temporary wells also using cash for work initiative.	- Rehabilitate storage and processing facilities. - Support farmers and agro-suppliers with credit facilities to improve access to inputs. - Repair equipment and machineries. - Rehabilitate irrigation infrastructure.	- Introduce crop insurance schemes. - Promote alternative crops and more diversified cropping systems and soil conservation practices. - Improve extension services. - Review relevant agricultural policies. - Expand advanced irrigation systems and introduce fees for water usage. - Improve/diversify market access.
Livestock Producers	- Support animal restocking and destocking. - Provide feed and vaccine. - Establish temporary shelters. - Provide emergency vet services.	- Rehabilitate animal shelters by distributing building materials or using cash or voucher schemes. - Provide subsidized feeds or feed-mills. - Expansion of vet services.	- Introduce livestock insurance. - Expand artificial insemination to increase productivity. - Regularize vet services. – Provide credit facilities. - Improve/diversify market access. - Improve extension services. - Revise relevant livestock policies.
Fishery/Aquaculture producers	- Support for restocking existing ponds. - Provide fish feed and meds. - Establish cash for work initiatives to rehabilitate ponds/hatcheries.	- Rehabilitation of ponds/hatcheries through voucher schemes and cash for work. - Provide subsidized animals.	- Provide credit facilities for aquaculture expansion. - Introduce effective extension services. - Improve/diversify market access.

The beneficiaries in livelihood assessments typically report needs for immediate relief or early recovery, while development agencies tend to introduce ideas for longer term planning, and sustainable development. In each of the groups of beneficiaries listed in Table 1 above, particular attention is usually given to gender balance to ensure women get the kind of support they need (UNDP, 2010). Nonetheless, there are few efforts to disaggregate male and female needs during post-disaster assessments and recovery process.

Other vulnerable groups such as youth, the aged, people with disabilities, and the landless will hopefully get special attention especially with the increased human impact focus (EU-GFDRR-UN, 2013).
The targeted numbers of intended beneficiaries (people affected) of course depends on the scale and intensity of the hazard and the vulnerability of the people affected.
Some people affected by disasters are able to recover on their own through existing insurance coverage, as members of church groups or other benevolent organizations, or through kinships and family networks. Others not directly affected might also benefit from post-disaster recovery efforts especially through Disaster Risk Reduction (DRR) and resilience building initiatives also called Building Back Better (BBB). In fact, these result in new and better infrastructures, economic investments, as well as livelihoods and job opportunities for communities at large.
The literature on actual people who benefited as a result of the conduct of a PDNA which led to a recovery plan is scarce. A statistical analysis of those who have actually benefited from related PDNAs in the agriculture sector is therefore not possible at this time, but it is strongly recommended that pertinent assessments which could provide such data are carried out. Nevertheless some beneficiary relevant lessons can be extracted from recovery programs as presented below.

5.1. Lessons learned from Case Studies

The revival of household and local economy has an important multiplier impact, which strengthens recovery and puts it on an upward trajectory. In many recovery programmes, the allocation of resources is largely for infrastructure reconstruction, and it tends to ignore the economic needs at the household and community levels. An emphasis on a more balanced recovery programme, which also empowers the affected households and communities through direct transfer of resources for restoration of livelihoods and other assets, would result in a more sustainable and equitable recovery.
A report published 3 years after the Pakistan 2005 earthquake noted that the agencies helping with recovery – the Pakistan Government, the Army, the international Financial Institutions and relief agencies – were not familiar with livelihood restoration and so major challenges were still present (Ahmad and Suleri, 2008). The report emphasised the need for a multidimensional livelihood assessment, a greater focus on assets recovery (livestock, crops, soil, etc.) as most attention was put on income regeneration, and for the livelihood strategies to be gendered. In addition, it stressed the need for strengthening capabilities to allow people to better utilise their assets.
In the PDNA of the Kenya drought (2008-2011) the inclusion of the Human Development Recovery Needs Assessment (HRNA) allowed a detailed assessment of the impact of the disaster on the livelihoods of the poor and showed the greater impact on those with lower Human Development Index (HDI). Nonetheless, this assessment did not lead to integrated livelihood recovery recommendations which remained largely macro-economic and sectorial in nature (Government of Kenya et al., 2012).

6. Conclusion and recommendations

Despite the existence of globally recognized methodologies such as PDNA, additional efforts are required to ensure a more transparent and well-coordinated recovery process in the aftermath of a disaster.
Post-Disaster Needs Assessments, should be constituted by follow-up mechanisms to verify the amount of funds pledged and disbursed to support the recovery process, possibly disaggregated by sector and sub-sectors, and indicating the source of funds (i.e. donors, government, etc.). In addition, a clear indication on the type of beneficiaries assisted or requiring assistance (divided by gender groups), should be also available, with potential identification of financial shortfalls required to provide the entire appealed support. The establishment and enforcement of these mechanisms should be discussed among the WB, EU and UN, which constitute the tripartite agreement of the PDNA methodology. All actors providing assistance during the recovery process, including the government of the country affected, should be informed in advance about the necessity of gathering specific information so that they can share whatever is required as part of their support efforts.

Due to the existing differences in the vulnerability and exposure to the disasters occurred in the formal and informal agriculture sector, it is generally recognized that this latter sector is usually considered the most affected. Nonetheless, there is no reliable information on the extent of support which is usually received by the two sectors. As a result more studies need to be conducted in these areas in order to ensure that both sectors are equally supported in the aftermath of a disaster, with particular attention on the informal sector where millions of smallholder farmers make their living and where most of the vulnerable people are recognized.
Finally, the PDNA methodology needs to be much more inclusive and accountable to the affected population by becoming more faithful to a people-centred approach. In this line, affected communities should be engaged more often during the assessment process in order to better understand how they were affected by the disaster and what they need most to recover and enhance their resilience capacities. This could be done through the use of more systematic primary data collection techniques such as surveys, to be included as part of the assessment methodology.

ABSTRACT

Over the last decades, there has been an increase in the occurrence of disasters worldwide, which is especially noteworthy in relation to climatological events (e.g. droughts), hydrological events (e.g. floods), and meteorological events (e.g. storms). For the agriculture sector, the increase of weather-related events is a significant concern given the high dependence of agriculture on climate. Yet, the impact of disasters on the sector is not well enough understood, given the limited statistics available and the lack of systematic reporting in countries.

The objective of this paper is to propose a methodology for monitoring the impact of disasters on agriculture and its sub-sectors (crops, livestock, fisheries, aquaculture and forestry). This would form the basis for setting up a monitoring system that can provide policy-makers and stakeholders at large with standardized data and metadata for evidence-based decision-making towards sustainable agricultural development and enhanced resilience.

Several approaches and methodologies exist to assess the impact of disasters. The basic methodological frameworks come from the Post-Disaster Needs Assessments (PDNA) conducted jointly by the World Bank, EU and United Nations with the leadership role of national Governments. A main conclusion from the literature discussing applications of these methodologies is the need to distinguish damage, i.e. total or partial destruction of physical assets existing in the affected area, from losses, i.e. changes in economic flows arising from the disaster.

Based on the analysis of 78 post-disaster needs assessments, the FAO's study on "The impact of disasters on agriculture and food security" found that agriculture absorbed 22 percent of all damage and losses caused by disasters in developing countries between 2003 and 2013. Furthermore, by analysing secondary data from FAOSTAT and other relevant sources, the FAO study found that significant drops in agricultural production, changes in agricultural trade flows and

declines in agriculture value added occurred after disasters in developing countries over the same period.

FAO aims at taking a broader perspective towards improving the amount and quality of the information available on disaster impacts in agriculture. The methodology proposed in this paper shall be designed also to support the monitoring of progress towards the achievement of global and national goals and targets on disaster risk reduction and resilience, including under the Sustainable Development Goals and the Sendai Framework for Disaster Risk Reduction.

Keywords: Natural hazards; Disaster impact assessment; Agricultural damage and losses.

1. Introduction

Over the last decades there has been an increase in the occurrence of natural hazard-induced disasters worldwide. Evidences show that extreme events such as droughts, floods and storms have occurred with high frequency and magnitude (CRED & UNISDR, 2015). These trends are particularly worrying for agriculture, considering the high dependence of the sector on climate and natural resources.

According to the Post Disaster Needs Assessment (PDNA) guidelines, the economic impact of disasters is measured as the sum of damage, i.e. monetary value of physical assets totally or partially destroyed, and losses, i.e. changes in economic flows arising from the disaster. Based on information obtained from PDNAs, the FAO study on The Impact of Disasters on Agriculture and Food Security showed that, between 2003 and 2013, 22 percent of the total economic impact of natural hazard induced disasters in developing countries was absorbed by agriculture, a figure much higher than previously reported. Yield trend analysis revealed that crop and livestock production losses after medium to large-scale disasters in developing countries averaged more than USD 7 billion per year over the same period (FAO, 2015). The study represented a first step towards filling the information and knowledge gap about the nature and magnitude of disaster impacts on agriculture, and highlighted the need for systematic monitoring and standardized assessment of damage and losses in crops, livestock, fisheries/aquaculture and forestry.

This paper describes a logical structure for linking the magnitude of the natural hazard to the corresponding damage and losses values, and proposes a standardized approach to measure damage and losses from natural hazard-induced disasters in agriculture. Overall, this paper fits in the FAO initiative for the development of an information system on damage and losses caused by disasters on the sector and its subsectors (crops, livestock, fisheries, aquaculture and forestry). As part of its commitment to enhancing the resilience of agriculture and rural livelihoods, FAO aims to support member countries to collect and report relevant data on the immediate physical damage caused by disasters on agricultural assets, as well as on the cascading negative effects of disasters on agricultural production, and value chains.

2. Logical steps for measuring disaster impact on agriculture

The logical structure behind a methodology for measuring the impact of disasters in agriculture involves three main steps:

1. The identification of the natural hazard and its magnitude.

2. The identification of the causal linkage between the hazard and damage and losses in agriculture.
3. The assessment of damage and losses caused by the hazard on agriculture, which constitute a measure of the disaster, i.e. the natural hazard impact on the primary sector.

The first step relies on the analysis of key indicators (e.g. climatic, environmental, geophysical, hydro-meteorological, biological indicators) in order to identify key characteristics of hazards, such as their location, area affected, intensity, speed of onset, duration and frequency. The second is the most delicate step: establishing a robust causal relation between the hazard and the impact on agriculture may be complex, as the effects should be isolated from idiosyncratic shocks such as civil conflicts, political instability or global macroeconomic shocks, which may play an important role in changing production dynamics. The third step involves the assessment of disaster impacts and the computation of the monetary value of damage and losses.

The definition of a standardized methodological framework is meant to support the process that goes from the collection and sharing of relevant data at global, national and sub-national level to the calculation of disaster's damage and losses in agriculture (Figure 1). The collection of relevant data includes the selection and use of multiple sources at different levels, including country-level observation data (e.g. agricultural surveys), earth observation data (e.g. satellite, drone-based imagery), and stressors data (e.g. climatic and environmental indicators), among others. The primary data gathered should be organized in order to develop relevant information on post-disaster situation, and a reliable baseline for robust counterfactual analysis. Finally, the assessment stage implies the application of methods for the attribution of monetary values to damage and losses in each agricultural sub-sector.

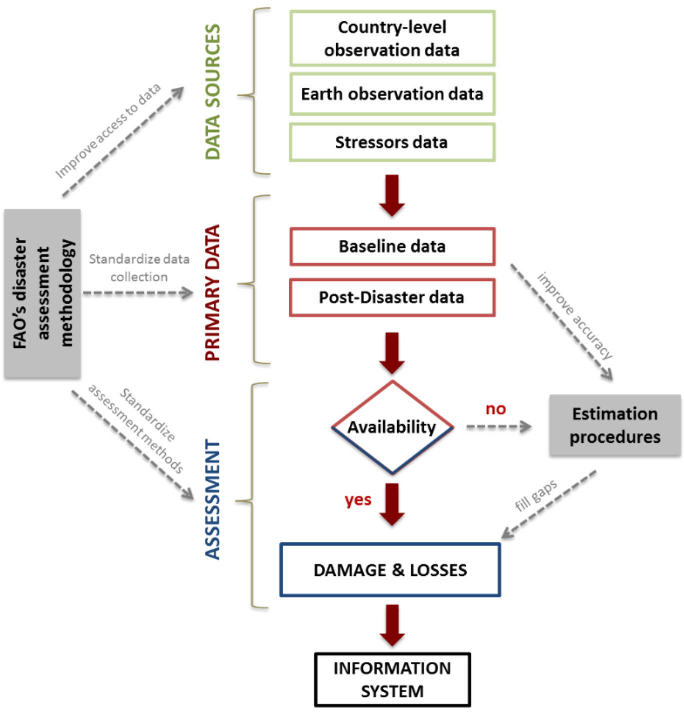

Figure 1: *Damage and Losses System Diagram: from data to D&L indicators*

In cases when vital baseline or post-disaster data are only partially available, estimation and imputation procedures can be implemented through a procedural cascading structure in order to provide approximate figures on disaster impact. The use of a set of statistical tools allows to (1) fill data gaps and provide robust numbers for both the baseline and disaster impact values; and (2) forecast the impact of natural hazard-induced disasters based on country-specific characteristics. The forecasting capacity is strictly linked to the availability of historical primary data on disaster impact collected through a standardized methodology, such as the one proposed in this paper.

Damage and losses data are expected to support research on disaster impact trends in agriculture, as well as to enhance the resilience of rural livelihoods by informing evidence-based policies, strategies and action plans in disaster risk reduction and management.

Starting from the above considerations, this paper builds on the PDNA guidelines in order to propose a standardized methodology for calculating damage and losses caused by disasters in each agricultural sub-sector. In particular, the paper seeks to define uniform computation methods for translating primary data on disaster physical impact into monetary values of damage and losses. The adoption of standardized and systematic reporting mechanisms on damage and losses data at country level are meant to provide policy-makers, and stakeholders at large, with a sound information base for decision-making. Ideally, the information should allow implementing ex-ante cost-benefit analysis of disaster risk reduction (DRR) as well as post-disaster resource allocation.

The analysis of damage and losses data on historical events, combined with information from early warning systems (e.g. GIEWS, EMPRES, IPC tool) could improve anticipation of disaster impact, and support actions to be taken before, during and in the immediate aftermath of an event. Accurate, up-to-date data on disaster impacts at the sector level would eventually inform the monitoring of progress towards sectoral resilience goals and targets set under key international agendas, including the Sustainable Development Goals (SDGs) and the Sendai Framework for Disaster Risk Reduction (SFDRR).

3. Damage and losses computation methods

Disaster impact assessment methods largely vary depending on the sectors addressed, the goals of the assessment, and the organizations, governments and research institutes involved. For the purpose of the FAO information system on damage and losses in agriculture, the key reference methodology is the Post Disaster Needs Assessments (PDNAs), developed jointly by the World Bank, the United Nations and the European Commission (EC, UN, World Bank, 2013). A key element of the PDNA methodology is the distinction between damage, i.e. total or partial destruction of physical assets existing in the affected area, from losses, i.e. changes in economic flows arising from the disaster.

Following the logical structure of the PDNA methodology, Table 1 provides a standardized definition of damage and losses in the crops, livestock, fisheries, aquaculture, and forestry sub-sectors, including an indication of the items and economic flows that should be considered in the assessments, as well as the proposed calculation methods for assigning a monetary value to damage and losses. Each sub-sector has been sub-divided into two main sub-components, namely production and assets.

The production sub-component measures disaster impact on production inputs and outputs. Damages include, for instance, the value of stored inputs (e.g. seeds) and outputs (e.g. crops) that were fully or partially destroyed by the disaster. On the other hand, production losses refer to declines in the value of agricultural production resulting from the disaster. In the case of perennial crops, for example, production losses correspond to the sum of the monetary values of (1) fully destroyed standing crops; (2) decline in production in partially affected areas, as compared to pre-disaster expectations; and (3) the discounted value of lost production in fully damaged areas, until perennial crops become fully productive again.

The assets sub-component measures disaster impact on facilities, machinery, tools, and key infrastructure related to agricultural production. Crop-related assets include, among others, irrigation systems, machinery, equipment; livestock-related assets include sheds, storage buildings; fisheries assets include ponds, hatcheries, freezers and storage buildings, engines and boats, fisheries equipment; forestry assets include, among others, standing timber, firebreaks and watch towers, forestry equipment and machinery, fire management equipment. The monetary value of (fully or partially) damaged assets is calculated using the replacement or repair/rehabilitation cost, and accounted under damage (EC, UN, World Bank, 2013). The assumptions and formulas proposed for the computation of damage and losses are listed and described in the Technical Annexes 1 and 2, respectively.

A central component of the proposed methodology is resilience, intended as the ability to prevent and mitigate disasters and crises as well as to anticipate, absorb, accommodate or recover and adapt from them in a timely, efficient and sustainable manner (FAO, 2013). The prevention and response components of resilience are embedded in the computation methods. A set of resilience parameters are linked to the 'Vulnerability' and 'Lack of coping capacity' dimensions of the Index for Risk Management- INFORM, an open-source methodology for quantitatively assessing crisis and disaster risk (De Groeve, Poljansek, & Vernaccini, 2015). The higher is the risk defined by INFORM at national level, ceteris paribus, the higher is the cost attached to the disaster in a specific area. In other words, given the same intensity of the natural hazard, the estimation of damage and losses will be higher in those areas where the level of risk defined by INFORM is higher.

The proposed methodology is based on a set of assumptions and exogenous knowledge-based parameters; hence, results might be biased for a variety of reasons. First, the lack of data and the impossibility to relax the assumptions implies the utilisation of estimation procedures according to a cascading structure defined within the methodology. Second, errors may occur due to noise for externalities or lack of sensitivity in the measurement. Third, the knowledge-based features of the methodology may modify the final output depending on the source of knowledge.

The damage and losses computation methods proposed in this paper focus uniquely on the impact of disasters on agricultural assets and production flows. Nevertheless, it is acknowledged that disasters have negative effects beyond agricultural production and along the entire food and non-food value chain. In medium- and large-scale disasters, high production losses can lead to increases in imports of food and agricultural commodities to compensate for lost production and meet domestic demand. They can also reduce exports and revenues, with negative consequences for the balance of payment. When post-disaster production losses are significant and in countries where the sector makes an important contribution to economic growth, agriculture value-added or sector growth falls, as does national GDP (FAO, 2015). At the community level, disasters may undermine rural livelihoods and challenge food security. While further research is needed to develop and standardize the assessment of the cascading effects of disasters on the agriculture sectors, these elements fall outside the scope of this paper.

Table 1: *Damage and losses assessment methodology*

Sub-sector	Component	Damage		Losses	
		Item(s)	**Measurement**	**Economic flow(s)**	**Measurement**
Crop	**Production**	Stored crops (annual and perennial); perennial trees; inputs stored (seeds, fertilizer, pesticide etc.); additional inputs bought for replanting (seeds, fertilizer, pesticide, labor etc.).	Annual crops: (1) Pre-disaster value of destroyed stored annual crops and inputs (e.g. stored seeds). (2) Cost of additional inputs (including labor costs) bought for replanting in fully damaged hectares, when replanting is possible within the same season.	Value of crop production (excluding stored crops).	Annual crops: (1) Pre-disaster value of fully destroyed standing crops minus pre-disaster value of replanted crops, when replanting is possible within the same season (2) Difference between expected and actual value of crop production in non-fully damaged harvested area in disaster year.
			Perennial crops: (1) Replacement value of fully damaged perennial trees. (2) Pre-disaster value of destroyed stored perennial crops (e.g. fruits), and inputs (e.g. seedlings). (3) Cost of additional inputs (including labor costs and cost of nursery trees) bought for replanting fully destroyed trees.		Perennial crops: (1) Pre-disaster value of fully destroyed standing crops (e.g. fruits). (2) Difference between expected and actual value of crop production in non-fully damaged harvested area in disaster year. (3) Discounted expected value of crop production in fully damaged harvested area until full recovery.
	Assets	Machinery, siloes, irrigation systems, equipment, tools.	Total destruction: replacement cost of fully destroyed assets at pre-disaster price.		
			Partial destruction: repair/rehabilitation cost of partially destroyed assets at pre-disaster price.		
Livestock	**Production**	Livestock units and livestock products (primary and secondary) stored or ready for sale.	Animals: Pre-disaster value of dead animals minus value of dead animals sold.		
			Livestock products: Pre-disaster value of destroyed stored livestock products (primary and secondary).	Production value of livestock products (primary and secondary)	Livestock products: (1) Difference between expected and actual value of livestock products (primary and secondary) from survived animals in disaster year. (2) Discounted expected value of livestock products (primary and secondary) from dead animals until full recovery of livestock.
	Assets	Machinery, siloes, equipment, tools, and other buildings e.g., cattle fattening and rearing pens,	Total destruction: replacement cost of fully destroyed assets at pre-disaster price.		
			Partial destruction: repair/rehabilitation cost of partially destroyed assets at pre-		

Sub-sector	Component	Damage		Losses	
		Item(s)	Measurement	Economic flow(s)	Measurement
		milking stalls, sheds, stables, pigsties etc.	disaster price.		
Fisheries	**Production**	Fish catch stored or ready for sale.	Pre-disaster market value of destroyed fish stored or ready for sale.	Value of fish catch.	(1) Difference between expected and actual value of annual fish cacth in affected area in disaster year.
	Assets	Boats, ice and fish storage facilities, fishing gear.	Total destruction: replacement cost of fully destroyed assets at pre-disaster prices. Partial destruction: repair/rehabilitation cost of partially destroyed assets at pre-disaster prices.		
Aquaculture	**Production**	Fish stock; fish stored or ready for sale	(1) Pre-disaster value of dead fish minus value of dead fish sold. (2) Pre-disaster value of destroyed fish stored or ready for sale.	Value of aquaculture production	(1) Difference between expected and actual value of aquaculture production in affected area in disaster year.
	Assets	Fishponds, ice and fish storage facilities, tools, machinery.	Total destruction: replacement cost of fully destroyed assets at pre-disaster prices. Partial destruction: repair/rehabilitation cost of partially destroyed assets at pre-disaster prices.		
Forestry	**Production**	Log stored or ready for sale.	(1) Pre-disaster value of destroyed log stored or ready for sale.	Value of log production.	(1) Pre-disaster value of log from destroyed production forests. (2) Difference between expected and actual value of log production in non-fully damaged harvested area in disaster year. (3) Discounted expected value of log production in fully damaged forest area until full recovery.
	Assets	Machinery, siloes, equipment, tools etc.	Total destruction: replacement cost of fully destroyed assets at pre-disaster prices. Partial destruction: repair/rehabilitation cost of partially destroyed assets at pre-disaster prices.		

4. Conclusions and way forward

This paper proposes a standardized methodological approach to assess damage and losses from natural hazard-induced disasters in agriculture, building on existing methodologies that are already implemented in several countries, such as Post Disaster Needs Assessment (PDNA). The systematic implementation of the methodology at national level would help refining and standardizing national methodologies for data collection, eventually leading to the establishment of an FAO global information system that supports resilient and sustainable sectoral development planning, implementation and funding.

The adoption of the methodology for regular damage and losses monitoring and reporting at national level will require strengthening the capacity of relevant national authorities involved in disaster impact assessment in agriculture. Furthermore, the development and use of mobile data collection tools would be an essential step to improve the efficacy and reduce costs of post-disaster impact assessments. The methodology will be tested through the development of a series of case studies on previous disasters, in order to further refine and fine-tune the logical steps, calculation methods and estimation procedures. The results of case studies, together with the data regularly collected at national level, will be analysed and disseminated in the FAO's periodic reports on The Impact of Disasters on Agriculture and Food Security.

TECHNICAL ANNEXES

Annex 1. Assumptions

The overall assumptions of the methodology for damage and losses assessment from natural disaster in agriculture, fisheries, aquaculture and forestry are:

1. Single disaster assessment. It is assumed that shocks to the agricultural sector are independent and their effects are not cumulative. Way forward: note that the complexity of linkages between different disasters must be further explored.
2. Prices used in the damage and losses assessment are always farm gate prices.
3. Annual crop are not affect the years that follow the disaster.
4. Changes in yields and changes in the size of the area harvested are assumed to be independent.
5. For perennial crops, yields are assumed to have a constant linear behaviour through time in the years before the disaster (e.g. 5 years' time series).
6. For perennial crop losses, all fully damaged hectares are replanted the same year of the disaster and no production is available until full recovery.
7. Replanting of the annual crops is feasible in the same season only if the natural hazard strikes before or during the sowing season. If replanting is still possible, the productivity is considered a linear function of the time available for replanting (e.g. if the planting is possible 5 months per year and the natural hazard strikes at the 4th of the 5 months, then 20% of the of total expected production for the same year can be retrieved. A more flexible functional form would allow to relax the linearity assumption and to have room for more accurate calibration.
8. It is assumed there is no mixed use of assets (infrastructure, machinery, tools) in order to avoid double counting. A relaxed version of this hypothesis is also proposed in the methodology.
9. The repair and rehabilitation cost of assets is linearly correlated with the level of damage.
10. Changes of area harvested are calculated as the difference of the first data available for hectares before the disaster and the first available after the disaster, in order to avoid accounting for changes in area harvested not strictly related to the shock(s) of the same year. Multiple shocks in the same year are still a source of bias in the methodology.
11. The area harvested after the disaster is assumed to be remain constant at pre-disaster levels in the counterfactual scenario of no disaster.
12. If the immediate substitution of assets destroyed or the repair of the damaged assets is not possible, an average rental cost of the assets is taken into account as a (linear) function of a specific resilience indicator (e.g. INFORM). The fit of the functional form deserves to be further explored.
13. It is assumed that no additional investments in assets are done except for investments needed to restore pre-disaster production.
14. The physical weight of each type of livestock is assumed to be constant across time but livestock-specific.

15. It is assumed that restoring the size of the livestock happens in bulk after a livestock-specific amount of time, if immediate intervention is not possible.
16. Following existing disaster assessment approaches, this methodology focuses on damage and losses. Potential benefits from natural disasters are not considered.
17. All projections are based on pre-disaster information.

Annex 2. Mathematics behind the methodology

Consider the following sets and subsets:

$$\forall\, i \in I = \{ I_{AC}, I_{PC}, I_L, I_{FI}, I_{AQ}, I_{FO} \}$$

where i is the agricultural output considered and subscripts flag the sub-sectors (AC=Annual Crops; PC=Perennial Crops; L=Livestock; FI=fisheries; AQ=Aquaculture; FO=Forestry). Hence I_{AC} is the list of agricultural outputs of sub-sector. Note that $I_C = I_{AC} \cup I_{PC}$, where C= Crop

$$\forall\, j \in J = \{\text{set of most granular geographical units available}\}$$

where the granularity of the geographical unit depends on data availability. For instance it can be regions, provinces, villages, households);

$$\forall\, k \in K = \{ K_{AC}, K_{PC}, K_L, K_{FI}, K_{AQ}, K_{FO} \}$$

where k is the is the asset (infrastructure, machinery, tool) used in order to produce an agricultural output. The subsets structure is depending on the agricultural output i category. If the asset characterization is strictly dependent on i, then it is represented as K_i. Note that $K_C = K_{AC} \cup K_{PC}$, where C= Crop. If asset k can not be exclusively associate to one item i, then the share of value of the asset attached to item i is proportionate to the share of the value production of item i over the total production value of all items that use that precise asset k;

$$x \in X = \{X_{AC}, X_{PC}, X_L, X_{FI}, X_{AQ}, X_{FO}\}$$

where x is the input of agricultural output production. Note that x can be item specific (X_{ij}), as the asset k_{ij}. Note that $X_C = X_{AC} \cup X_{PC}$, where C= Crop.

Also, consider t as the first time unit when post-disaster data are available; and $t-1$ as the first time unit when pre-disaster data are available. For instance, if data of year 2013, when typhoon Haiyan stroke the Philippines, have been collected after the natural hazard stroke, then we consider $t = 2014$ and $t-1 = 2013$. If data for that year have been collected before the disaster then $t = 2013$ and $t-1 = 2012$. Note that pre-disaster prices and labour force cost are used. Integrating price volatility is out of the scope of the methodological effort done so far. In order to discount values through time it is used

$\rho = \frac{1}{1+r}$ *is the time discount factor and r is the interest rate* (*e.g.* 10%)

Finally, $y_{ij,t}$ is defined as the yield of item i in zone j at time t per spatial unit (i.e. hectare) and $1(s < m_{iN}) = \begin{cases} 1 \text{ if } s < m_{iN} \\ 0 \text{ otherwise} \end{cases}$ is an indicator function in which s corresponds to the moment when the disaster hits and m_{iN} is the moment when the sowing season of item i ends.

The methodology is presented by sub-sector, distinguishing damage from losses per component (production and assets) and considering further decompositions, for example in the case of crops sub-sector where annual and perennial crops are treated separately (sub-components).

The methodology also takes into account both prevention and response components of resilience. Note that resilience is both endogenously defined (e.g. variation in yields due to disasters) and exogenously parametrized (e.g. the capacity to sell the meat of animals dead because of the disaster).

Consider the following definitions, which rely on different subsets of the afore-mentioned sets according to the sub-sector:

$q_{x,ij}$ *is the quantity of input x in zone j needed for producing i in one hectare;*

$\bar{q}_{ij,k,t}$ *is the stored average quantity of item i in zone j per unit of infrastructure k;*

$\bar{q}_{x,ij,t}$ *is the stored average quantity of input x for item i in zone j per unit of infrastructure k;*

$\Delta q_{kj,t} = E_{t-1}[q_{kj,t} \,|\{q_{kj,t-1}, \dots, q_{kj,t-n}\}] - q_{kj,t}$

is the unexpected change of the number of assets fully damaged at time t in zone j;

$\Delta q_{ij,k,t}$ *is the unexpected change in quantity stored of item i in zone j in each asset k;*

$\Delta q_{x,ij,t}$ *is the unexpected change in quantity stored of input x in zone j for item i in each asset k;*

$q_{kj,t}$ *is the number of assets k in zone j at time t;*

$\Delta q_{zj,t} = E_{t-1}[q_{zj,t} \,|\, \{q_{zj,t-1}, \dots, q_{zj,t-n}\}] - q_{ij,k,t}$

is the unexpected change in quantity of stored product z in zone j at time t;

$p_{x,ij,t-1}$ *is the price of input x for item i in zone j at time* $t-1$;

$\bar{c}_{kj,t-1}$ *is the repair (rental) average cost in zone j per unit of capital k that has been only partially(fully)destroyed; that has been only partially (fully destroyed) destroyed;*

$p_{zj,t-1}$ *is the price of one unit of product z (primary or secondary)in zone j at time* $t-1$;

$p_{zj,t-1}$ *is the price of one unit of weight of stored product z in sone j at time* $t-1$;

$p_{ij,t}$ *is the price of of one unit of weight of item i in zone j at time t;*

$l_{ij,t-1}$ *is the labour force cost per unit of time for one hectar of item i production in zone j;*

$T_i = T_{i,l} + T_{i,\$}$

is the number of time units needed for the production of item i in one hectare to be restored, decomposable in the effective working time needed $(T_{i,l})$ *and the waiting time due to credit constraints* $(T_{i,\$})$;

$\bar{w}_i$ *is the average weight of item i;*

T_k *is the time needed to asset k to be reconstructed, expressing the response component of resilience;*

$ha_{ij,t}$ *is the number of hectares devoted at item i in zone j at time t;*

$\Delta ha_{ij,t} = E_{t-1}[ha_{ij,t}] - ha_{ij,t}$ *is the unexpected change in the quantity of hactares where i is produced;*

$k_{ij} \in K_{PC}$ *is the number of trees per hectare of item i in zone j;*

$\Delta y_{ij,t} = E_{t-1}[y_{ij,t} \,|\, \{y_{ij,t-1}, \dots, y_{ij,t-n}\}] - y_{ij,t}$

is the unexpected change in yields per unit (e.g. km or ha) of geographical extention;

$\Delta y_{zj,t} = E_{t-1}[y_{zj,t} \,|\, \{y_{zj,t-1}, \dots, y_{zj,t-n}\}] - y_{zj,t}$ *and*

$y_{zj,t}$ *is the yield of product z (primary or secondary) per item i (i.e. animal) in zone j at time t;*

$\mathcal{I}(\Delta q_{kj,t} > 0)$ *implies that only assets k partially or fully destroyed are taken into account;*

s is the month when the disaster hits;

m_{i0} *is the month when the sowing season of item i begins;*

m_{iN} *is the month when the sowing season of item i ends;*

$\beta = f(R)$ *is a function of a specific resilience index R (e.g. INFORM) s.t.* $\beta \in [0;1]$.

α *is the share of the value dead animal that can be sold.*

CROP DAMAGE

1. CROP PRODUCTION DAMAGE

1.1. **ANNUAL CROP PRODUCTION INPUT DAMAGE.** $\forall\, i \in I_{AC} \wedge \forall\, j \in J$, given $x \in X = \{set\ of\ inputs\ for\ crop\ production\}$, the Damage to all Input x of Annual Crop i in zone j is

$$DIAC_{ij} = \beta \cdot \left(\sum_{x \in X} \left[p_{x,ij,t-1} \cdot q_{x,ij} \right] + l_{ij,t-1} \cdot T_i \right) \cdot \Delta ha_{ij,t} \cdot 1(s \in [m_{i0}; m_{iN}])$$

1.2. **PERENNIAL CROP PRODUCTION INPUT DAMAGE.** $\forall\, i \in I_{PC} \wedge \forall\, j \in J$, given $x \in X = \{set\ of\ inputs\ for\ crop\ production\}$, the Damage to Inputs x of Perennial Crop i in zone j is

$$DIPC_{ij} = \left(\sum_{x \in X} \left[p_{x,ij,t-1} \cdot q_{x,ij} \right] + l_{ij,t-1} \cdot T_i + p_{ij,t-1} \cdot k_{ij} \right) \cdot \Delta ha_{ij,t}$$

1.3. **STORED CROP DAMAGE (PRODUCTION AND INPUT).** $\forall\, i \in I_{PC} \wedge \forall\, j \in J$, given $x \in X_C$ and $k \in K_C$, the Damage to Stored Crops (inputs and production) is

$$DSC_{ij} = p_{ij,t-1} \cdot \sum_{k \in K_C} \Delta q_{ij,k,t} + p_{x,ij,t-1} \cdot \sum_{k \in K_C} \sum_{x \in X_C} \Delta q_{x,ij,t}$$

Note that $\Delta q_{ij,k,t} = E_{t-1}[q_{ij,k,t}] - q_{ij,k,t}$ and $\Delta q_{x,ij,t} = E_{t-1}[q_{x,ij,t}] - q_{x,ij,t}$ where $E_{t-1}[\cdot]$ is the expectation function of $[\cdot]$ at time $t-1$. Because of a systematic lack of these type of data, this methodology proposes the following estimation procedures:

$\Delta q_{ij,k,t} = \sum_{k \in K_C} \bar{q}_{ij,k,t} \cdot \Delta q_{ij,t}$ and $\Delta q_{x,ij,t} = \sum_{k \in K_C} \bar{q}_{x,ij,t} \cdot \Delta k_{ij,t}$

2. ***CROP ASSETS DAMAGE***

2.1. **CROP ASSETS TOTALLY DAMAGED.** $\forall\, i \in I_{PC} \wedge \forall\, j \in J$, given $k \in K_i \subset K_C$, the Damage of Assets Totally destroyed for Crops production is

$$DATC_{ij} = \sum_{k \in K_i} p_{kj,t-1} \cdot \Delta q_{kj,t}$$

Note that the estimation function $E_{t-1}[\cdot]$ is conditional on the time series of quantities of q_{kj} in the pre-disaster period for n units of time. This implies a direct relation with the size of investments in assets, which are assumed to be null except for investments needed to restore pre-disaster production.

2.2. **CROP ASSETS PARTIALLY DAMAGED.** $\forall\, i \in I_{PC} \wedge \forall\, j \in J$, given $k \in K_i \subset K_C$, Damage of Assets only Partially destroyed for Crops production is

$$DAPC_{ij} = \sum_{k \in K_i} \bar{c}_{kj,t-1} \cdot \Delta q_{kj,t}$$

CROP LOSSES

1. ***CROP PRODUCTION LOSSES***

1.1. **ANNUAL CROP PRODUCTION LOSSES.** $\forall\, i \in I_{AC} \wedge \forall\, j \in J$, given $y_{ij,t}$, the Losses of Annual Crops Production component are

$$LACP_{ij} = p_{ij,t-1} \cdot \Delta y_{ij,t} \cdot ha_{ij,t} \cdot 1(\Delta y_{ij,t} > 0) + \\ + \left(1 - \frac{m_{iN} - s}{m_{iN} - m_{i0}} \cdot 1(s \in [m_{i0}; m_{iN}]) \right) \cdot p_{ij,t-1} \cdot y_{ij,t-1} \cdot \Delta ha_{ij,t}$$

1.2. **PERENNIAL CROP PRODUCTION LOSSES.** $\forall\, i \in I_{PC} \wedge \forall\, j \in J$, given $y_{ij,t}$, the Losses of Perennial Crops Production component are

$$LPCP_{ij} = \sum_{g=0}^{T_i} \rho^g \cdot E_{t-1}[p_{ij,t-1} \cdot y_{ij,t-1}] \cdot \Delta ha_{ij,t} + p_{ij,t-1} \cdot \Delta y_{ij,t} \cdot ha_{ij,t}$$

2. ***CROP ASSETS LOSSES.*** $\forall\, i \in I_C \wedge \forall\, j \in J$, given $k \in K_i \subset K_C$, the Losses of Assets partially or fully destroyed used for Crops production are

$$LAC_{ij}=\sum_{g=0}^{T_k}\rho^g\cdot\left\{\sum_{k\in K_i}\bar{c}_{kj,t-1}\cdot\Delta q_{kj,t}\cdot 1(\Delta q_{kj,t}>0)\right\}$$

LIVESTOCK DAMAGE

1. ***LIVESTOCK PRODUCTION DAMAGE.*** $\forall i\in I_L\wedge\forall j\in J$, given $z\in Z_{stored}=$ *{set of livestock primary and secondary stored products}* $\subset Z_L=\{set\ of\ livestock\ primary\ and\ secondary\ products\}$, the Damage to the Production component of Livestock is

$$DPL_{ij}=\sum_{z\in Z_{stored}}\{\Delta q_{zj,t}\cdot p_{zj,t-1}\}+(\Delta q_{ij,t}\cdot\bar{w}_i)\cdot(p_{ij,t-1}-\alpha\cdot p_{ij,t})$$

2. ***LIVESTOCK ASSETS DAMAGE***
   2.1. **LIVESTOCK ASSETS TOTALLY DAMAGED.** $\forall i\in I_L\wedge\forall j\in J$, given $k\in K_i\subset K_L$, the Damage of Assets Totally destroyed for Livestock production is

$$DATL_{ij}=\sum_{k\in K_i}p_{kj,t-1}\cdot\Delta q_{kj,t}$$

   2.2. **LIVESTOCK ASSETS PARTIALLY DAMAGED.** $\forall i\in I_L\wedge\forall j\in J$, given $k\in K_i\subset K_L$, Damage of Assets only Partially destroyed for Livestock production is

$$DAPL_{ij}=\sum_{k\in K_i}\bar{c}_{kj,t-1}\cdot\Delta q_{kj,t}$$

LIVESTOCK LOSSES

1. ***LIVESTOCK PRODUCTION LOSSES.*** $\forall i\in I_L\wedge\forall j\in J$, given $z\in Z=$ *{set of livestock primary and secondary products}*, the Losses of Livestock production (primary and secondary) are

$$\sum_{g=0}^{T_i}\rho^g\cdot\left\{\sum_{z\in Z}(\Delta q_{ij,t}\cdot p_{zj,t-1}\cdot y_{zj,t-1})\right\}+\sum_{z\in Z}(q_{ij,t}\cdot p_{zj,t-1}\cdot\Delta y_{zj,t})$$

2. **LIVESTOCK ASSETS LOSSES.** $\forall i\in I_L\wedge\forall j\in J$, given $k\in K_i\subset K_L$, the Losses of Assets partially or fully destroyed used for Livestock production are

$$LAL_{ij}=\sum_{g=0}^{T_k}\rho^g\cdot\left\{\sum_{k\in K_i}\bar{c}_{kj,t-1}\cdot\Delta q_{kj,t}\cdot 1(\Delta q_{kj,t}>0)\right\}$$

FISHERIES

Consider the following additional definitions:

$$y_{ij,t}=\frac{\bar{w}_{ij}\cdot q_{ij,t}}{area_{ij,t}}\ where\ \bar{w}_{ij}\cdot q_{ij,t}$$

$is\ quantity\ of\ fish\ i\ catch\ (e.g.in\ tons)(average\ weight\ times\ the\ number\ of\ fishes);$

$area_{ij,t}\ is\ the\ number\ of\ unit\ of\ area\ where\ item\ i\ (i.e.type\ of\ fish)\ in\ zone\ j\ at\ time\ t\ is\ catched;$

FISHERIES DAMAGE

1. ***FISHERIES PRODUCTION DAMAGE.*** $\forall i\in I_L\wedge\forall j\in J$, given $k\in K_i\subset K_{FI}$, the Damage of Fisheries Production component is

$$DFiP_{ij}=p_{ij,t-1}\cdot\Delta q_{ij,k,t}\cdot\bar{w}_i$$

Note that the estimation procedure is equivalent to the one proposed for stored crops.

2. ***FISHERIES ASSETS DAMAGE***
   2.1. **FISHERIES ASSETS TOTALLY DAMAGED.** $\forall i\in I_{FI}\wedge\forall j\in J$, given $k\in K_i\subset K_{FI}$, the Damage of Assets Totally destroyed for Fisheries production is

$$DATFi_{ij}=\sum_{k\in K_i}p_{kj,t-1}\cdot\Delta q_{kj,t}$$

2.2. **FISHERIES ASSETS PARTIALLY DAMAGED.** $\forall\, i \in I_{FI} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{FI}$, Damage of Assets only Partially destroyed for Fisheries production is

$$DAPFi_{ij} = \sum_{k \in K_i} \bar{c}_{kj,t-1} \cdot \Delta q_{kj,t}$$

FISHERIES LOSSES

1. ***FISHERIES PRODUCTION LOSSES.*** $\forall\, i \in I_{FI} \wedge \forall\, j \in J$, the Losses of Fisheries production are

$$LFP_{ij} = area_{ij,t} \cdot p_{ij,t-1} \cdot \Delta y_{ij,t}$$

2. ***FISHERIES ASSETS LOSSES.*** $\forall\, i \in I_{FI} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{FI}$, the Losses of Assets partially or fully destroyed used for Fisheries production are

$$LAF_{ij} = \sum_{g=0}^{T_k} \rho^g \cdot \left\{ \sum_{k \in K_i} \bar{c}_{kj,t-1} \cdot \Delta q_{kj,t} \cdot 1\left(\Delta q_{kj,t} > 0\right) \right\}$$

AQUACULTURE

Consider the following additional definitions:

$$\Delta area_{ij,t} = E_{t-1}\left[\Delta area_{ij,t}\right] - \Delta area_{ij,t}$$

is the unexpected change in spatial unit quantity (e.g. cube metres) where item i is produced;

AQUACULTURE DAMAGE

1. ***AQUACULTURE PRODUCTION DAMAGE.*** $\forall\, i \in I_{AQ} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{AQ}$, the Damage of Aquaculture Production component is

$$DAQP_{ij} = \left(p_{ij,t-1} - \alpha \cdot p_{ij,t}\right) \cdot \bar{w}_i \cdot \left(\Delta q_{ij,t} + \Delta q_{ij,k,t}\right)$$

Note that the estimation procedure of $\Delta(\cdot)$ is equivalent to the one proposed for stored crops.

2. ***AQUACULTURE ASSETS DAMAGED***

2.1. **AQUACULTURE ASSETS TOTALLY DAMAGED.** $\forall\, i \in I_{AQ} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{AQ}$, the Damage of Assets Totally destroyed for Aquaculture production is

$$DATAQ_{ij} = \sum_{k \in K_i} p_{kj,t-1} \cdot \Delta q_{kj,t}$$

2.2. **AQUACULTURE ASSETS PARTIALLY DAMAGED.** $\forall\, i \in I_{AQ} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{AQ}$, Damage of Assets only Partially destroyed for Aquaculture production is

$$DAPAQ_{ij} = \sum_{k \in K_i} \bar{c}_{kj,t-1} \cdot \Delta q_{kj,t}$$

AQUACULTURE LOSSES

1. ***AQUACULTURE PRODUCTION LOSSES.*** $\forall\, i \in I_{AQ} \wedge \forall\, j \in J$, the Losses of Aquaculture production are

$$LAQP_{ij} = \Delta area_{ij,t} \cdot p_{ij,t-1} \cdot y_{ij,t-1} + area_{ij,t} \cdot p_{ij,t-1} \cdot \Delta y_{ij,t-1}$$

2. ***AQUACULTURE ASSETS LOSSES.*** $\forall\, i \in I_{AQ} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{AQ}$, the Losses of Assets partially or fully destroyed used for Aquaculture production are

$$LAAQ_{ij} = \sum_{g=0}^{T_k} \rho^g \cdot \left\{ \sum_{k \in K_i} \bar{c}_{kj,t-1} \cdot \Delta q_{kj,t} \cdot 1\left(\Delta q_{kj,t} > 0\right) \right\}$$

FORESTRY DAMAGE

1. ***FORESTRY PRODUCTION DAMAGE***

$\forall\, i \in I_{FO} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{FO}$ and $z \in Z_{stored}$ = {set of forestry primary and secondary stored products} $\subset Z_{FO}$ = {set of forestry primary and secondary products} ,the Damage of Forestry Production component is

$$DFoP_{ij} = \Delta ha_{ij,t} \cdot \bar{y}_{ij,t-1} \cdot p_{ij,t-1} + \sum_{z \in Z_{stored}} \left\{ \Delta q_{zj,t} \cdot p_{zj,t-1} \right\}$$

2. **FORESTRY ASSET DAMAGE**

   2.1. FORESTRY ASSETS TOTALLY DAMAGED. $\forall\, i \in I_{FI} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{FI}$, the Damage of Assets Totally destroyed for Forestry production is

$$DATFi_{ij} = \sum_{k \in K_i} p_{kj,t-1} \cdot \Delta q_{kj,t}$$

   2.2. FORESTRY ASSETS PARTIALLY DAMAGED. $\forall\, i \in I_{FI} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{FI}$, Damage of Assets only Partially destroyed for Forestry production is

$$DAPFi_{ij} = \sum_{k \in K_i} \bar{c}_{kj,t-1} \cdot \Delta q_{kj,t}$$

FORESTRY LOSSES

1. ***FORESTRY PRODUCTION LOSSES.*** $\forall\, i \in I_{FO} \wedge \forall\, j \in J$, given $z \in Z_{FO} = \{set\ of\ forestry\ primary\ and\ secondary\ products\}$, the Losses of Forestry production (primary and secondary) are

$$\sum_{g=0}^{T_i} \rho^g \cdot \left\{ \sum_{z \in Z} \Delta ha_{ij,t} \cdot p_{zj,t-1} \cdot y_{zj,t-1} \right\} + \sum_{z \in Z} \left(ha_{ij,t} \cdot p_{zj,t-1} \cdot \Delta y_{zj,t} \right)$$

2. ***FORESTRY ASSETS LOSSES.*** $i \in I_{FO} \wedge \forall\, j \in J$, given $k \in K_i \subset K_{FO}$, the Losses of Assets partially or fully destroyed used for Forestry production are

$$LAAQ_{ij} = \sum_{g=0}^{T_k} \rho^g \cdot \left\{ \sum_{k \in K_i} \bar{c}_{kj,t-1} \cdot \Delta q_{kj,t} \cdot 1\left(\Delta q_{kj,t} > 0\right) \right\}$$

Annex 3. Error analysis: calculation of error intervals in measurement

In order to represent at least part of this variability in the outcome measurements, the following error interval procedure is proposed.

1. **Min-Max Interval.** The methodology presents a set of exogenous parameters per sub-component, distinctly for damage and for losses.

   1.1. For each parameter, it is defined an *average* value, a *minimum* and a *maximum*. All three values are primarily based on the existing concerned literature and on experts' judgment.

   1.2. The outcome values for damage and for losses are calculated three times for each sub-component, using the *average* values of the exogenous parameters, the values that *minimize* the outcome, and the values that *maximize* the outcome.

Outcomes can also be aggregated per component, sub-sector, or totally as all sub-components are mutually exclusive and additive.

2. **90% Confidence Interval per level of geophysical stressor.**

In order to identify the magnitude of a natural hazard, climatic and geophysical stressors information is collected at the most cost-efficient level of granularity.

2.1. Categories of intensity of the stressors are defined. For instance, in the case of Typhoons, wind speed (in accordance with the topography of the area) is a strong determinant of the magnitude of the natural hazard, and four categories are identified.
2.2. For each cluster (i.e. category of stressor's intensity), the mean of damage and mean of losses in zones j falling under that precise cluster are calculated.
2.3. Each mean of step 2.2. is provided with a 90% confidence interval.
2.4. Hypothesis test of difference between means is calculated. The T test tests the internal validity of step 2.

NEW SOFTWARE, APPS AND TOOLS FOR DATA COLLECTION IN AGRICULTURE STATISTICS

Session Organizer
J. Parsons | USDA National Agricultural Statistics Service | Washington, DC | USA

ABSTRACT

Technology continues to change at a rapid rate and has become increasingly consumerized. The internal and external stakeholders of government statistical agencies have come to expect statistical agencies to provide products, tools and services at a comparable level to multinational information technology firms. Statistical organizations operate in complicated environments and often use customized, unique tools that employ sophisticated statistical techniques for both internal external use cases. This session will be focus on new, innovative data collection and processing tools with a focus on services that meet the needs of an increasingly mobile and consumer oriented set of stakeholders. We would like to focus on innovative data collection tools that are being used to manage data collection, leverage automated data reporting opportunities, improve data collection in the field, increase the speed of data delivery, improve the quality of data collected, increase response rates, and provide a quality response with minimal data discrepancies. Our goal is to acquire a high quality responses using new technologies that are responsive, usable and reduce burden. Examples of concrete projects, plans or ideas on how to harness the new technology and methods that are being developed to create better statistics are highly welcomed.

Categories of agricultural producers

Agricultural enterprises (large &medium) include business partnerships, limited liability or additional liability companies, private (closed) joint-stock companies, public (open) joint-stock companies, production cooperatives, agricultural communities, unitary state enterprises and subsidiaries of non-agricultural business entities

Small agricultural enterprises (including micro enterprises) include legal entities – commercial organizations listed in the Unified State Register of Legal Entities

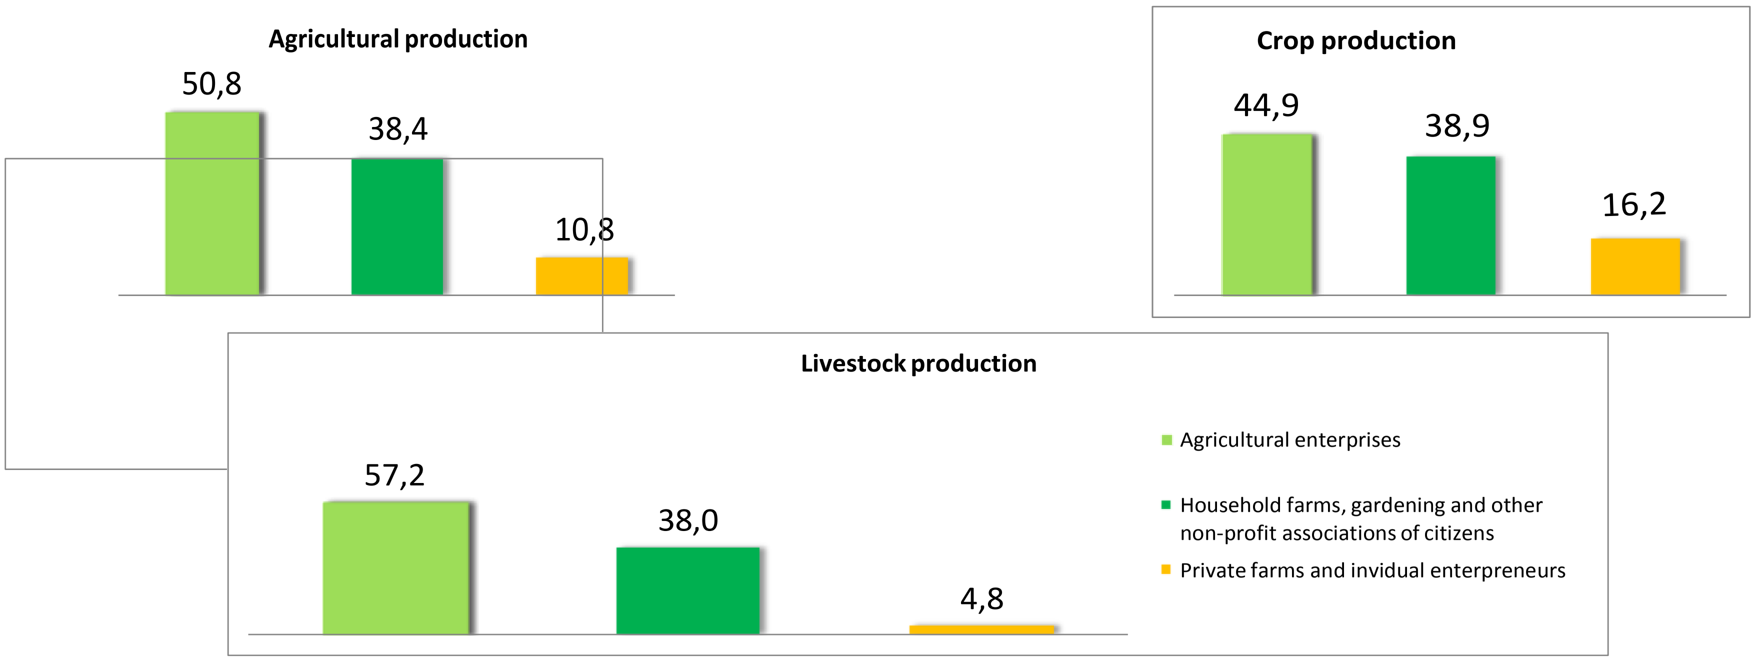
Private (peasant) farm –is the property jointly owned by immediate family or legal relatives, who collectively and personally conduct entrepreneurial activities, production or other business operations (production, processing, storage, transportation or sales of agricultural products)

Individual entrepreneur - a citizen (physical person), who conducts entrepreneurial activities without legal entity registration, who is registered in accordance with the Civil Code of the Russian Federation; and has a Certificate of state registration of individual entrepreneur with the listed types of activities

Household farm – is a noncommercial entity for the production or processing of agricultural products for on-farm consumption by individuals or immediate family members on the land plot, which is provided or purchased for private household farming **Gardening, vegetable-growing and dacha type non-profit association of citizens** - a noncommercial organization of volunteers created for the purposes of addressing their common social and operational issues related to their activities in horticulture, vegetable growing and dacha maintenance

Agricultural economy by categories of agricultural producers in 2015

(in current prices, in percent)



COMBINED METHOD OF SURVEY BY TYPE OF AGRICULTURAL ACTIVITIES:

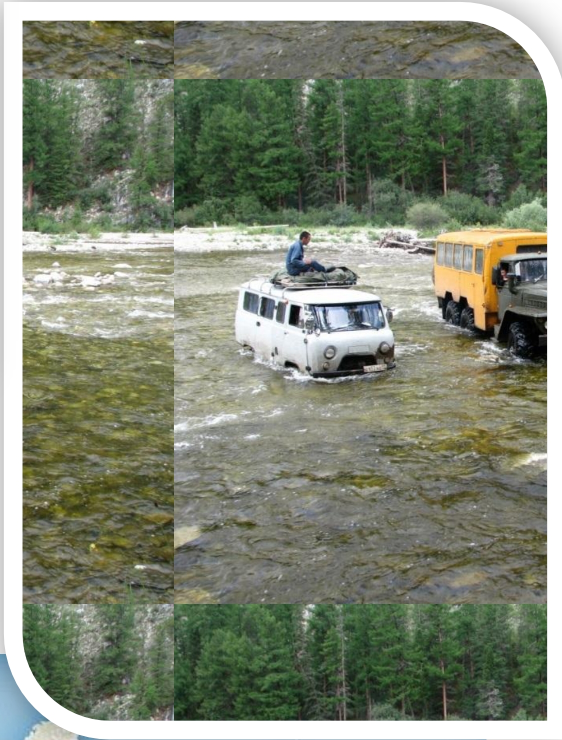
- at least once in 10 years - the Russian agricultural census
- no later than 5 years after regular agricultural census – agricultural micro census
- during the intercensal period:
  - complete enumeration - in large and medium agricultural enterprises;
  - sample surveys - of small agricultural enterprises and individual entrepreneurs

2016 Russian agricultural census

July 1 - August 15, 2016

in remote regions

September 15 - November 15, 2016



Remote regions

The number of agricultural producers, covered by the Russian agricultural census

Category of census subjects	Census-2016
Agricultural enterprises, in total, thsd., including:	40,4
Agricultural enterprises (without micro enterprises)	17,4
Micro enterprises	18,7
Subsidiary enterprises of non-agricultural entities	4,3
Private farms and individual entrepreneurs, thsd.	206,8
Household farms, in total, mln.	23,3
including those:	
in rural areas in	14,9
urban areas	8,4
Gardening, vegetable-growing and dacha-type non-profit associations of citizens, thsd.,	76,3
Number of land plots in them, mln.	12,7

Information sources
Statistical Business Register
Lists of houses in urban settlements, formed for the Russian Population Census 2010
The Unified State Register of Rights in Immovable Property and Transactions Involving Such Property
Information, provided by the regional bodies of state supervision over the technical condition of self-propelled vehicles and other equipment
Information about state technical inventory of the facilities, related to the town-planning activity in Russia
The Unified State Land Register, The Federal Service for State Registration, Cadastre and Cartography
Information from regional bodies of the Federal Service for Veterinary and Phytosanitary Surveillance

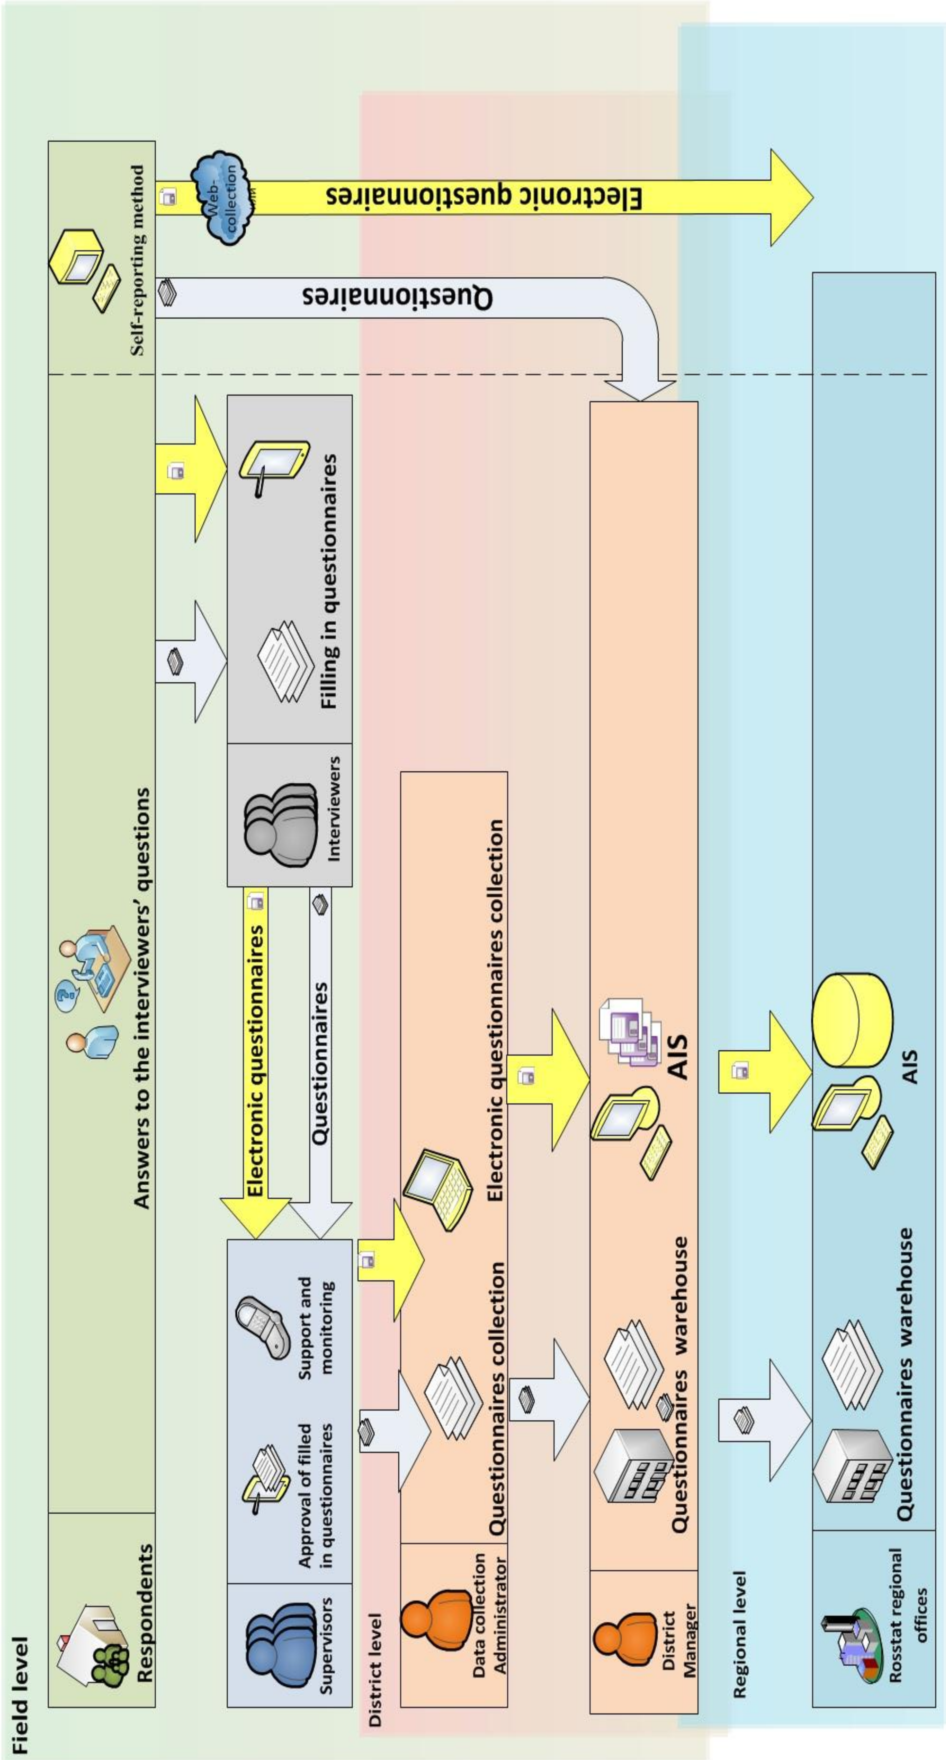
Data collection methods of the Russian agricultural census' objects

- **Complete enumeration**:
  - Agricultural enterprises ,
  - Private farms and individual entrepreneurs,
  - Gardening, vegetable-growing and dacha-type non-profit associations of citizens,
  - Household farms in rural areas
- **Sample survey:**
  - Owners of the land plots, comprising gardening and non-profit citizen groups - (10% sample),
  - Household farms in towns and urban settlements - (20 % sample)

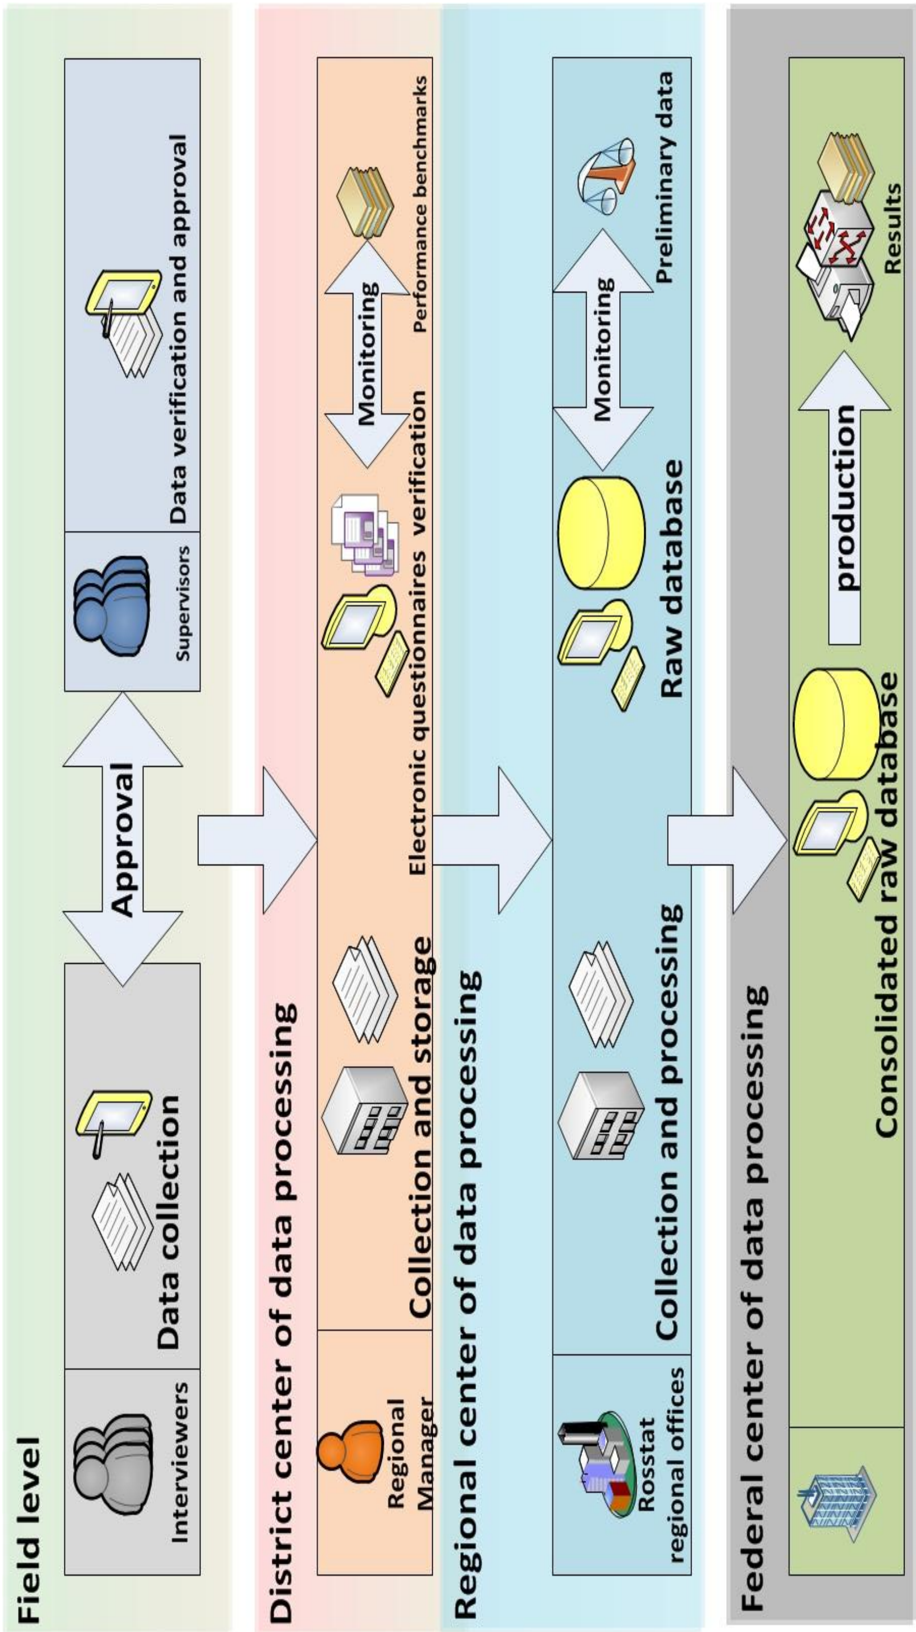
Data collection methods of the Russian agricultural census

- **filling** of questionnaires by respondents, using machine-readable forms of documents
  - Agricultural enterprises ;
- **electronically via the Rosstat internet site**
  - Agricultural enterprises;
  - Private farmers and individual entrepreneurs;
- **questioning respondents using questionnaires for further scanning**
  - Private farmers and individual entrepreneurs;
  - Household farms and other personal farms;
  - Gardening, vegetable-growing and dacha-type non-profit associations of citizens;
  - Owners of the land plots, comprising non-profit citizen groups;
- **questioning respondents by enumerators, using tablets**
  - Household farms and other personal farms.

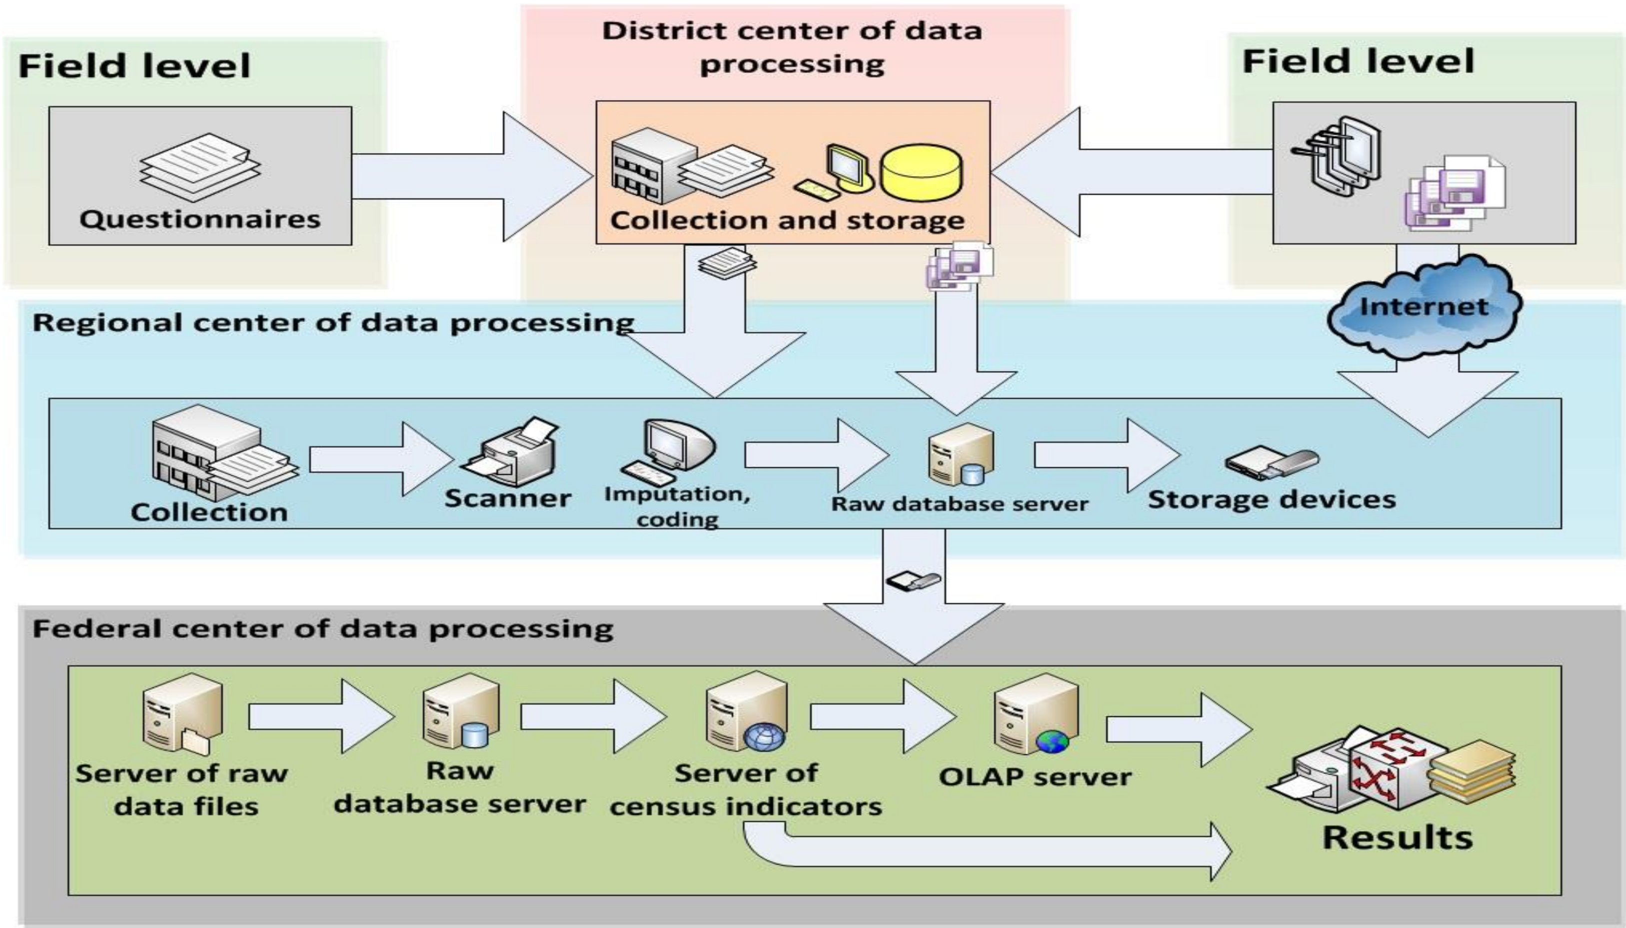
2016 Data Collection



Data processing centers



Census technological cycle



Intercensal period

Agricultural enterprises	**Combining complete enumeration with sample survey** (depending on type of business)
Large and medium	***Crop production and livestock*** monthly complete enumeration reports (including indicators - acreage, livestock farm animals, production and sale of agricultural products) - on short program; annual accounts - on broader program.
Small **small enterprises (except micro enterprises)** **micro enterprises**	**Sample survey** *Crop (acreage and crop production) – twice a year* *Livestock (livestock farm animals and livestock production) - monthly* *Crop and livestock production - annually*
Private farms and individual entrepreneurs	**Sample survey** – annually *Sown areas and crop production; livestock farm animals and livestock production;* *Sale of agricultural products.*
Household farms	**Multi-purpose sample survey** - monthly *Crop, livestock, sale of agricultural products, the cost of purchasing industrial goods, payment of production services.*

The use of satellite images to forecast agricultural production

Artur Łączyński
Central Statistical Office, Agriculture Department
Niepodległości 208
Warsaw, Poland
E-mail a.laczynski@stat.gov.pl

DOI: 10.1481/icasVII.2016.f39b

ABSTRACT

In the first part of the speech, the results of cooperation between the Department of Agriculture in the Central Statistical Office and the Institute of Geodesy and Cartography in Warsaw will be presented. The presentation will be focused on the possibility of satellite image use to forecast agricultural production. A short description of NOAA AVHRR satellite images will be presented. Furthermore, a satellite imagery receiving system, which consists of a parabolic antenna with the diameter of 1.2 m, a signal receiver and specialised software enabling data recording, will be described. The software provides automatic operation of the station, namely, recording of images as soon as the NOAA satellite comes within the range sufficient for receiving signals, designated by the minimum "view" angle of the satellite. It also provides up-to-date information on the position of the satellite in relation to the area of Poland, as well as the time of the nearest recording. During recording, it allows for "viewing" the image in 2 radiation ranges - near-infrared and thermal infrared. While speech, a system of crops condition estimation using comparative maps will also be discussed. The final products in the Crop Yield Assessment System are comparative maps of the NDVI value as compared to an average year and the previous year. In order to generate these products, a specialised module has been developed as part of the ArcMap software. This module, using software functions, enables execution of creation of ten-day compositions from the corrected images of the NDVI and creation of comparative maps of the NDVI distribution in comparison to an average year and the previous year. These maps are generated on a 1 km2 grid and averaged to voivodships (NTS 2) and in selected voivodships to poviats (NTS 4).

In the second part of the paper, it will be presented a comparison of yield estimation for a few crops, carried out by experts for field crop production with the data obtained from maps of NDVI indicator distribution. It will be presented comparing the imaging index NDVI with data obtained from estimates developed in the Central Statistical Office, Agriculture Department for 2015, as a model to represent optimal weather conditions for crop production from wheat and all cereals. The map of agricultural drought in Poland in 2015 will also be presented.

Keywords: satellite imagery, yield estimation, harvest statistics

1. Introduction

The role of the official statistics is delivering high quality data concerning broad variety of topics. The very important domain of the official statistics is agriculture as a part of wider classification of land cover or use. Because of its characteristics such as large area or huge spatial and temporal variability, agriculture is predestined to survey techniques that can globally survey areas of whole countries or regions delivering data in short time intervals during a year.

Therefore, the satellite imagery can be successfully used for agriculture and different land cover/use classifications. In agriculture, the most common applications of satellite images can be attributed to crop area estimation, plant production estimation / prediction as well as measuring plant growth conditions or effects of extreme weather conditions (e.g. droughts, floods, frost damages). The above mentioned examples do not exhaust possibilities of using satellite images. However, for the needs of this publication only application in estimation of agricultural production would be described.

The satellite images are usually classified as Big Data. In many projects launched by EUROSTAT, use of Big Data sources in combination with existing official statistical data is studied to improve current statistics and create new statistics in various statistical domains, namely, agriculture. The more important running projects belonging to multisource statistics, where the satellite data are investigated, are following:

ESS ADMIN VIP - use of administrative data in statistics including issues related to multisource statistics

ESSNET ADMIN - quality of multisource statistics

ESSNET BIG DATA - matching administrative data i.e. LPIS with big data i.e. satellite imagery in agriculture statistics

The Central Statistical Office cooperates closely with the Institute of Geodesy and Cartography in Warsaw, which provides results of NDVI for poviats (NTS 4) as well as production forecasts for cereal crops for voivodships (NTS 2). This multiannual cooperation yielded with the systematically updated data base and the sustainable model of vegetation assessment.

2. Materials and methods

<u>Yield estimates of Central Statistical Office</u>

The Central statistical Office collects information concerning areas, yield and harvest from different sources. The basic information about crop areas comes from farm surveys (e.g. Farm Structure Survey) or administrative data like IACS (Integrated Administration and Control System). Information about plant production is obtained from field experts in each gmina (NTS 5). The estimated yields are representative for voivodships (NTS 2). Furthermore, the voivodship and country yield and harvest estimates are reviewed by regional and country experts. In estimation of harvest also market data are taken into account. The estimates are published three times a year starting from the end of July.

<u>Method of satellite imagery processing in the Institute of Geodesy and Cartography</u>

One of the first systems for monitoring of agricultural areas CCAP (Crop Condition Assessment Program) was created by the Canadian Centre for Remote Sensing CCRS. This programme was based on the use of satellite images taken every ten days by the NOAA AVHRR (Advanced Very High Resolution Radiometer) for determination of the development state of crops. The technology developed by the CCRS was implemented in 1996 in the Institute of Geodesy and Cartography in Warsaw, see fig. 1.. This technology consists of the following stages:

- recording of satellite images acquired by AVHRR scanners installed on the NOAA series satellites for the area of the entire country within the vegetation period of the cultivated plants,
- geometric and radiometric processing of the recorded images taken by the NOAA AVHRR,
- determination of the vegetation index - NDVI, on the basis of the radiation value recorded by the NOAA AVHRR scanner,
- creation of ten-day compositions for agricultural areas on the basis of daily images of the NDVI distribution,
- preparation of comparative maps of the NDVI distribution in comparison with an average year and with the previous year for particular ten-day periods of the vegetation season,
- determination of the process of changes in the value of the NDVI describing the development of cultivated plants within the vegetation season.

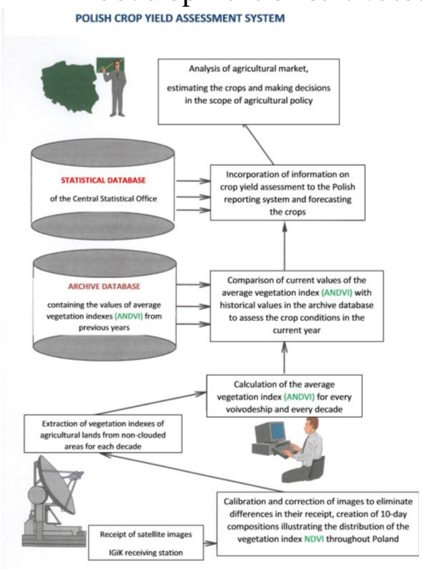

Figure 1: *The diagram of the crop yield assessment system operation.*

Satellites launched by the American agency NOAA are equipped with several instruments for environment research. An instrument used for acquiring information about reflection of radiation from land and about surface temperature is the AVHHR scanner (Advanced Very High Resolution Radiometer). The latest version of this instrument (AVHRR3) can register radiation in 6 scanning ranges:

channel 1 - 0.58 - 0.68 μm
channel 2 - 0.72 - 1.0 μm
channel 3A - 1.58 - 1.64 μm
channel 3B - 3.55 - 3.93 μm
channel 4 - 10.3 - 11.3 μm
channel 5 - 11.5 - 12.5 μm

The first two channels provide information about reflection of radiation in the full-visible and near-infrared range. Channels 3A and 3B cover medium infrared range, and channels 4 and 5 (thermal infrared) provide information about land temperature.

Images recorded by the NOAA AVHRR scanner cover an area of ca. 2400 x 2400 km. Depending on the location of the orbit in relation to the receiving station, they may be received 2 - 4 times per day. For the purpose of monitoring of the area surface, images recorded in early afternoon (12:30 a.m. - 3:00 p.m.) are most often used. Field resolution of images in the nadir point is 1.1 x 1.1 km. The images are transmitted to the data receiving station in the HRPT format (High Resolution Picture Transmission) - it is the basic transmission format; they can also be received in the LAC format (Local Area Coverage). "Raw" images recorded by the receiving station require specialised software in order to process them to a state enabling environment condition analysis.

The receipt system consists of a parabolic antenna with the diameter of 1.2 m, a signal receiver and specialised software enabling data recording. The software provides automatic operation of the station, namely recording of images as soon as the NOAA satellite comes within the range sufficient for receiving signals, designated by the minimum "view" angle of the satellite. It also provides up-to-date information on the position of the satellite in relation to the area of Poland, as well as the time of the nearest recording, and during recording it allows for "viewing" the image in 2 radiation ranges - near-infrared and thermal infrared. The images recorded in the HRPT format are saved in the relevant system folder connected to the data receiving software, and then transmitted to the image processing system for the satellite images taken by the NOAA AVHRR.

Currently, for processing of satellite images taken by the NOAA AVHRR, the Institute of Geodesy and Cartography uses specialized module developed as part of the Chips software for Windows. This module covers full processing of data in 5 stages:

- import of the image in the HRPT format to the format of the software, along with analysis of image quality and extraction of information about orbit parameters, used in the subsequent data geometrisation,
- interactive geometric adjustment of the "raw" satellite image taken by the NOAA AVHRR to the reference picture,
- rectification of the image to a specified map projection (Albers projection), as well as to defined dimensions (700 x 700 km),
- radiometric calibration of the image in order to obtain pictures of albedo distribution in channels 1 and 2 and radiation temperature in channels 4 and 5,
- establishment of derivative products - a picture of distribution of the Normalised Difference Vegetation Index (NDVI) and a picture of temperature distribution of the area surface.

The final product of the module of the NOAA AVHRR Chips software for Windows is a set of geometrically adjusted and radio-metrically calibrated images in channels 1 - 5 of the AVHRR scanner, as well as derivative products. The data are prepared in the export format for use in the final stage of the Crop Yield Assessment System operation.

The final products in the Crop Yield Assessment System are comparative maps of the NDVI value as compared to an average year and the previous year. In order to generate these products, a specialised module has been prepared as part of the ArcMap software. This module, using software functions, enables execution of the following stages of works:

- atmospheric correction of daily images taken by the NOAA AVHRR in channels 1 and 2,
- creation of ten-day compositions from the corrected images of the NDVI,
- determination of agricultural areas of Poland by means of a mask created on the basis of the land cover map, drawn up under the CORINE Land Cover Programme,
- determination of threshold values of cloud cover and determination of ten-day composition unaffected by cloud cover for agricultural areas of the country,

- creation of comparative maps of the NDVI distribution in comparison, to an average year (designated on the basis of the NDVI value from 1992 - 2008) and to the previous year

These maps are generated on a 1 km2 grid and averaged to provinces. Information on the condition of crops is expressed by the relation of the NDVI in the current ten-day period to the value of this index in the same ten-day period of an average year or the previous year.

Comparative maps are supplied in ten-day intervals throughout the crops vegetation period (1st April - 30th September) to the Central Statistical Office, Department of Agriculture. On the basis of information from subsequent ten-day periods, charts are also created presenting changes in the NDVI within the vegetation season, as well as comparisons of comparative maps for the whole vegetation season. These products are supplied to the Department of Agriculture of the Central Statistical Office as part of the annual reports on the consecutive stages of the works.

3. Results and discussion

The monitoring of vegetation is expressed by indicator NDVI, which can be observed during the season. The seasonal differences are attributed to plant growth cycle as it can be presented in fig. 2. The interregional differences can be also noticed because of different cropping schemes and agricultural specialisation as well as climatic conditions.

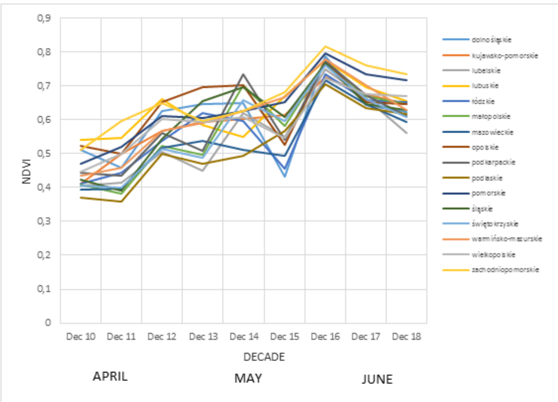

Figure 2: *NDVI changes during the first half of the vegetation period in 2015 for the different NTS2 regions (voivodships) of Poland.*

The NDVI values can compared with the same period of the previous year or an average year for a chosen region. In fig. 3, the regional differences (for NTS 4 – poviats) for June 2016 in comparison with June 2015 have been presented. Weaker vegetation (pink colour) is visible for the south eastern, central and north western Poland, which can be attributed to effects of drought in the second half of 2015 and majority of the first half of 2016.

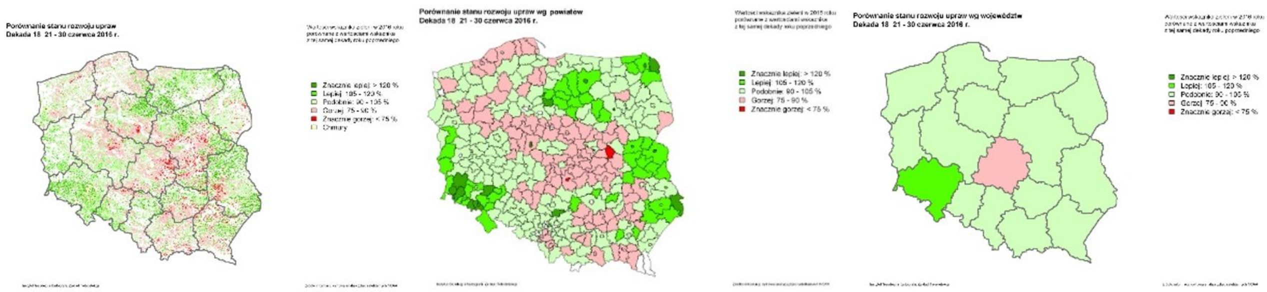

Figure 3: *Comparison of NDVI values of June 2016 with NDVI values in 2015. Data are presented for 1 square km grids, for NTS 4 regions and generalised for NTS 2 regions.*

Nevertheless, in the very south western region the vegetation is much better developed that a year ago. The analysis of the generalised and grid images shows huge decrease of details. However, the selection of agricultural areas helps to separate them from the other land cover classes.

The additional information from satellite imagery interpretation can be detection and determination of dangerous weather conditions or disasters. In agriculture, such disastrous situation can happened due to droughts, floods, hurricanes, freezing. Fig. 4 presents assessment of droughts prepared by Institute of Geodesy and Cartography in 2015. The intensity of red colour indicates drought in August 2015. The drought maps are very important for yield and harvest estimates as well as for farmers, agricultural advisors, administration or can be used by insurance companies.

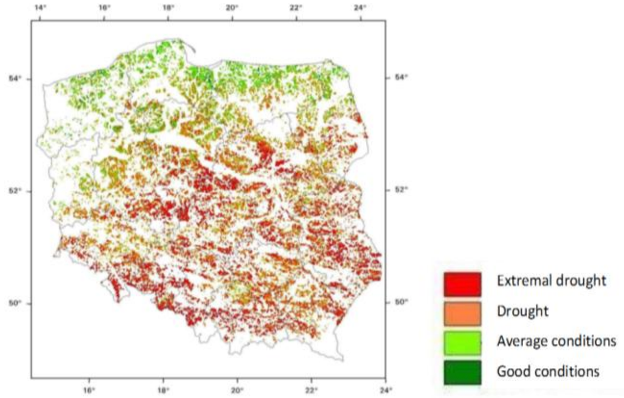

Figure 4: *The drought in August 2015 in Poland.*

The analysis of NDVI is a very helpful tool to assess the development of crop plants, which is ancillary to yield and harvest estimates. However, this indicator cannot be directly referred to yield estimates because the other factors such as start of vegetation period in a given year have to be considered. This issue is very important in terms of climate changes, when the vegetation period can start earlier resulting in earlier harvest and shifting NDVI values in a given year.

In the Central Statistical Office, the basis for the yields and harvest estimates are estimates of regional experts working on areas of gminas (NTS 5). Thus, about 2500 estimates are prepared and compiled for whole Poland each year. Simultaneously, data from modelling based on satellite imagery are delivered by the Institute of Geodesy and Cartography. The Fig. 6 presents the yield estimated for wheat in 2016. The yields are generalised for NTS 2, which is the standard grouping for official statistics. Data from satellite imagery interpretation are ancillary to yield and harvests estimates prepared by Central Statistical Office. In 2016, the modelling based on satellite images was applied for whole Poland for the first time. Thus, assessment of this data is still ongoing.

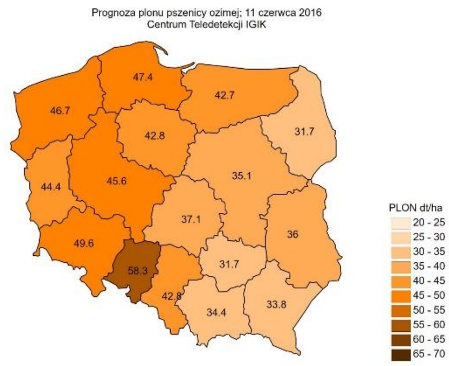

Figure 5: *The wheat yield estimates (dt/ha) for NTS2 regions in Poland in 2016.*

In 2015, the yield and harvests estimates based on modelling were studied in four NTS 2 regions (voivoships: dolnośląskie, warmińsko-mazurskie, wielkopolskie, zachodniopomorskie). The results were compared with the official data based i.e. on expert estimates, what was illustrated in Tab. 1.. The similar data were obtained also for all cereals.

Table 1: *Title of the table* (above the table, 12 pt italics, left-justified)

Voivodship (NTS 2)	Estimated yields (dt/ha)		Yield difference	
	Satellite	Statistical	dt/ha	%
DOLNOŚLĄSKIE	48,7	53,0	4,3	108,8
WARMIŃSKO-MAZURSKIE	43,3	50,9	7,6	117,6
WIELKOPOLSKIE	44,1	48,9	4,8	110,9
ZACHODNIOPOMORSKIE	46,1	59,2	13,1	128,4

The comparison shows that the yields and in consequence harvests are underestimated by the models based on satellite data. The above mentioned results cover only a few regions. The explanation of the differences could be attributed to use of long time series with yield low estimates. In recent years, the yield increase is being noticed due to development of highly specialised agricultural holdings and farm modernisation. The further validation of the results from interpretation of satellite imagery would be continued in 2016 for the whole territory of Poland. In coming years it is planned to switch to the satellite technics and modelling of harvest estimates as the basic source of information in this domain.

The experiences with satellite imagery interpretation show a huge potential for use in agricultural statistics. The vegetation monitoring and yield estimation are good examples of practical applications. Furthermore, the extremely important issue for agriculture statistics is assessment of crop area. The need for pilot studies and thematic project appears especially in recent years, when access to high resolution images has increased due to COPERNICUS or LANDSAT programmes. The official statistics is tapping in these new data sources but appropriate validations and methodological as well as quality review has to be carried out. The new initiatives of EUROSTAT concerning big and administrative data projects are good examples of such trend.

Making the Best Selection and Utilization of New IT Tools for Data Warehouse Systems

ABSTRACT

There are many types of databases. For this topic the focus will be on the data warehouse. While a data warehouse can be defined in a wide variety of ways, for this discussion the focus will be around a data warehouse based on the Inmon concept of having one enterprise data warehouse which serves as the source for all other data based systems in an organization. On line analytical processing, or OLAP, will also be the targeted type of system for the purpose of this discussion. In short, the data system is optimized for rapid data retrieval and analysis.

Most entities recognize the utility of data and its retention. As these data stores grow, more and more resources are needed to hold the data, make backup copies of it, create new copies for reporting, and many other uses. Planning for the best methods of accessing and coordinating data have always been of paramount importance. Many organizations are still working on making maximum use of their data for adding value to all business processes. In many places even with efficient planning for how to use data, however, a point has been reached where the amount of data preserved can be problematic for retrieval with the IT tools which have been available in the past.

The National Agricultural Statistics Service has used the same data warehouse system for more than 17 years. There have been upgrades to hardware and software, along with needed structure changes, but no major shift in types of processors or software vendors. The system has served well, but recently the agency has seen more and more need to schedule certain analytical queries for 'off' hours when there would be few users on the system. One of the most basic reasons for having a data warehouse is the ability to analyze data and make use of it. Large queries accessing every known table and row could take up to five hours to run on the system as it was designed. It was also found that the software provider was not planning to make more substantive upgrades to the system, but would instead put resources into other products they felt were more in keeping with current trends.

Any decision for changing the data warehouse would affect literally hundreds of in-house agency applications. Along with considerations of cost, support, and integration, there was recent research into new massive parallel processing systems which could yield dramatic increases in query speeds. This presentation will detail the planning, areas of consideration, and comparison of features available in newer systems which lead to the purchase of a new data warehouse appliance for the agency and potential decreases in query time from hours to minutes or even seconds.

Keywords: Data Warehouse, Massive Parallel Processing

1. Introduction

1.1 An agency within the United States Department of Agriculture (USDA), the National Agricultural Statistics Service (NASS) conducts hundreds of surveys every year and prepares reports covering virtually every aspect of agriculture in the United States. Our mission is to provide timely, accurate, and useful statistics in service to U.S. agriculture. The surveys and related work are conducted mainly in twelve Regional Field Offices and five call centers across the United States.

1.2 NASS has used the same data warehouse system for more than 17 years. There have been upgrades to hardware and software, along with needed structure changes, but no major shift in types of database or software vendors. The system has served well, but recently the agency has seen more and more need to schedule certain analytical queries for 'off' hours when there would be few users on the system.

1.3 One of the most basic reasons for having a data warehouse is the ability to analyze data and make use of it. The largest queries, accessing every known table and row, began taking more time to process, taking up to five hours to run on the system as it was designed. The software behind the database engine had been purchased over time by a number of vendors. It was announced that the most recent software provider was not planning to make more substantive upgrades to the system, but would instead put resources into other products they felt were more in keeping with current trends. This was a concern with a steady progression of the hosting hardware and operating systems possibly leading to more errors or speed problems with the warehouse system which would not be upgrading.

1.4 Any decision for changing the data warehouse would affect literally hundreds of in-house agency applications. Along with considerations of cost, support, and integration, there was recent research into new Massive Parallel Processing (MPP) systems which could yield dramatic increases in query speeds. This presentation will detail the planning, areas of consideration, and comparison of features available in newer systems which led to the purchase of a new data warehouse appliance for the agency and potential decreases in query time from hours to minutes or even seconds.

2. Background

2.1 There are many types of databases. For this topic the focus will be on the data warehouse. While a data warehouse can be defined in a wide variety of ways, for this discussion the focus will be around a data warehouse based on the Inmon concept of having one enterprise data warehouse which serves as the source for all other data based systems in an organization (Inmon, 1993). On line analytical processing, or OLAP, will also be the targeted type of system for the purpose of this discussion. In short, the data system is optimized for rapid data retrieval and analysis.

2.2 Most entities recognize the utility of data and its retention. As these data stores grow, more and more resources are needed to hold the data, make backup copies of it, create new copies for reporting, and many other uses. Planning for the best methods of accessing and coordinating data have always been of paramount importance. Many organizations are still working on making maximum use of their data for adding value to all business processes. In many places even with efficient planning for how to use data, however, a point has been reached where the amount of data preserved can be problematic for retrieval with the IT tools which have been available in the past.

2.3 The variety of data available has also increased. The internet has virtually exploded with new and varied data and data sources. While there are still differences in internet access across the globe, the coverage and availability is growing at an increasing pace, with over 1000 percent growth in some areas of the world since the beginning of the century (Bell, 2011). Multi-media data and Big Data concepts are available if one has a suitable system, with enough speed potential and analytical tools, to take advantage of them (Beyer & Edjlali, 2015).

2.4 NASS was a comparatively early adopter of data warehouse concepts and has gathered a great deal of historic data over time. Most of the agency data is structured and uses detailed metadata. These characteristics affected the field of choices in warehouse products, making those with more open formats or ‘no sql’ choices more problematic in our case. There were early concerns about any cloud offerings, as well. Most of this was regarding either real or perceived security concerns. The selection team was open to possibilities but concerned that the timing might not yet be right for a cloud product.

2.5 More and more vendors are offering data warehouse appliances. Instead of purchasing a variety of hardware and software separately and then doing the integration within your own organization, there are now viable choices for systems which have already been designed and tested for optimum performance from a combination of hardware and software. Queries that might have taken hours on self-assembled systems can potentially take only seconds on pre-configured appliances (Beyer & Edjlali, 2015).

3. Steps Taken

3.1 With the current system in place for nearly two decades, there was some expectation at NASS that whatever new system was selected should be something that could grow with the agency and with the changing needs. The current system had over 11 billion rows of data, grew from over 250 surveys’ data annually, and was accessed by several hundred in-house software application systems and two primary Commercial Off The Shelf (COTS) software packages for business analytics and statistical analysis. The agency staff were particularly familiar with one COTS business intelligence analytical tool considered the standard tool for its purpose.

3.2 Investigation and planning were needed, but also some degree of speed in the decision. In our case ‘speed’ meant the investigation/selection project should take less than one fiscal year in order to take advantage of funding that could not be guaranteed in subsequent years. Even with time concerns, however, the agency would follow the three historic ‘pillars of progress’ which had been observed in the past NASS data warehouse implementation: 1) Focused Direction; 2) Sound Evaluation and Development; 3) Solid Implementation (Yost, 1999).

3.3 A seven person team was formed for the purpose of investigating options for replacement of the data warehouse system. Members were drawn from among the database administrators, metadata specialists, contract database support, the application software architect, and data analysts from outside of the IT division. The IT Division Head was the executive sponsor and the IT Division Senior Project Manager provided support for budgetary and procurement concerns.

3.4 From the literature available and based on the original cost of the current solution, a very broad estimate of purchase cost was put forward. This was needed at the beginning to plan and help in discussions with senior management. If the upper managers were put off by the cost or the upcoming degree of effort then any project could be considered defeated before it began. By setting the general expectations early in the project senior manager support was fully behind the process. This helped in a wide variety of ways, including recruiting team members and building favorable support.

3.5 The general timeline for the project was:

Dec. 2014:	Establish initial project plan
	Collect market information
	Reach out to business users
	Determine criteria for further investigation and selection
Jan. -Feb. 2015:	Request contract specialist from procurement staff on team
	Selection of pool of vendors based on criteria for products
	Prepare Proof Of Value (POV) trial criteria for vendors
Feb – Apr. 2015:	POV with vendors (four total)
May - June, 2015:	Report of findings to Data Services Branch staff
	Report of findings to NASS Enterprise Architecture Council
	Report to Senior Executive Service
June – Sept. 2015:	Work with contract specialist to procure recommended product

3.6 Communication was key. The project team included statisticians from the business community, who were also heavy/frequent users of the data warehouse. These same people helped to spread information and interest for the project. Other business side users were invited to help in developing the POV tests to be used with the various vendors. Evaluation results and periodic status messages were communicated directly among the team, with the entire Data Services Branch staff, the NASS Enterprise Architecture Council and the Senior Executive Team. All of this helped in planning and to promote acceptance and a favorable climate of acceptance for the general direction and product choices of the team.

3.7 A separate project team was also formed to review choices for a new analytical software tool. That effort was conducted in much the same way as the analytical database team's project, with both teams communicating with each other.

3.8 Instead of creating all of the selection criteria from scratch, the team chose to use a third party authoritative source to describe the features desired. In our case the publicly available Gartner ***Magic Quadrant for Data Warehouse and Data Management Solutions for Analytics*** report was an excellent resource. An abridged version was advertised and available via the web and we received the entire report via a subscription service (Beyer & Edjlali, 2015). This had several benefits. The research was current, in-depth, and forward looking. In this case it helped narrow the field considerably when it was found that only four of the vendors in the 'Leaders' quadrant also produced appliances. And a major benefit in our situation was the ability to provide a third party list of characteristics and rating to our procurement office in support of the team's methods and ultimate recommended selection.

3.9 A special comparison was made with a leading vendor cloud offering. This was in anticipation of trends in the industry and potential questions from stakeholders. NASS is a statistical agency dealing in confidential data protected by law. Even the appearance of a compromise in data security can lead to lower response rates to agency surveys. The Agricultural Advisory Committee (composed of public and private stakeholders in statistical reporting) had even made previous recommendations against some cloud systems housing our data. In addition to any concerns about public opinion, there is also an official accreditation process for federal government systems. There are several federal programs underway specifically for the purpose of certifying cloud based offerings for various purposes. The Department of Agriculture also has some internal initiatives with the goal of providing cloud services. Ultimately it was decided that cloud offerings were not yet at a stage of acceptance either internally or externally in terms of confidential data security or the perception needed for our data security. As government certification programs advance, this may change and cloud offerings may be a more viable option in the future.

3.10 Market research consisted of internet sources and searches (including the previously mentioned magic quadrant report), vendor meetings, demonstrations, attendance in public conferences on the topic, and internal stake holder meetings. The team compiled a list of other government agencies doing similar work to our own. Calls and meetings were organized to enquire about these agencies' own data warehouse solutions, planning direction, and general satisfaction with their current systems and vendors. General comparison criteria during the market research included:

- Architecture.
- Scalability
- Reliability
- Performance
- Compatibility (with existing environment and code in place)
- Administration tools (availability, and ease of use)
- Price (a formal decision was based on best overall value, not simply lowest purchase price)

3.11 Our investigations led to a special focus on two characteristics. The systems using both preconfigured appliances and described as using massive parallel processing (MPP) presented the potential for the greatest speed increases. Simply put, MPP means dividing the work for different parts of an application or data retrieval among multiple processors. In the majority of the vendors we reviewed, the solutions included specialized processors and a set number of specific disc drives associated with any one processor. It was difficult to get a precise estimate ahead of time of what the speed increase would be without testing with a specific data structure and volume. Estimates ranged from 10 to 100 times faster (Lopes, 2015). All of the vendor systems reviewed showed significant speed increases over the current NASS data warehouse. The system ultimately selected returned the longest running known queries roughly 100 times faster. Queries that would typically take over five hours, returned results in roughly three minutes.

3.12 Once the field of potential vendors that excelled in our initial criteria was established at four, the Proof Of Value (POV) trials were begun. Vendors were allowed to conduct the tests off site from our own facility. All were given a group of representative queries for benchmarking times. All were given the same test data which had been approved by our agency Security Staff and statistical staff to ensure there was no release of confidential data and to prevent any confusion leading to any appearance of releasing confidential data. The team visited each vendor and took along specific queries and use cases for testing. Each vendor was asked to specifically demonstrate the ability of their system to be accessed by one COTS statistical software package and one COTS analytical software package. Both of these are considered standards and are in wide use in the agency. The broad criteria used in the evaluations included:

- Benchmark and test case performance.

- Workload of database migration
- Post migration work on in-house applications and programs.
- Backup and restoration
- DBA technical requirements
- Administration tools (availability, and ease of use)
- Price (a formal decision was based on best overall value, not simply lowest purchase price)

3.13 The project team created a project plan and documented the steps taken. The team also created a slide presentation which could be used to communicate the process and give a comparison of the vendors involved showing all of the criteria in side-by-side comparisons. The same groups which were consulted at the project initiation were again presented with results and recommendations. The presentation and approval sessions included a dry run within the team to ensure there was consensus and record notes and details for items that generated discussion. The findings were then presented to the IT Division Head, the Data Services Branch staff, the NASS Enterprise Architecture Council, and to the Senior Executive Team. All of this sought to ensure alignment within our agency planning and with the USDA capital planning and investment direction. Once any lingering questions were answered we sought final approval from the IT Division Head.

3.14 Working through the federal government procurement process was the final step. The team had worked diligently to be sure a contract specialist was engaged months before sending the final recommendation. The contract specialist worked with the team to ensure that all the required forms and steps were followed and completed. Because this person’s expertise was in federal contracting and not in IT or data warehousing, there were many opportunities to help in their understanding of terms and clarification of concepts and requirements.

3.15 The size of the procurement in terms of monetary value was also a consideration. In our purchasing system the higher the value, the longer the time period is for notice of the potential contract to vendors, and the more demanding the process for documentation of the salient characteristics of the intended system. Purchasing something costing over one million dollars requires more rigor in documenting the selection process and can also increase the potential for vendor protests. The artifacts developed by the team proved to be invaluable as documentation in the actual contracting process. It was used to demonstrate thoroughness, objectivity, and as a rationale for the recommended purchase.

4. Current State and Next Steps

4.1 NASS procured two appliance systems to be placed in physically separate USDA data centers; one for production and one for disaster recovery (DR). We also procured two development blade servers for testing purposes that will reside in our headquarters location. The purchase was made in September, 2015. The equipment was delivered in early calendar 2016. USDA has been undergoing continuing consolidation of data center resources and deployment of the NASS data warehouse system had to be scheduled between many of these activities. The primary appliance was put in place in March 2016 and the DR appliance was put in place in April 2016. The selection team has turned the project over to the Data Services Branch Staff for setup, population and integration of the units.

4.2 The fundamental plan is to parallel test the new system through the next year’s survey cycle, incorporating all of the same data and inputs, leading to creating the same outputs. Where differences are found, further work will be needed to document and change either the new or old system if needed. This is no small task due to the release of over 400 statistical reports and the existence of hundreds of systems/applications involved in the annual process.

4.3 One large challenge is the integration of all of the feeder systems through the Extract, Transform, & Load (ETL) process. There are discussions under way about the best ways to adapt the current procedures to the new products and potential paradigm shifts to an Extract, Load, and Transform (ELT) process. With the speed potential of the new system, it may often make sense to do data transformations within the appliance rather than at the feeder system or within the ETL programming currently in place. This potential speed increase also points toward the efficiency of doing other analytical operations within the database system rather than extracting data with another tool and pulling that over the network to the analyst's workstation. While this may seem like an obvious improvement to systems integrators it has proven to be a persistent problem with agency employees.

4.4 The agency has a public facing web system based in the same data warehouse technology. This 'Quick Stats' system provides the public with the latest estimates. The new data warehouse platform must also be integrated into Quick Stats with little or no interruption to public service.

5. Lessons Learned

5.1 Lessons learned include:

- Do preliminary research on technical possibilities and price ranges
- Think strategically and look to the future
- Secure senior management buy-in early
    - Include budget considerations
- Communicate, communicate, communicate
    - Include entities outside of IT
    - Include your procurement staff early in the process
- Where ever possible use third party and objective sources in your market research
- Plan the work and document as you go
    - Keep the documentation of comparisons as objective as possible
- Test the options as much as possible before committing to any particular solution
    - Document the testing
    - Document why a particular direction was chosen
        - In-house vs. cloud
        - Structured vs. unstructured data
- Consider all of the other systems and data interactions
    - Can they work with any new solution
    - What changes will be needed?
    - Will there be any required paradigm shifts (ETL vs. ELT)

6. Conclusion

6.1 NASS and other statistical organizations are 'data factories'. Our agency mission is to provide timely, accurate, and useful statistics in service to U.S. agriculture. It can be difficult at times to remember that we are *not* IT systems integrators. Everything we do should be put in place to support the business mission. Our data warehouse replacement team had to consistently remind ourselves of that as we went through the process. That reminder promoted some of the decisions to move toward a pre-engineered appliance. There were advantages in not only speed of queries and results but in ease of maintenance and reduction of workload in areas where we did not need to focus. When one buys a refrigerator, you do not have to assemble the compressor and charge the Freon unit. It is delivered, plugged in to power, and generally works.

6.2 Communication takes time but proved to be an overall time saver in the end. By including both our business partners and our procurement staff, we promoted understanding, minimized 're-telling' of the story, and negotiated a good business deal for the product and services. We also found that some advance favorable opinion of what was being done had preceded the team to a variety of meetings. When the time came for final approvals, stakeholders reached a consensus fairly quickly because of their involvement in the process.

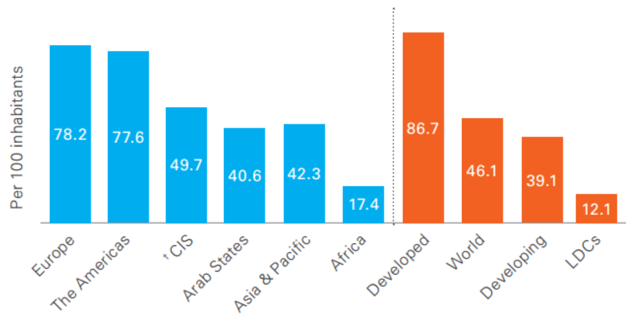
ABSTRACT

This paper presents the use modern technologies implemented by UNODC in the monitoring of Alternative Development projects established in social and economically vulnerable agricultural areas in Colombia. The system supports data capture applications implemented via smartphones with the ODK and GeoODK arquitecture. Collected data include georeferenced field boundaries, field areas, geotagged photos, and socio-economic questionnaires. Offline collected data is stored in a relational database which is directly queried by several web applications that publishes and visualizes data reports and indicators in almost real time. A key feature of the designed infrastructure is the tight integration between data collection, processing, storing and visualization that ensures straight access to the raw data and derived indicators. The system is a low-tech solution and has been automated in order to secure data collection and minimize data loss or input errors. We present the system as an example of efficient information systems implemented by institutions working in developing countries with limited infrastructure.

Keywords: data collection, survey, monitoring, information, ODK.

1. Introduction

Currently more than 3.2 million people have access to the Internet and almost half of the world population has access to mobile broadband subscriptions (International Telecommunication Union, 2015). A large share of the adoption of communication technologies is happening in developing and least developed nations, which provide thriving conditions in places where physical infrastructure still limits the exchange of goods and until recently, ideas. As shown in Figure 1, as of 2015, the percentage of mobile broadband subscriptions reached 86.7% in developed countries and about 40% in developing countries (Dutta, 2009). There is, however, an increasing technology divide between developing countries and the rest of the world as shown also in the figure (left) (International Telecommunication Union, 2015).



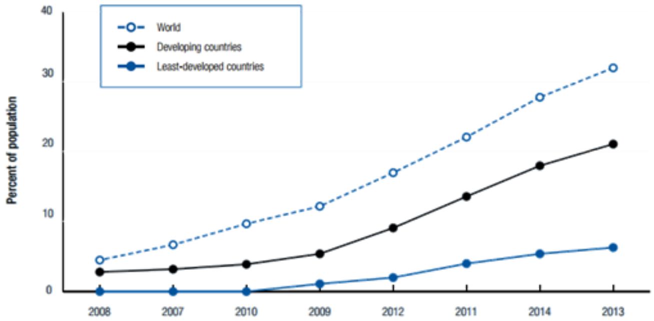


Figure 1. Left: percentage of mobile broadband subscriptions in 2015. Right: Mobile broadband penetration over the last years by region

As expressed by ITU, societies that transitioned to information technologies are experiencing a positive impact on economics, government, businesses and education, moving faster to the achievement of United Nations Sustainable Development Goals. The steady growing penetration rates of mobile broadband subscriptions in developing countries over the last years indicates that there are excellent business opportunities for the private sector but also enabling conditions for government and institutions to improve the knowledge of territorial and socioeconomic indicators of its populations.

Developing nations still face the legacy of paper loaded processes, red tape and slow data collection rates, which ultimately compromise the possibilities of data analysis and data dissemination to the final users. In this environment, data collection is so difficult, that often, completed questionnaires are dumped into boxes awaiting the availability of human and financial resources to interpret and make sense of their information. Publication of collected data often comes late, when decisions have been made, attention has already shifted to another project, and funds are depleted.

Recent ICAS conferences have reported efforts on the use of ICT systems to collect data and implement agricultural censuses. Those undertakings reflect specially the state of the art in developed countries or in national statistical agencies that have the infrastructure to invest on these endeavours. However, as exemplified by this paper, the development of infrastructure, communication networks, user communities, global positioning systems, software and hardware facilitates today reliable data collection, processing and dissemination at a low cost and a fast rate.

This paper reflects on the implementation of the information cycle of data collection, data processing and data visualization for the collection of agricultural and socio economic data. These processes have been implemented by UNODC in Colombia to document rural development transformations in areas affected by illicit crops. The experience is implemented in vulnerable remote rural areas, which largely match the conditions of least developing countries. As presented in this report, the developed system has resulted in timely data collection in areas monitored by UNODC in Colombia and an advanced organizational know-how of information systems.

2. The information cycle

UNODC supports the Colombian Government in the monitoring of the implementation of rural development programmes aimed at ensuring food security and socio economic integration of vulnerable communities immersed in areas affected by illicit crop cultivation (**insert note**). UNODC has been providing this support for more than a decade under several government administrations and policy implementations. The solution presented in this paper is the result of the evolution of a process that started in the early 2000's and has been improved and adjusted to honour the conditions of the policy implementation and the situation on the ground.

Under the Alternative Development monitoring programme, UNODC verifies: 1) the physical transformation of the territories being supported by the Government, and 2) the socio economic transformation of the communities targeted by the Alternative Development programme. This requires the collection of the following data in the field:

1) Measurement and georreferencing of parcels supported by the Alternative Development Programme. This includes the registration of the parcel boundaries, and capture of photographs of the area. Enumerators also collect data on land characteristics such as land ownership, land suitability and planted crops.

2) Administration of interviewing questionnaires inquiring about social, economic, environmental and institutional indicators related to the rural district of the participating household.

In the interventions of 2012, 2013 and 2014 a total of 34,000 households were registered in the Programme. Each household parcel was measured while questionnaires were administered randomly to selected households based on a stratified sample. Parcels were measured and identified at the beginning of the intervention, while interviewing questionnaires were administered during field visits at the beginning, mid-term and final stage of the project. This temporality permitted to monitor territorial performance of the communities involved in the program.

The information cycle of the implemented agricultural survey includes all the necesary steps to ensure: a) efficient data collection, b) data processing, c) analisis of derived information and d) publication and visualization of results. The transition from one stage to the next is an interrelated process, tightly integrated with coupled by technology, software, users and infrastructure (Figure 2).

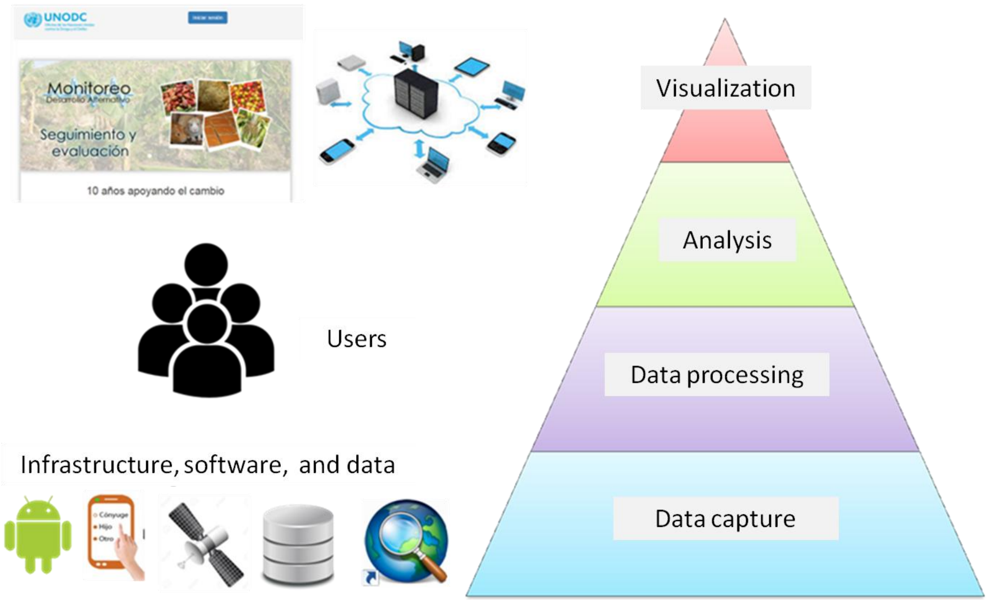

Figure 2. Stages of the information cycle: from data collection to visualization and dissemination

3. Data collection

We based data collection on the Open Data Kit project developed at the University of Washington (Hartung et al., 2010). This project includes several applications that assist during data collection:

ODK design: language and interface to design survey questionnaires. Questionnaires are implemented in the XLM/Xform standard which allows interoperability and readability by various systems. To facilitate multiuser form design, we used Google spreadsheets. Questions and logical flow of the questionnaire were validated and translated into an XLM file using the XLSform conversion tool.

ODK collect: ODK collect is the client application deployed to Android systems (currently supporting Android versions > 4.1). This application provides the ability to log into a specified server to download blank forms using defined user credentials. The server hosts the blank forms as well as completed submissions sent by collectors as explained below.

With the blank forms downloaded to the Android device, the enumerator can initiate data collection. Several forms can be stored in the same device, and with forms having a size of a few kilobytes, there is no practical restriction to the volume of collected data that can be stored in a device. The application interprets the questions, the flow and the logic conditions implemented in the form. For instance, the application prevents enumerators from leaving unanswered mandatory questions, or moving to the next question if some logical rule is violated with the current answer. Similarly, the application skips irrelevant questions depending on the answers of the interviewed household.

Collection of Geographic data: to enable spatial data collection we used GeoODK, a modified version of ODK Collect (Nordling, 2015). GeoODK facilitates the collection of polygons using the Geotrace geometry, where polygon vertices are recorded in continuous mode every few seconds or, alternatively, when requested by the user. Point data is also collected to register the location of the interview.

Location accuracy depends on the GPS chipset of the recording device being used. With the implemented system, any Smartphone device equipped with a built-in GPS can be used to collect the alphanumeric and spatial data. To streamline technical support, two devices were selected, based on their robust construction, GPS reliability, battery duration and cost (Figure 3).

Figure 3. View of the Monterra Garming GPS and Moto G Android smarthphone used for data collection

4. Data processing

Storage of collected spatial and alphanumeric data was centralized via the ODK Aggregate application. ODK Aggregate provides a ready-to-deploy server and data repository to: 1) retrieve blank questionnaire forms to be used in ODK Collect; 2) Accept finalized forms (submissions) from ODK Collect and manage collected data; 3) Visualize the collected data using maps and simple graphs; 4) export data (e.g., to a CSV files for spreadsheets, SQL database or as KML files for Google Earth).

ODK Aggregate can be deployed in several configurations, such as Google's App Engine, Amazon web servers or the organization server. Given the ease of configuration and server reliability needed for intensive and continuous data collection, we set up a hybrid system that stores collected data by mobile devices into an SQL database hosted by Google's App Engine and continuously synchronizes to a local repository.

We developed an R routine to process the data, normalize it and reshape it to the required format and structure of the local SQL database system. The script reads the CSV data, checks for new information and reshapes the data accordingly. The R system communicates directly with the database management system and stores the new records into the relational tables of the UNODC database (Figure 4).

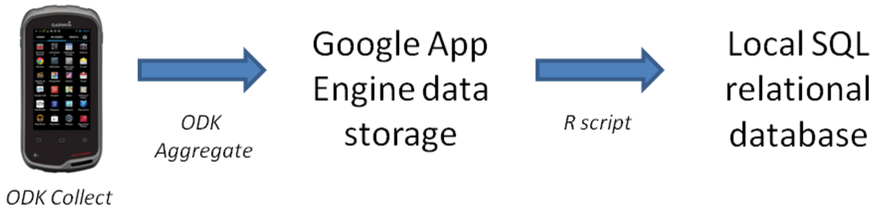

Figure 4. Flow of data from collection to storage into an SQL database

The spatial data collected in ODK undergoes the same transformation as the rest of the data described previously, but required a different treatment during the transformation in the R script. Spatial data is registered in the XLM form as an alphanumeric data type noted by a sequence of vertex coordinates in WGS84 system. The R script implements the following operations:

- Verifies and fixes topological errors: this involves removing signal overshoots and spiky vertices affected by the quality of the GPS signal during data capture.
- Verifies and closes open rings to transform them into polygons.
- Verifies spatial data consistency. i.e polygons should be located in a given municipality.

5. Data visualization

The automation of all previous steps needed to transfer data into a relational spatial database facilitates almost real time visualization of collected data. For instance, Figure 5 illustrates a digital interactive web map showing the locations of Alternative Development projects. Data visualization and reporting of collected data is supported by modern open web technologies like PhP, JavaScript and the Leaflet mapping library. Applications like interactive maps or data collection dashboards have been designed at UNODC to retrieve information directly from the relational Database and publish to the web.

An important development for the project was the possibility to serve spatial data directly from the database stored in UNODC servers to dynamic web maps. The common approach of serving shapefiles or text files is popular, but when data is dynamically and continuously updated the automation of a synced database becomes relevant.

6. Users

A fundamental step in the implementation of a successful survey is user training. In UNODC enumerators have extensive experience in collecting data. However, not all of them were equally savvy in the use of Android systems, applications and digital content management. Several thematic trainings were held to explain the basics of the operation in the field and how to verify the correct configuration of the device as well as data transferring. Data analyst and survey coordinators were also trained on the use of the web visualization tools and dashboard of data collection campaign.

7. Discussion

This document presented the configuration of a tightly integrated system between data capture, data processing and visualization with an system suitable for the type of infrastructure present in developing countries. The system has been successfully deployed at UNODC for the monitoring and georreferencing of rural households participating in the Alternative Development program. The system relies on the ODK architecture for spatial data collection in disconnected mode and information technologies like scripting languages for data processing and web applications for visualization.

Data collection is, perhaps, the most crucial stage of the information cycle process. The opportunity to measure a field or interview a farmer is an irreplaceable event as the conditions enabling data collection are unique considering weather, financial resources, staff availability, field security and objects being measured. Teams long accustomed to conventional analogue data collection will initially be reluctant to the idea of a digital collection system, given the intangible nature of digital data as compared to conventional paper forms. To facilitate adoption of the system and reassure field enumerators at UNODC, we develop a dashboard on the website where they can login to trace the submitted data. The system provides them general indicators of their work such as the number and type of questionnaires effectively received, and a point map of the visited locations.

The deployed infrastructure is economic in terms of hardware and software resources. Most importantly, it is flexible and can be adapted to available budget. If for instance, a server is not locally available, data can be hosted permanently on third party servers for a low cost (e.g. Amazon, Google). Several GPS enabled Smarthphone devices can also selected depending on the local market availability. What is more crucial for the implementation of a full-fledged project as described here is to count with expert knowledge on information technologies. This is needed for database design and maintenance, server configuration for data collection, data scripting for data processing, and programming of web applications for visualization and data reports.

Fortunately local knowledge is growing rapidly in developing countries. Furthermore, there are generous developer communities in the Web around open technologies as the ones presented here. For instance, the ODK user community is moderated at the University of Washington and daily support is provided to ODK users, with a large volume of knowledge accumulated in the history of its forums. The same happens with the communities of R, PhP, Javascript and Leaflet. This shared knowledge adds a vital level of support that accelerates local knowledge and ensures sustainability.

8. Results

The impact of the implementation of the described system has enabled timely and accurate data collection and dissemination under a low cost implementation, using open source technologies. Firstly, data has been captured in an efficient way, with minimal data errors, minimal data loss and a more fresh transition between collected data to indicators and data visualization. Field enumerators have been relieved from carrying paper forms to the field and from memorizing questionnaires guidelines as the application guides the enumerators through the questionnaire restrictions and the logic flow.

Secondly, the information technology capacities of UNODC has grown rapidly with a group of information technology professionals that before spent most of their time scanning, editing and digitizing collected data, to a more rewarding and exciting environment where they develop skills in data manipulation, database management and data visualization tools. We consider this highly relevant, to close the digital divide between developed and developing nations, and ultimately, to promote a higher impact of information technologies in developing countries.

ABSTRACT

As the world embarks in a major effort to achieve the Sustainable Development Goals, there is a high demand for high quality and timely agricultural statistics in order to design and implement effective policies, allocate investments, monitor and evaluate progress. Most of the Governments in developing countries are thus searching for cost-effective methods of collecting high quality data on agriculture. Literature from small surveys conducted by research institutes suggest that using Computer Assisted Personal Interview (CAPI) technologies could be a cost effective alternative to the traditional Paper and Pen Interview (PAPI) method. Additionally, there is preliminary evidence that CAPI can improve data quality, shorten interview duration, and that enumerators prefer CAPI to PAPI. As National Statistical Systems (NSSs) operate in a very different context from research institutes and the applicability of these findings are limited. This paper analyses paradata on cost, interview duration, data quality, and enumerator feedback on various surveys conducted by National Statistical Systems (NSSs) in Uganda and Tanzania. The results confirm that CAPI is cost-effective across multiple surveys. Statisticians in Uganda also indicated there were an increase in data quality after using CAPI. Additionally, data from a questionnaire administered to enumerators in both countries showed that they indeed prefer CAPI over PAPI. The analysis of interview duration did not indicate that CAPI interviews are shorter, but this is likely due to factors other than the survey instrument.

Keywords: CAPI, National Statistical Systems, Data collection, Surveys

1. Background and Introduction

January 1st, 2016 marked the official beginning of the 2030 Sustainable Development Agenda agreed upon by leaders from all over the world in September 2015. The Sustainable Development Agenda (SDA) defines 17 Sustainable Development Goals (SDGs) that promote sustainable economic growth, elimination of poverty and inequality, and address a host of social needs. Under these goals there are 169 individual targets. The SDGs will be monitored by indicators developed by the Inter Agency and Expert Group on SDG Indicators (IAEA-SDGs) and then agreed upon by the UN Statistical Commission. It is anticipated that 2 indicators will be assigned to each target creating approximately 338 indicators (United Nations 2016).

The National Statistical Systems (NSSs) are the natural sources of information for producing the data needed for the SDG indicators. With such a large suite of indicators, it is apparent that there will be a substantial cost of collecting this data and ensuring that it is timely and reliable. The burden is particularly high on NSSs in developing countries that face resource constraints. Accordingly, any cost-savings tools for data collection would be advantageous to the SDG process.

A large share of the cost of data collection traditionally carried out using Pen and Paper Interivewing (PAPI) relates to theprinting of the questionnaire itself, transporting them to and from the field, as well as transferring the data into a digital format so it can be analysed, and storing the completed questionnaires. Computer Assisted Personal Interviewing (CAPI) tools which collect data using electronic devices completely eliminate some of these costs. However, the adoption of CAPI has been slow, due to concerns about the fixed cost of equipment, reorganization of statistical processes, and training, quality of technology, lack of Internet connectivity, human capacity and resistance to change. Indeed, there is so far little systematic evidence on the advantages of using CAPI over PAPI to collect data for official statistics.

By using paradata provided by the Ugandan Bureau of Statistics (UBOS), the National Bureau of Statistics of Tanzania (NBS), and the Ministry of Agriculture, Livestock and Fisheries (MALF) of Tanzania on various surveys conducted using CAPI and PAPI, this paper analyses the differences in implementing CAPI and PAPI based surveys across four dimensions: cost, interview duration, data quality, and enumerator opinion. The paper aims at assisting survey managers in developing countries to take a decision on whether to invest in CAPI. Results, however, should be taken with caution as equipment and training cost have been constantly declining in recent years and an ever-growing number of devices and user-friendly software are being marketed and, in some cases, are freely available.

2. Literature review and previous findings

The literature comparing CAPI and PAPI survey methods in developing countries is restricted mostly to small sample surveys carried out by research institutes. As NSSs face very different contexts than research institutes, the findings may be of limited use. However, an overview of the main results relating to costs, interview duration, data quality, and enumerator opinion is informative.

2.1 Cost

It is well established that, there is a high fixed cost of switching to CAPI due to the purchase of equipment such as tablets or smartphones, servers for data storage, etc. However, there are also savings generated from the reduction or elimination of some variable costs including double data entry, paper storage costs, less data cleaning resulting from higher quality data, and elimination of printing costs (Zhang, et al 2012; King, et. al 2013, Leisher 2014).Caeyers, et. al (2010)found that the break-even number of interviews where the reduction of variable costs associated with PAPI by using CAPI equals the fixed costs of purchasing equipment was 4,000 interviews. Accordingly, surveys with sample sizes below 4,000 respondents would be more expensive using CAPI, but it would be cost-effective for larger samples. Note that this assumes the equipment is only used for one survey. If the fixed cost of the equipment were to be spread over more surveys, this break-even point would certainly decline. Also, the prices of electronic devices that can be used for CAPI have declined greatly in recent years, which would cause this number to decline further. This suggests that CAPI becomes cost-effective after some threshold, and surveys conducted on large sample sizes will benefit more from CAPI. That said, an issue is whether this trend holds for even larger census size samples as substantially more equipment is needed.

2.2 Interview duration

Shorter interviews result in lower respondent fatigue and improve data quality. Caeyers, et. al (2010) found a positive correlation between the number of errors recorded during an interview and interview duration. More studies than not which examine the relationship between the method of data collection and interview duration show that CAPI interviews tend to be shorter. The idea being that selecting options from a list on a smart phone or tablet is generally quicker than hand writing answers on paper (CSO 2016; Zhang, et al 2012**)**. One study involving sample surveys in Kenya and Tanzania found that on average CAPI interviews were 16 minutes shorter than interviews conducted using PAPI. Notably this same study indicated that this time saving was not realized until after 3 days of data collection (Leisher 2014). Another study specifically designed to compare CAPI and PAPI using a Randomized Control Trial (RCT) showed that interviews conducted using CAPI were 10 percent shorter than PAPI (Caeyers, et. al 2010**)**. On the other hand, a few studies have found longer interview durations by using CAPI or no statistically significant relationship at all (King, et. al 2013**)**.

2.3. Data quality

In terms of data quality, most if not all CAPI products allow survey designers to program validation conditions that detect erroneous data and display a warning message to the enumerator. Furthermore, routing errors are eliminated because skip patterns are programmed into the structure of the questionnaire and automatically enforced. Finally, since the data is immediately digitized during the interview, potential data entry errors during the transcription from the paper into a database are eliminated. Indeed, studies have found that data entry errors wereeliminated using CAPI (Zhang, et. al., 2012, King, et. al 2013). Furthermore, the literature comparing results from the same questionnaire using both PAPI and CAPI found that the percentage of interviews containing erroneous data was much less for interviews conducted using CAPI (Caeyers, et. al 2010).

2.4 Enumerator opinion

The individuals affected the most by the choice of using CAPI or PAPI are the interviewers themselves. If all enumerators strongly prefer the traditional PAPI method, that may be enough justification to keep using it. The available literature suggests that enumerators prefer using electronic devices over paper questionnaires, for reasons such as less weight to carry around, reduced worry about correctly following skip patterns, easier organization and less risk of damaging completed surveys because of weather conditions. The only worry cited was the possibility of technical failure during an interview (Zhang, et al 2012; King, et. al 2013).

In summary, the literature indicates that CAPI shows promise as a cost-effective alternative to the traditional PAPI methods with the potential to improve data quality, reduce respondent through shorter interviews, and indeed when asked, enumerators seem to prefer CAPI tools. However, this evidence comes from on small sample surveys conducted by research institutes and, therefore, the conclusions are not necessarily applicable for NSOs that operate in a very context.

3. Methodology and data sources

The UBOS, NBS, and MALF assembled available data on costs, start and end time of interviews, and data quality for a number of surveys. A questionnaire was also distributed to a random sample of enumerators to assess their overall opinion of using CAPI to collect data in both countries.

3.1. Ugandan Bureau of Statistics

UBOS provided data for the first four waves of the National Panel Survey (NPS) from 2009 to 2014, a nationally representative multi-topic householdsurvey.The first wave was performed using PAPI, while waves 2-4 were administered using a combination of Ultra-mobile PCs (UMPCs) and Lenovo tablets. The software used was Capture with Enhanced Survey Technology (CWEST). The number of questions in the four surveys varied between 1,090 and 1,152 and targetedinformation on education, health, labor, housing conditions, non-agricultural enterprises, vulnerable groups, agriculture (crops, livestock, and fisheries), water and sanitation. Each wave collected data from about 3,000 households.

Comparing the 4 waves of the NPS offers the opportunity to assess the cost and quality differences between CAPI and PAPI, as well as how the costs of adopting CAPI changes over time.

Furthermore, UBOS has a rich pool of enumerators with vast experience and knowledge of both PAPI and CAPI making them ideal respondents for comparing PAPI and CAPI. The start time, end time, and dates were provided for Waves 1 and 4 so that the duration of interviews could be compared.

3.2. National Bureau of Statistics (NBS) and the Ministry of Agriculture, Livestock and Fisheries (MALF) of Tanzania

NBS provided cost data for the 4th wave of the National Panel Survey and for the Tanzania Demographic and Health Survey (DHS). Both of these surveys were conducted using PAPI, so for comparison,MALFprovided datafor the 2015 Livestock Field Officer Survey (LOS) conductedentirely using CAPI. Data regarding the start time, end time, and date of each interview was available for theLOS survey. Many of the enumerators mobilized for the LOS had been employed by NBS meaning that they had experience conducting surveys on CAPI and PAPI. Accordingly, they were an ideal pool of respondents.

4. Analysis and Results

4.1. Cost comparison

Tables 1 and 2 below show a cost comparision per interview of each survey by cost category in 2005 Purchasing Power Parity (PPP[1]) dollars. Enumerator, and supervisor costs are the product of the number of enumerators and supervisors, daily remuneration, and number of days worked. Cost for data cleaning for surveys in Tanzania were computed the same way using the human resources for data cleaning. Data cleaning costs could not be estimated for Uganda.

The paper questionnaire costs include printing, transportation to/from field, and the product of the cost of yearly storage and required number of years. Even when a survey is implemented using CAPI, there are minor paper questionnaire costs because enumerators are given back-up questionnaires incase of equipment failure. The electronic equipment costs include the purchase price of the electronic devices used for data collection, accessories (e.g. extra batteries, anti-glare covers; etc.), data transfer, generators for recharging, and consulting fees if required. The costs of the electronic devices and accessories were divided by 5 as experience at UBOS showed that this type of equipment usually lasts for 5 rounds of data collection, after which it needs replacement.

It is notable that for the DHS and NPS-Wave 4 surveys conducted in Tanzania, double data entry was conducted: once in the field, and once in the office. The field data entry was conducted using tablets for the DHS and laptop computers for the NPS, which contributed to the equipments costs. It should also be noted that computers used for cleaning are not included in these figures. This is based on the assumption that an institution would likely use the same number of computers for CAPI and PAPI surveys.

In both countries, the cost per interview of surveys implemented with CAPI is lower than PAPI. Consistently, these savings can be attributed to lower paper questionnaire costs, and the elimination of data entry by CAPI. In Tanzania, the cost of data cleaning are also lower for the CAPI survey due to the higher data quality and the precoding of variables programmed into the questionnaire. In Uganda, the expenses of paper questionnaires decreased with subsequent years using CAPI. This is because UBOS gained confidence with the technology and printed fewer back-up paper questionnaires.

Furthermore, a minor contributing factor of the lower costs of CAPI is the fact that these values are given in PPPs. In Uganda, the enumerator and supervisor salaries were constant across

[1]Purchasing Price Parity were used because they provide a standard unit of measure to compare expenditures across multiple countries. More information can be found at www.worldbank.org.

all waves. So when the values were converted into PPPs, they appear lower because inflation is taken into account. In current local currency units, the enumerator and supervisor were the same across all four waves of the NPS.

Table 1: *Cost per interview in Tanzania in 2005 PPP values*

Description	**NPS – Wave 4**	**DHS**	**LOS**
Year	2014-2015	2015-16	2015
Sample Size	5,010	13,376	415
Number of questions	782	879	239
Method of data collection	PAPI	PAPI	CAPI
Costs			
Enumerators salaries	124.63	67.95	62.06
Supervisor salaries	32.40	14.84	32.85
Data Entry	24.09	14.10	-
Cleaning costs	10.80	2.72	0.21
Paper questionnaire cost	11.60	8.45	0.07
Electronic equipment cost	7.66	2.24	11.21
Cost per interview	211.18	110.29	106.40

Note: Values converted from Tanzanian Shillings to 2005 PPP values using the World Development Indicators (2016).

Table 2:*Cost per interview in Uganda in 2005 PPP values*

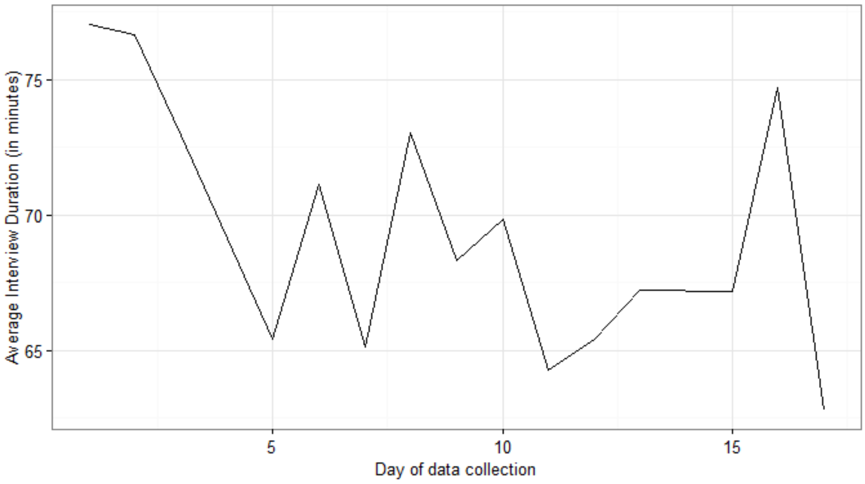
Description	**Wave 1**	**Wave 2**	**Wave 3**	**Wave 4**
Year	2009-2010	2010-2011	2012-2013	2013-2014
Sample Size	3000	3000	3000	3000
Number of questions	1090	1097	1152	1148
Method of data collection	PAPI	CAPI	CAPI	CAPI
Costs				
Enumerators salaries	91.46	81.05	63.96	61.42
Supervisor salaries	45.27	40.12	31.66	30.40
Data Entry	28.38	-	-	-
Cleaning costs	NA	NA	NA	NA
Paper questionnaire cost	35.04	6.21	4.44	3.68
Electronic equipment cost	-	8.14	7.26	7.07
Cost per interview	200.16	135.52	107.33	102.56

Note: Values converted from Ugandan Shillings to 2005 PPP values using the World Development Indicators (2016).

4.2. Interview Duration

As mentioned in Section 2, Leisher (2014) found that the interview duration of CAPI surveys decreased after the first 3 days of data collection. Figure 1 below reflects this same experience in the Tanzania LOS. The average interview duration by day drops from 77 minutes on the first day of data collection to 66 minutes by day 5. Thereafter the average duration of interviews fluctuated, but never reached more than 75 minutes. Notably, the LOS involved a long and complex game as well as very challenging questions involving scenario building and behavioural projections. Thus, the data from this survey does not provide a good comparison with the other surveys from Tanzania, whichare based on straightforward questionnaires.

Figure 1:*Average duration of interviews for the LOS survey in Tanzania*



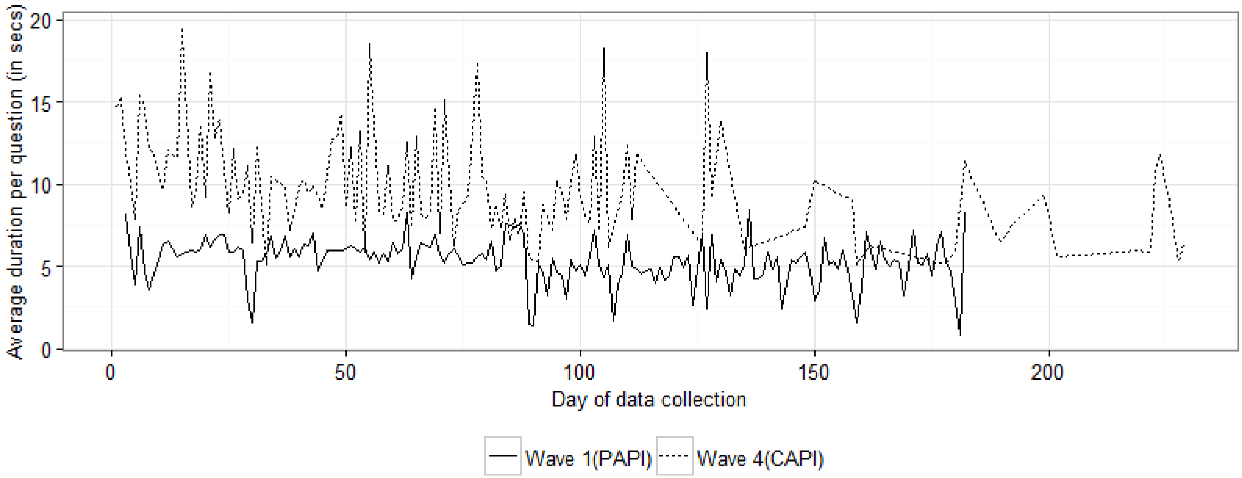
The start times and end times for Waves 1 and 4 of the NPS in Uganda were provided, and the duration of each interview was computed. Wave 4 had more questions than Wave 1, so the duration of each interview was divided by the number of questions. The duration of interviews across the two surveys were independent, ordinal, and did not follow a normal distribution.As a result, a Wilcoxon Sum Rank test was performed check if the difference was statistically signficant.

Table 3:*Comparison of interview durations across Waves 1 and 4 of the Uganda NPS*

Item	Wave 1	Wave 4
Number of questions	1090	1148
Median duration per question (in seconds)	5.83	7.67
Mean duration per question (in seconds) **	5.57	8.48

Note: ** Indicates p-value <.05 as measured using the Wilcoxon Rank Sum test.

Figure 2:*Average per question in seconds for Waves 1 and 4 of the Uganda National Panel Survey*



Note: Missing values were imputed using linear interpolation.

Figure 2 shows the time series of average interview duration by day of data collection for both waves. Almost the entire series of Wave 4 conducted using CAPI lies above Wave 1 signaling that the CAPI interviews took longer. The Wilcoxon Sum Rank test indicates that the results are statistically significant confirming that interviews conducted with CAPI were longer in duration. This finding is at odds with previous literature that finds CAPI interviews are frequently shorter in duration.This can perhaps be explained by the fact that this survey is a panel, and in later waves, there is more information to cooberate from previous waves resulting in longer interviews. Furthermore, problems were reported with the tablets during Wave 4 including “black outs” and “freezing”. These issues may have resulted in longer interview durations during the 4th Wave. Notably, these types of problems were not reported in other survey using CAPI.

4.3. Data Quality

As the PAPI and CAPI surveys were implemented in Tanzania by different institutions, no one was available to provide a comparision on the quality of data collected across the two methods. However, since the same staff at UBOS implemented all waves of the NPS, UBOS was in a excellent position to provide comparision.

According to senior statisticians inside UBOS, there was gradual improvement in the quality of data following the introduction of CAPI. First, most of the inconsistences previously found in data collected using PAPI were eliminated because they were addressed at the design stage in the programming of consistency checks. However some inconsistencies were still found, but were addressed through the regular updates to the application during data collection. Thiswould not have been possible using PAPI.

Furthermore, CAPI facilitates the linking of the different modules due to prior programming and fixing of ID codes making data from different modules collected at the same household easier to merge. For Wave 4 for example, there was no need to re-enter names of household members from the household roster and it was easier to add new members of the households. In the case of PAPI, entire household rosters had to be rewritten for different modules which resulted in mistakes, and lower quality data.

In all cases, an analysis of the raw data – before being cleaned – would be needed to assess any significant difference in data quality between CAPI and PAPI. Unfortunately, this raw data was not available.

4.4. Enumerators'opinion

A questionnaire asking the enumerators sex, age, number of surveys implemented using electronic questionnares, number of surveys implemented using PAPI, and the rating of their experience using both tools was completed by 11and 21 randomly selected enumerators in Tanzania and Uganda respectively.

Figure 3:*Enumerator experience rating of CAPI and PAPI surveys*

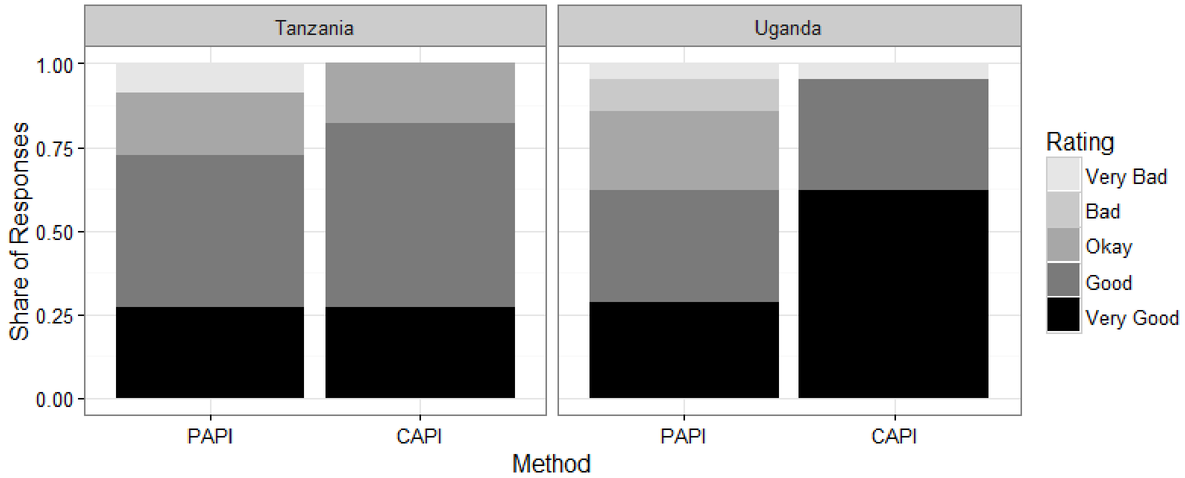


Figure 3 shows that more than 75 percent of enumerators rated their experience as "Good" or "Very Good" in both Tanzania and Uganda. Only one enumerator in Uganda described his/her experience as "Very Bad". Notably, this same respondent indicated that his/her experience with PAPI was also "Very Bad". The overwhelming positive experience with CAPI reveals an enumerator preference for electronic surveys.

4. Conclusions and Recommendations

As countries begin developing a strategy for collecting the data demanded by the SDG framework, additional pressure will be placed on NSSs with already signficant resource contraints. Accordingly, institutions must look for tools which reduce the cost of data collection without jeopardizing data quality. Experiences from small surveys conducted by research institutes indicate that CAPI could be a cost-effective alternative to PAPI due to reduced cost of printing paper questionnaires, and data cleaning costs resulting from higher quality data. Also, one study (Caeyers, et. al 2010) found that CAPI is more cost-effective for surveys with large sample sizes as the sample size increases, the fixed costs are offset by a reduction in variable costs. Some studies(CSO 2016; Zhang, et al 2012;Leisher 2014; Caeyers, et. al 2010**)**. also found a reduction in interview duration using CAPI reducing respondent burden, and that enumerators frequently prefer collecting data using electronic devices. Despite being informative, research institutes operate in a very different context than NSSs. As a result, the results form the currently available literature are of limited the applicability toNSSs.

This paper represents a first attempt to assess the advatanges and disadvantages of using CAPI vs PAPI by analyzing quantitative and qualitative information of cost, duration, data quality and enumerators' opinions from conducting large-scale surveys.Results indicate that the fixed costs of purchasing equipment for CAPI surveys is compensated by lower variable costs, andCAPI interviews are longer than PAPI interviews.The laterresult is highly questionnable and maybe due to equipment failure as well as the use of a longitudinal survey. Also, statisticians in Uganda report an increase in data quality from switching to CAPI, andenumerators in both Uganda and Tanzania show a strong perference for surveys using CAPI.

This paper, though building on quantiative and qualitative information from only two countries, confirms that CAPI could represent a low-cost effective option to collect high quality data in countries with financial and human resource constraints. The advantages of CAPI over PAPI are also expected to become larger in the coming years, because of improvements in equipment, softwareand availability of internet services in rural areas especial for developing countries. Additional evidence is however needed to substatiante these findings. It is recommended that NSSs start systematically collecting and analysing paradata on their PAPI and CAPI based surveys, in order to better assess when to allocate their scarce resources for data collection through PAPI or CAPI.

SPATIAL AND ECONOMETRIC ANALYSIS IN AGRICULTURE STATISTICS

Session Organizer
P. Sckokai | Università Cattolica del Sacro Cuore | Milano | Italy

ABSTRACT

The application of spatial models to agricultural data analyses is a novel and emerging field of applied research. Researchers in agricultural, food and environmental economics increasingly need to understand the extent of spatial variability of data and to construct models accordingly, accounting for the geographical aspects involved in economic phenomena as well as for the spatial interconnections between the units of observation, in order to increase the precision of the estimatesand of the related predictions.
Spatial statistical and econometric methods provide a toolbox for the geographical analysis of agriculturerelated topics and their potential can be already appreciated from the application to a variety or highly relevant themes such as a) the analysis of environment in relation to farmland values and the spatial extent of the environmental externalities; b) the relevance of urban-rural interactions in shaping structural change in agriculture and in modelling hierarchy and distance in the diffusion of urbanization; c) the spatial impact of soil heterogeneity and the development of precision agriculture.
The application of these methodological approaches to a growing number of topics, as well as the potential for empirical applications that follows the increasing integration of geographical information into several databases, is marking the progresses made by the discipline. Modern spatial methods allow for a variety of empirical applications including spatial models analysing the geographical scope of agro-economic and environmental spillovers and models that address several aspects of spatial heterogeneity: the spatiallyvarying behaviours of agents, the presence of multipleequilibria in space and the spatially-related nonlinearities in the predictors.
Although the natural field for the empirical application of these methods is the cross-sectional or longitudinal analysis of agricultural data across territorial administrative units, for which data are normally available in national statistics, new ways of integrating geographical information into agricultural statistics arealso emerging. In particular it is worth recalling the integration into individual level survey of the geographical coordinates related to the location of the farm or household, and the use of territorial statistics produced by the aggregation of data taken from farm-level surveys such as the Farm Accounting Data Network (FADN) of the European Union (EU).
The session will host both methodological and empirical contributions, preferably covering issues in line with the conference Agenda, thus related to the relationship between agriculture, sustainable development and the environment. Case studies related to developing countries will be especially welcome.

ABSTRACT

Inter-state diversity has been a perennial feature of Indian agriculture. The study probes if per capita income from agriculture has converged across states and finds evidence in favour of beta convergence. Spatial econometric techniques used indicate significant spatial dependence in agricultural growth. Infrastructure like roads, irrigation, and electricity, diversification in cropping pattern and quality of human capital are found to aid in growth. However, excessive rainfall tends to decrease growth rate in India. The spill-over across states are found to be primarily driven by roads, irrigation and rural literacy and we also find significant impact of spatial income growth providing evidence in favour of agglomeration effects. Hence, investments in human capital, physical infrastructure specially water management and incentives towards growing crops which yield higher returns will aid agriculture growth in India.

1. Introduction

The level and growth of agricultural income plays an undisputed role on poverty reduction, food security and employment generation (Ravallion and Datt 1996; Warr 2003; Kumar, et al, 2011). On comparing the impacts of growth in agriculture, secondary and tertiary sector on rural poverty alleviation, Ravallion and Dutt, 1996 find the highest impact is from agricultural sector. This is not surprising given that 68 % of total population in India live in rural areas and out of the total rural working population 50 % are employed in agriculture as cultivators and agricultural labour (Source: Principal Census Abstract, 2011). Kumar, et al (2011) finds evidence of a significant negative relationship between farmer's poverty and agricultural NSDP per person through a log-linear regression model. The relationship between nutrition and agriculture has been explored in many past studies. Gulati, et al (2012) finds a significant negative relationship between agricultural performance and income measures and malnutrition index. Gillespie, et al (2012) direct us towards the direct and indirect pathways through which income from agriculture can act as a way out from the curse of malnutrition. For all these reasons, from a policy perspective it is desirable to achieve some degree of convergence in the level and growth of agricultural income across regions.

However, inter-state disparity has been an enduring feature of Indian agriculture. Over the years, states in India have shown variation among themselves across various dimensions like cropping pattern, income generated from agriculture, value of output produced and land and productivity. Studies like Bhalla and Singh (1997), Bhide et al (1998), Chand and Chauhan (1999), Mukherjee and Koruda(2003), Ghosh(2006), Somashekharan, et al (2011), Birthal, et al (2011) and Mukhopadhyay and Sarkar (2014) have documented the rise in inter-state disparity. However, they also found that along with high spatial variation, there has been temporal variation in performance as well. Growth rates of better performing states in the past like Punjab and Haryana have dropped while that of states which were poorer performers earlier like Madhya Pradesh, Gujarat have gone up.

The difference across states is potentially because of differentials in agro-ecological conditions, cropping pattern, input usage, infrastructural support etc. It is widely accepted that agricultural growth is hugely dependent on agro-climatic conditions of a region. A state with favourable agro-climatic condition might have an upper hand in agriculture production and hence have higher chance of generating more income from the same. However, advancement in technology, investments aiding growth in infrastructure and input use and other state level policies can help a state initially un-favourably endowed, to perform better than it would have been in their absence. Reducing inter-state disparity has been one of the primary developmental concerns of policy makers in India.

Inter-state disparities are typically studied using beta and sigma convergence measures in the empirical literature. Sigma convergence is said to occur if the dispersion of income or any other variable of interest across a group of economies or regions declines over time. The idea of beta convergence has been derived from the Solow growth model which predicts that because of diminishing returns to capital, growth will be strong when regions first begin to accumulate capital but will slow down as the process of capital accumulation continues and that regions will converge with one another over time as initially growing regions will slow down and regions growing later will catch up with them. Beta convergence is said to be occurring when a poor economy/region tends to grow faster than the rich one. Formally, this result is obtained if a regression of income growth on initial income level has a significant negative slope coefficient. There are two forms of beta convergence viz. unconditional or absolute wherein all regions are assumed to converge to the same steady state and conditional beta convergence wherein regions are assumed to converge to different steady states depending on the region specific characteristics.

Studies like Bhide et al (1998), Chand and Chauhan (1999), Mukherjee and Koruda (2003), Ghosh (2006), Somashekharan et al (2011) and Mukhopadhyay and Sarkar (2014) have explored convergence across Indian states on various agricultural outcomes for example on per capita agriculture net state domestic product (NSDP), per capita food grain production, land and labour productivity, and total factor productivity growth. Findings from all these studies point towards increasing divergence across states when tested through sigma convergence measure and unconditional beta convergence. Bhide et al (1998) find states converging in the shorter time interval of five years but in the longer time interval of ten years, they find that state level growth rates converge to different levels. They find that changes in rainfall and irrigation to be significant in driving growth although they do not explore factors driving convergence. Ghosh (2006) on controlling other factors driving growth finds evidence in favour of conditional beta convergence and found that human capital, physical capital and rural infrastructure drive convergence in Indian agriculture.

Internationally in the broader literature on convergence for aggregate economy, studies like Rey and Montourri (1999), Egger and Pfaffermayr (2006) among many others have documented evidence in favour of significant spatial dependence in convergence across regions. The underlying idea is that a region's growth performance is dependent on where it is located either because of its own geographical features for example topography, climatic condition etc. or because of the fact that a region shares its geographical neighbourhood with another region i.e. through spatial spill-over. These two pathways linking geography and growth have been discussed in detail in Abreu et al (2005). The first pathway wherein a region's performance is believed to be because of its own geographical features is called 'absolute geography' while the second pathway wherein a region performs in a certain way because of the fact that it is geographically located near another region is known as 'relative geography'.

The significance of role of relative spatial dependence in agriculture i.e. impact of geographical location of regions with respect to each other on land use, deforestation patterns, farming decisions and land price volatility is gaining popularity in recent years (Irwin and Bockstael, 2002, Nelson and Hellerstein, 1997 and Binkley, 1994, Florax et al, 2002 and Schmidtner, 2012).The underlying idea is that forces driving regional agricultural performance could exhibit significant geographical dependence because of agro-climatic zones being spread over multiple regions, spill-over of information and technology and trade and transportation infrastructure into neighbouring regions, institution of market, common river basins across regions etc. Because of the inter-play of these and other possible factors, regions act like interacting agents and not as isolated 'absolute' units..

Econometrically, controlling 'absolute' location in estimation implies that the impact of being located at a particular point in space is controlled by explicit region specific geographic factors and/or region dummies or through fixed effect estimation techniques. Incorporating 'relative' location in estimation technique implies that the effect of being located closer or farther away from specific regions is being controlled. This is done through spatial weight matrices which help in quantifying spatial dependence across regions by giving it a structure and the same are used in estimation techniques.[1]As will be seen later, the spatial econometric models and estimation techniques to assess the role of relative geography requires the use of panel data. Consequently, they do not permit incorporating multiple time-invariant absolute

[1]For details on absolute and relative location, refer Abreu, De Groot and Florax(2005).

geographic factors in the empirical model. Nevertheless, absolute geography is incorporated into the model as state fixed effects.

The impact of geographic factors, in particular relative geography, on convergence, to our best possible knowledge, has not been studied in the empirical literature on Indian agriculture. This study aims to fill this gap in the literature on Indian agriculture. It examines spatial convergence across states in per capita income from agriculture, through sigma and beta convergence measures, controlling for relative geography in our empirical models for beta convergence. We identify the drivers of convergence of per capita income and test if differences in the same across 17[2] major states of India have narrowed down over the period from 1967-68 to 2010-11. The methodology used for the study is drawn from Barro and Sala-I-Martin, 1992 and spatial econometrics literature (Anselin, 1988, Elhorst, 2003).The analysis has been done at the state level because of paucity of a rich data set for such a long time span at a lower level of geographical aggregation for example districts although spatial dependence is expected to be stronger at a lower level of geographical aggregation.

One of the contributions of this study is use of alternative spatial weight matrices. We try out four different spatial weight matrices viz. state-contiguity based, inverse distance based, common border based and district contiguity based in this study beyond the conventional matrices used in the literature. This helps us to compare and identify the spatial weight matrix which explains spatial dependence across states in the best possible manner. Further the use of alternative matrices adds robustness to our results.

Findings from the study give evidence in favour of significant spatial dependence across regions and highlight the importance of inputs and infrastructure in growth in agriculture. In particular, we are also able to identify the channels of spatial spill over on income convergence. Further, we find that spatial dependence is robust across different spatial weight matrix and that district based spatial weight matrix explains spatial dependence in the best possible manner among all other matrices.

The rest of the paper is organized as follows: The next section briefly describes the methodology adopted and data used in the study. The growth performance of the states from 1967-68 to 2010-11 have been compared and spatial patterns discussed in section 3. Section 4 reports the results of the analysis while section 5 provides some concluding remarks.

[2]These 17 states contribute more than 96% of the national Net Domestic Product (NDP) from agriculture. The states are Andhra Pradesh (AP), Assam, Bihar+Jharkhand, Gujarat, Haryana, Himachal Pradesh (HP), Jammu & Kashmir (JK), Karnataka, Kerala, Maharashtra, Madhya Pradesh +Chhattisgarh (MP), Orissa, Punjab, Rajasthan, Tamil Nadu (TN), Uttar Pradesh+ Uttarakhand (UP) and West Bengal (WB)

Methodology and data used

As discussed, the two commonly used approaches to test income convergence in literature are sigma and beta convergence. Sigma convergence refers to reduction in dispersion in the levels of income across regions over time. Beta convergence estimation is based on a log-linear approximation around the steady state of a Solow type growth model. In this approach, an empirical relationship between the initial income level in a region and the subsequent growth rate is estimated. A significant positive association shows high growth rate for richer economies and hence a divergent growth scenario while a significant negative relationship indicates convergence i.e. that poorer regions are growing faster than the richer ones and hence is evidence in favour of "catching up" by the poorer states. It is based on the Neoclassical growth model which predicts that regional incomes will overtime converge to their respective steady states, which depends on savings rate, population growth rate and rate of technological progress in a region, which are assumed exogenous in the model. Therefore, the exogenous rates at which all the factors of production in an economy grow, determine the long run steady rate of growth of the economy.

Studies like Quah, 1993, a, b; Barro and Sala-I-Martin, 1992Young, 2008 have acknowledged that beta convergence is not a sufficient condition for sigma convergence. Sala-I-Martin (1994) suggests that beta convergence measure is more interesting concept since it responds to questions, such as, whether poor economies (countries or regions) are predicted to grow faster than rich ones, how fast the convergence process is, whether the convergence process is conditional or unconditional and whether there is a different convergence process between groups of economies with different structures. However, Quah, 1993a suggests that sigma convergence is of greater interest since it speaks directly as to whether the distribution of income across economies is becoming more equitable. Additionally, Quah, 1993b shows that a negative relationship between growth rates and initial values do not indicate a reduction in cross-sectional variance and it is also possible to observe a diverging distribution (sigma dispersion) in presence of such negative relationship. Given that there is no general consensus on this issue, in this study, both approaches have been used to analyze convergence across states in Indian agriculture. Additionally, spatial dependence among states has also been controlled in the estimation of beta convergence.

Spatial dependence is said to occur when observations of a particular spatial unit is dependent on observations of its neighbours. It implies that there exists a relationship between what happens at different points in space. Econometrically, one of the first and most important steps towards quantifying relative spatial dependence is specifying the structure of spatial relationship among regions. Empirically, spatial dependence is quantified through spatial matrix (*W*)(Anselin, 1988, Elhorst, 2003, 2010a). '*W*' is a symmetric 'nxn' matrix where 'n' is the number of regions and the numerical values of the elements of the matrix are driven by the criteria of neighbourhood definition. *W* can be defined on the basis of context of the study. By convention, the diagonal elements are set to zero,$w_{ii}=0$. However, *W* must satisfy two basic rules of being finite and non-negative (Anselin, 1988). In the simplest case, the weights are defined on the basis of contiguity i.e. regions are assigned 'one' in the matrix if they share borders and 'zero' otherwise.

It is necessary that the relative spatial location is specified correctly in *W* so that the relation among states is appropriately controlled for in the estimation strategy. Eventually *W* will determine the extent and possibility of spatial spill over across regions which are later controlled through the spatial models. Stetzer (1982) shows that the specification of weight is important for parameter estimation, especially when sample sizes are small and the data is auto correlated. Griffith and Lagona (1998) show that incorrectly specified weight matrix can lead to a loss of efficiency of the estimators. Monte-Carlo study by Stakhovych and Bijmolt (2009) conclude that a weights matrix selection procedure that is based on 'goodness-of-fit' criteria increases the probability of finding the true specification. In case the spatial interaction model is estimated based on different spatial weights matrices and the log-likelihood function value of every model is estimated, one may select the spatial weights matrix with the highest log-likelihood function value (Elhorst, 2010b). This method of selecting spatial weight matrices has been criticized by Harris & Kravtsova (2009). They claim that it would only find the best among the competing spatial weight matrices and will not be able to identify the true spatial relationship unless one of the competing matrices is actually the true spatial relationship. However, Elhorst (2010B) argues that, 'the Monte Carlo results found by Stakhovych and Bijmolt (2009) partly refute this critique. Although there is a serious probability of selecting the wrong spatial weights matrix if spatial dependence is weak, the consequences of this poor choice are limited because the coefficient estimates are quite close to the true ones. Conversely, although the wrong choice of a spatial weights matrix can distort the coefficient estimates severely, the probability that this really happens is small if spatial dependence is strong.'(Pp: 17, Elhorst; 2010 b). Elhorst (2010b) additionally stress on the importance of correct specification of spatial weight matrices and suggests that researcher must correctly specify it and check for robustness.

In this study, we have used and compared four spatial weight matrices namely, state-contiguity based, inverse-distance based, shared border based and district-contiguity based matrices. In case of state-contiguity based matrices, weight 'one' implies that states are contiguous to one another and 'zero' implies that they are not. In case of inverse-distance based matrix, inverse of the Euclidean distance between the geographical centroid of two states is used as the weight. This weighing scheme ensures that higher weight is given to states which are closer to each other and vice-versa. In case of length of border based spatial weight scheme, weights are assigned according to the length of the border shared between two states. The idea behind using length of shared borders between states is that spatial spill-over is expected to be proportional to the possibility of connectivity between two states which is more for states with higher length of shared borders. For example if a state shares its borders with two other states, then through this spatial weight matrix, higher weight is given to the state with which it shares longer border compared to the second state with which it shares a smaller border length.

In case of contiguous-district based spatial scheme, weight is assigned according to the total number of contiguous districts between two states. The idea behind using districts based spatial weight matrix is again to control spatial effects in a manner that they are proportional to the possibility of spatial spill-over. States in India are spread across diverse agro-ecological zones and hence controlling state level contiguity does not guarantee that spatial dependence is completely incorporated. Quite often districts within a state are more homogeneous to contiguous districts in the neighbouring states than non-contiguous districts of the same state. For example eastern and western parts of the state of Uttar Pradesh fall under different agro-ecological zone, while eastern part is similar to eastern state of Bihar, western part is similar to northern state of Himachal Pradesh. Hence, giving a uniform weight of 'one' to both Bihar and Himachal Pradesh will not correctly quantify the spatial dependence. This district based matrix will give a higher weight to states with which Uttar Pradesh has more number of contiguous districts. Although this does not ensure that spatial dependence is completely controlled, it is expected to be an improvement over basic state level contiguity. All the matrices have been row standardized.[3]

[3]Lesage and Pace (2009)

Spatial dependence is typically detected using Global and local Moran's I-tests. If these tests reject the null of absence of spatial dependence, then spatial modelling should be used to explain the behaviour of the data. Global Moran's I-test statistics for the presence of global spatial dependence among the spatial units is given by:

$$I = \frac{n}{\sum_i \sum_j w_{ij}} \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}(x_i - \bar{x})(x_j - \bar{x})}{\sum_{i=1}^{n}(x_i - \bar{x})^2} \quad (1)$$

Where n is the number of regions, w_{ij} is the element of the weight matrix W, x_i is the value of the variable at region i and $\bar{x}$ is the cross-sectional mean of x. A significant correlation statistic indicates presence of spatial dependence. However, these global tests overlook the local spatial dependence. It is possible that for a given year global spatial detection tests indicate no spatial relation while local spatial tests indicate strong dependence across some regions in the total set of regions. Hence, to have a better idea on local spatial dependence, local Moran's I-tests are used. For each location, these values compute its similarity with its neighbours and test whether the similarity is statistically significant.

For each location, local Moran's I-test statistic can be computed and this is given by

$$I_i = \frac{(x_i - \bar{x}) \sum_j w_{ij}(x_j - \bar{x})}{\sum_i (x_i - \bar{x})^2 / n} \quad (2)$$

Under the null hypothesis of no spatial dependence, both the global and Local Moran's I-test statistic asymptotically follow a standard normal distribution.

Once, spatial dependence is detected, relationships across spatial units are incorporated in the estimation strategy. There can be three types of spatial relation: (1) spatial dependence in dependent variable i.e. spatial lag model, (2) spatial dependence in error i.e. spatial error model and (3) spatial dependence in explanatory variables i.e. spatial Durbin model. A full model in a panel framework, once all types of spatial interactions are incorporated will be as follows:

$$Y_{i,t} = \eta_i + \rho Y^*_{i,t} + \alpha + X_{i,t}\beta + X^*_{i,t}\theta + u_{i,t}, \quad (3)$$

$$u_{i,t} = \lambda u^*_{i,t} + \varepsilon_{i,t}$$

where the variable $Y^* = WY$ captures the spatial dependence among the dependent variables, $X^* = WX$ the spatial effects among the independent variables, and $u^* = Wu$ the spatial effects among the disturbance terms of the different units, $\boldsymbol{\rho}$ is called the spatial autoregressive coefficient, $\boldsymbol{\lambda}$, the spatial autocorrelation coefficient, while $\boldsymbol{\theta}$, just as $\boldsymbol{\beta}$, represents a $K \times 1$

vector of fixed but unknown parameters. W is a nonnegative $N \times N$ spatial weights matrix of known constants representing the spatial arrangement of the units in the sample.

However, if all three forms of spatial interaction effects are estimated simultaneously, then it is not possible to distinguish and identify one from another (Lee and Yu, 2010). According to Lesage and Pace (2009), the cost of ignoring spatial dependence in the dependent variable and/or in the independent variables is relatively high because of omitted variable bias and the estimator of the coefficients for the remaining variables is biased and inconsistent. In contrast, ignoring significant spatial dependence in the disturbances will only cause a loss of efficiency. Elhorst (2012) suggests that the best option to estimate a spatial model is to exclude the spatially auto correlated error term and to consider a model with spatial interaction effects in dependent and explanatory variables (Spatial Durbin model). Both Anselin (1988) and Lesage (2009) show that least squares estimators, if used in case of models with spatially lagged dependent variables lead to biased and inconsistent estimates. They recommend the use of maximum likelihood estimation techniques to estimate the coefficients of the model. In panel data framework, Lee and Yu (2010) show that the maximum likelihood estimator of the spatial lag and of the spatial error model with spatial fixed effects, as set out in Elhorst (2003, 2010), will yield inconsistent estimates of all parameters of the spatial lag and of the spatial error model with spatial and time-period fixed effects. To correct this, they propose a simple bias correction procedure based on the parameter estimates of the uncorrected approach. Panel data suffers from initial values problem and this is controlled through dynamic panel models where the lagged value of the dependent variable is also used as an additional explanatory variable. This corrects the autocorrelation problem in panel data models (Wooldridge (2005), Pfaffermayr (2012)).

Hence, in this study, spatial dynamic conditional beta convergence and sigma convergence across states in income from agriculture has been explored for 17[4] states in India from 1967-68 to 2010-11. The only consistent state level data available on income from agriculture for states in India from 1967 onwards is net state domestic product (NSDP) from agriculture. Our primary variable of interest is annual growth in NSDP per rural population. Data on NSDP was collected from EPW Research Foundation and rural population from CENSUS. The

[4]The 17 states are Andhra Pradesh (AP), Assam, Bihar+Jharkhand, Gujarat, Haryana, Himachal Pradesh (HP), Jammu & Kashmir (JK), Karnataka, Kerala, Maharashtra, Madhya Pradesh +Chhattisgarh (MP), Orissa, Punjab, Rajasthan, Tamil Nadu (TN), Uttar Pradesh+ Uttarakhand (UP) and West Bengal (WB)

newly formed states of Jharkhand, Chhattisgarh and Uttaranchal have been clubbed together with their parent states of Bihar, Madhya Pradesh and Uttar Pradesh respectively to maintain uniformity in the panel data set.

For purpose of analysis, the time period from 1967-68 to 2010-11 has been divided into following three sub phases on the basis of changing policies in agriculture sector. This aids in better understanding of the changing pattern of growth of agricultural income in India.

- 1st sub-phase : 1967-1977: the period of green revolution
- 2nd sub-phase: 1978-1989: period of falling public investment in agriculture
- 3rd sub-phase: 1990-2010: period of economic reforms

Figure 1plots the shares of public investments i.e. share of gross fixed capital formation (agriculture) in GDP from agriculture (both at constant 2004-05 prices). Investments were higher in the latter half of 1960s (sub phase 1 in our study) compared to the beginning of 1980s. The 1980s and 1990s are characterized with low levels of public investment in agriculture. One can however see a rising trend in late 1990s and early 2000s[5].

[Figure 1]

Following other studies on Indian agriculture (like Fan et al, 2000, Binswanger, 1993), we have controlled for state level inputs, infrastructure, human capital, and rainfall, besides spatial variables while testing for conditional beta convergence .The conditional convergence equation using a spatial dynamic panel fixed effects model in a maximum likelihood framework used for the analysis can be written as:

$$\begin{aligned} growth_{it} &= ln(y_{i,t}) - ln(y_{i,t-1}) \\ &= \alpha_i + \beta\, ln(y_{i,t-1}) \\ &+ \delta growth_{i,t-1} + \gamma_1 inputs_{it} \\ &+ \gamma_2 infrastructure\ and\ other\ state\ level\ characteristics_{it} \\ &+ \gamma_3 human\ capital_{i,t} + \gamma_4 rainfall_{i,t} + \gamma_5 spatial\ variables_{i,t} + \epsilon_{i,t} \qquad (4) \end{aligned}$$

Here, coefficient of β gives evidence in favour or against convergence across states α_i is the state specific effects and the impact of the other factors on growth can be obtained from coefficients$\gamma_1 to\ \gamma_5$.

[5]The rise in share of gross fixed capital in the 3rd phase has been controlled in the study through year dummies as number of years post rise in investment was very low to accommodate a separate phase and perform a robust statistical analysis.

Among inputs we control for land, tractors, fertilizer and livestock as inputs in agriculture. The annual data on land use is available in "Land use statistics, Department of economics and statistics, ministry of agriculture". Data for number of tractors was obtained from quinquennial livestock Census which is conducted by Department of animal husbandry, dairying and fishing, Government of India. The data has been interpolated using compound growth rate to get a panel data set on tractors used from these quinquennial surveys. Fertilizer use has been defined as total fertilizer (Nitrogen+Phophate+Potassium) consumed in kilograms per unit total cropped area. The data for fertilizer consumed is available state-wise and annually from "Fertilizer Statistics". Livestock has been defined as number of livestock per unit total area of the state. Data for number of livestock in total and also number of cattle, buffaloes, goats and sheep was collected from quinquennial livestock census conducted by conducted by Department of animal husbandry, dairying and fishing, Government of India. The data from these quinquennial surveys has been interpolated using compound growth rate to get a panel data set on total livestock and its types.

Infrastructure and other state level characteristics have been controlled through road quality, irrigation, electricity, state expenditure on agriculture and cropping patterns. Road quality is defined as a ratio of total surfaced road length to total road length (both in kms.) in the state. The state-wise annual data on total road length and surfaced road length was collected from "Basic Road Statistics" and "Statistical abstracts of India". Electricity is defined as percentage of villages electrified. Annual state-wise data for the same was obtained from EPRWF database. A dummy variable with value equal to 'one' when less than 100 per cent villages have been electrified and 'zero' if 100 per cent villages are electrified. Irrigation is defined as share of gross area irrigated in total cropped area. State-wise annual data on gross area irrigated and total cropped area from "Land use statistics, Department of Economics and Statistics, Ministry of Agriculture". State expenditure on agriculture is defined as state expenditure in agriculture per unit sq. km. area.[6]. State-wise annual data on expenditure was collected from "Finances of state government" published by RBI. Cropping pattern is defined as share of area under different crops. State-wise annual data was collected from "Area, Yield, Production of Principle Crops" by Ministry of Agriculture. Share of area under

[6]Expenditure on agriculture and allied activities include expenditure on crop husbandry, soil and water conservation, animal husbandry, dairy development, fisheries, forestry and wild life, plantations, food storage and warehousing, agriculture research and development, food and nutrition, community development and other agricultural programmes. Both revenue and capital expenditure have been included. This data is available from 1972.

different groups of crops namely cereals, pulses, fibre, oilseeds, sugar and all other crops have been clubbed together as rest.

As in other studies on Indian agriculture (Fan et al, 2000), rural literacy rate has been used as a proxy for quality of human capital. This is defined as percentage of literate rural persons in total rural population. Data on rural literacy rate was collected from CENSUS (various years). The years between two consecutive censuses were interpolated using assuming constant growth rates.

Rainfall has been controlled in such a manner that the impact of different levels of deviation of actual rainfall from the normal levels can be differentiated. Three rain dummies have been defined on the basis of absolute percentage deviation of actual average annual rainfall from normal average annual rainfall. The dummies are based on rain dummy_1 =‘one’ if percentage absolute deviation of rainfall from normal is between 5 and 10 per cent otherwise zero. Rain dummy_2 =‘one’ if percentage absolute deviation of rainfall from normal is between 10 and 20 per cent otherwise zero and rain dummy_3 =‘one’ if percentage deviation of actual average annual rainfall is between 20 and 100 otherwise zero. Average annual data on rainfall was collected from various publications of Statistical abstract of India.

Spatially weighted variables have been constructed by weighing the neighbouring states using the different spatial weight matrices described earlier; i.e. these newly created variables are the weighted means of observations of neighbouring states where the weights are used according to the spatial weight criteria in the models.

Growth performance across states

As a prelude to examining convergence in agricultural income across states, we first look at the growth performance across states. Figure 2 and Table 1, which give the levels and growth of per capita NSDP at 2004-05 constant prices, brings out some interesting features on the regional pattern of agricultural growth in India. Taking the entire period, the all India annual compound growth rate of NSDP from agriculture at 2004-05 constant prices was 2.29 per cent. During this entire period, the highest growth rate was recorded by northern state of Punjab (4.78 per cent) while the lowest growing state was eastern state of Assam (0.50 per cent).The other states with high growth in the entire time period were Haryana in the north, Maharashtra and Gujarat in the west and West Bengal in the east. Apart for Assam, the states with low growth were Andhra Pradesh in the south and Uttar Pradesh in central India, JK and

HP in the north. The coefficient of variation of growth rates across states in the entire time period was 39.26 per cent.

There were important changes in the regional growth pattern in the sub-phases. In sub-phase 1 (green revolution phase), growth rate of income from agriculture in India was 5.42 per cent. This period recorded the highest growth rate among all the sub-phases. However, this phase also recorded a high coefficient of variation across states (51.75 per cent). Growth rate was highest for Punjab (13.77 per cent) in north while it was lowest for Andhra Pradesh (0.32 per cent) in south. The other states with a high growth rate in this phase were Haryana in the north-west, Gujarat in the west and Bihar and West Bengal in the east. And the states with low growth rates were Andhra Pradesh and Tamil Nadu in the south, Assam in the east, Uttar Pradesh and Madhya Pradesh in central India.

In the 2nd sub-phase, growth rate of agricultural income at the national level fell to 0.69 per cent. This was the phase with the lowest growth rates and highest disparity measured in terms of coefficient of variation (78 per cent). States like Bihar (-1.34 per cent), Jammu and Kashmir (-0.85 per cent) and Tamil Nadu (-0.83 per cent) recorded a negative growth rate in this sub-phase. Growth rate of Orissa (4.62 per cent) was the highest while Bihar grew at the lowest rate. The states which performed better compared to the rest of the states were Orissa and West Bengal in east, Madhya Pradesh in central India, Punjab and Himachal Pradesh in the north while the states which performed the worst during the 1980s were Bihar in the east, Jammu and Kashmir in north, Tamil Nadu in south, Rajasthan and Gujarat in west.

The all India growth rate in the third sub-phase was 1.46 per cent and the coefficient of variation fell to 49.87 per cent. Maharashtra, Gujarat, Kerala, Andhra and TN grew at the highest rates while the states like Madhya Pradesh, Uttar Pradesh, Himachal Pradesh, Assam and Orissa grew at the lowest rate. Clearly, western and southern states were the best performers in this phase and eastern states performed the worst and had negative growth rates.

Hence, there is both evidence of rising spatial disparity across states and also of catching up in the sense that some of the states like Gujarat and Maharashtra in the west, which were comparatively poorly performing in earlier phases were recovering in the later sub-phases. This catching up process will be empirically tested using beta convergence estimation in the next section.

Table 1- growth performance across Indian states

Figure 2: Levels and growth of NSDP agriculture per rural person

Figure 3 plots the coefficient of variation (CV) of levels of per capita NSDP from agriculture and key infrastructure like roads, electricity, irrigation and state expenditure on agriculture across states from 1967 to 2010 to have a better idea of pattern of inter-state disparity. All the key infrastructure and per capita income show a decline in CV in the 1970s (sub-phase 1). In sub-phase 2, the decline continues except for income and power. In sub-phase 3 however, CV increases for all except expenditure on agriculture and power consumption.

[Figure 3]

Results

Spatial dependence across states

The empirical analysis begins with testing for spatial dependence through local and global Moran's I-tests described earlier. These tests are carried out for all the four alternative spatial weight matrices defined on the basis of state-contiguity based matrix, inverse-distance between two states, district-contiguous based matrix and length of borders shared between two states.

The results of global Moran's I computed have been given in Table 2 which shows that it is significant for all the weight structures from 1970. Moran's I result for significant years shows positive autocorrelation i.e. regions with similar levels of per-capita income were also geographically closer. The value of the Moran's I statistic can be interpreted as the level of spatial dependence[7]. Moran's I values for inverse distance based spatial weight matrices are the lowest compared to all other spatial weight matrices.

Table 2: Results of global Moran's test

The plot of global Moran's I in Figure 4 shows that spatial dependence has declined from 1970 to 1990 but there is a turn-around since late 1990s after which there seems to be a positive trend in spatial dependence. But it was particularly high in early 70s and 90s.

[Figure 4]

While global Moran's I detects the aggregate spatial pattern, local Moran test (Anselin, 1995) detects local dependence and helps locate areas of strong spatial linkages. Local Moran's I

[7] Rey and Montouri (1999).

for 1966 and 2010 are given in Table 3[8]. States have significant local spatial dependence in 1966 when there was no significant global spatial dependence.

Table 3-Results of Local Moran's test

States which had significant local spatial dependence for almost all the years were Northern states like Punjab, Haryana, Himachal Pradesh and Uttar Pradesh and eastern states like Bihar, West Bengal, Orissa, Assam , western states like Madhya Pradesh, Maharashtra, Rajasthan and Gujarat and Andhra Pradesh in south.

Sigma convergence

Figure 5 which plots the standard deviation of log of NSDP per rural person from agriculture for the entire time shows evidence in favour of sigma convergence in phase 1 as it can be seen that standard deviation of income across states follows a declining trend only in phase 1. However, we find evidence against sigma convergence in the later phases.

[Figure 5]

Figure 6 plots the global Moran's I statistics and standard deviation of log of per capita income over time for the full and different sub-periods. These plots point to a negative relationship between the two. Indeed, a simple correlation[9] between standard deviation of log of income and global Moran's I statistic for all the spatial weight criteria over the years confirms this. The correlation coefficient of Global Moran's I using contiguity, inverse distance, border and district based spatial weight matrix are -0.65, -0.61,-0.61 and -0.67 respectively and they are statistically significant at less than 1 percent level. This implies that a greater spatial dependence across states can help in reducing the inter-state disparity in per capita income. A similar significant correlation of -0.80, -0.79, -0.86 and -0.85 is seen for contiguity, inverse distance, border and district based spatial weight matrix respectively at less than 1 percent level in the first sub-phase also though in the second and third sub-phases, the correlation coefficient is not significant. This inverse relation between sigma convergence measure and spatial dependence possibly points towards the conceivable role of spatial dependence as a channel in reducing inter-state disparity. The results of beta convergence discussed below bring out this relationship more explicitly.

[Figure 6]

---

[8]Results of local Moran's I for other years have not been shown in the table owing to paucity of space. They can be shared on request

[9]Rey and Montouri (1999) also find a statistically significant positive correlation between standard deviation and Moran's I statistic of per capita income of US.

Beta convergence

Table 4 gives the results of conditional beta convergence models. Annual growth rate of per capita income (NSDP) from agriculture is the dependent variable and explanatory variables are per capita income and other state specific characteristics discussed earlier. We estimate non-spatial model in Model 1 of Table 4. Hausman test confirms that fixed effects model performs better than random effects model. Therefore, we find that absolute geography which has been controlled through state fixed effects significantly drives agricultural growth convergence. In models 2-5, we estimate spatial models controlling for state fixed effects. Lagged per capita income (β) is significant and negative in all the models, indicating statistically significant evidence in favour of beta convergence within Indian states over the entire period 1967-68 to 2010-11.

Like other studies on convergence in Indian agriculture, our results show evidence in favour of conditional beta convergence but no such evidence in favour of sigma convergence. Ambivalence in results from beta and sigma convergence is not new in this literature. The concerns in empirical literature regarding these measures of convergence are discussed in Azariadis and Drazen (1990), Quah (1993 b), Durlauf and Quah (1999), and Islam (2003), Young et al, 2008. A negative beta coefficient, implying convergence, is consistent with a rising variance which indicates a lack of sigma convergence. Additionally, in presence of multiple equilibriums this approach tends to reject the null hypothesis of no convergence too often (Bernard and Durlauf, 1996). Further studies like Quah, 1993, a, b; Barro and Sala-I-Martin, 1992 Young, 2008 have acknowledged that beta convergence is not a sufficient condition for sigma convergence. Even existing studies on convergence in Indian agriculture like Ghosh (2006), Birthal, et al (2011) find no evidence of convergence when measured through sigma convergence but do find evidence in favour of robust conditional beta convergence.

One plausible reason driving this lack of unanimity can be that these two measures explore different aspects. While sigma convergence measures whether the distribution of the levels of variable of interest is becoming more equitable, beta convergence measures ask a very different question. Conditional beta convergence explores whether after controlling for region specific characteristics, growth rates are inversely correlated to levels in variable of interest. Young, et al (2008) show in their analysis that it is possible that regions are beta converging towards one another yet random shocks are pushing them away from each other leading to unambiguous results from beta and sigma measures. Another plausible explanation can be possibility of club convergence among regions. That is if states are not all converging to unique steady states after controlling for state specific characteristics, are they converging to multiple equilibriums.

Turning to the role of spatial dependence, if any, on the basis of log-likelihood, AIC and BIC, we find that spatial models (models 2 – 5) perform better than the non-spatial model (model 1) for the entire period (1967-68 to 2010-11) which confirms the presence of significant spatial dependence in income growth in Indian agriculture. As literature does not provide much guidance on the spatial weight criteria, the spatial models have been compared on the basis of log-likelihood, AIC and BIC and the contiguous districts based spatial matrix (model 5) performs the best among all other models. This confirms that spatial dependence across states in India is controlled better through contiguous district based spatial weight matrices where higher weight is given to states with more number of contiguous districts. There is a lot of diversity within the states in India and hence often one can find more homogeneity between contiguous districts of neighbouring states compared to non-contiguous districts on the same state. The contiguous-district based spatial weight matrix controls for this spatial homogeneity among neighbouring states. The results from the other spatial weight matrices (models 2-4) give evidence of significant spatial dependence thereby adding robustness to our results.

Results show that channels of spatial spill-over in income from Indian agriculture has been income growth, rural literacy, gross area irrigated and road quality. Spatial income growth is positive and significant for all the models implying that higher growth of a state has positive spill-over effect over its neighbours. In case of contiguity based matrix (model 2), additionally spatial literacy has a positive coefficient implying that states with higher literacy rate have a positive impact over income growth of their neighbours. In case of inverse distance based spatial matrix (model 3), it can be seen that spatial impact is through road quality i.e. higher road quality accelerates growth in neighbouring regions through better connectivity/networking possibilities. Using length of shared borders between states (model 4) and number of contiguous districts (model 5) as weighing criteria, rural literacy, gross area irrigated and road quality have a positive and significant spatial on growth in income among states. Infrastructure therefore has significant spatial dependence across states and aids in growth in neighbouring states.

The findings are in line with studies on other countries like Tong (2012) found significant spatial spill-over through road infrastructure. Similarly there are a number of studies like Patton and McErlean, 2005 on land market, Schmidtner et al (2011) for farming decisions in Germany, which give evidence of significant spatial lag dependence which has often been interpreted as an agglomeration effect. Studies like Alston (2002) discuss knowledge based channels in detail and conclude that it as a primary source of spatial spill-over in agriculture. We believe that rural literacy acts as a channel of spatial spill over through diffusion of knowledge externalities from neighbouring states. With evidence in favour of increasing inter-state migration (Lusome and Bhagat, 2006) it is conceivable that diffusion of knowledge gets accentuated through migration. Further, demonstration effects can also be a possible channel through which literacy acts as significant channel of spatial spill over. It is widely accepted that literacy increases the prospect of adoption of newer technology, farming techniques thereby further accentuating agriculture growth and income at the state level. With higher inter-state mobility and plausible demonstration effects we believe that literacy acts as an important channel of spatial spill over.

With regard to spatial irrigation, to the best of our knowledge we could not find evidence in existing literature on the plausible reasons for its significant. One possible reason for spatial irrigation to have spill-over effect could be that when neighbouring states receive irrigation investments, especially large surface irrigation projects, its impact does not suddenly stop at the state boundaries. In fact quite often such projects tend to cover several states across multiple agro ecological zones thereby potentially leading to a spatial spill-over across states.

Among inputs, tractors, land and livestock play a statistically significant impact in all the models[10]. Both tractor and land ownership have a positive impact on growth indicating the importance of asset ownership in growth of income. Among livestock, only buffaloes and sheep play a significant role in growth while other forms of livestock remained insignificant and hence were dropped from the analysis. Interestingly, buffaloes have a negative impact on growth in spatial models (insignificant in non-spatial model) while sheep have a positive impact. Livestock not only acts as an input in agriculture production process but also acts as a source of income in the form of wool, meat, milk etc. Although the reason driving the negative relation between buffaloes and growth and insignificant relation between cattle and

[10]Fertilizer consumed per unit of cropped area is not significant in any of the models and hence has been dropped from the analysis.

goats and growth is not very clear, it is possible that these results point towards a non-optimal mix of different types of livestock dominated by bovines[11].

Results show that infrastructural support in a state has statistically significant impact on its income growth. Key infrastructure like gross area irrigated, villages electrified, road quality and state expenditure on agriculture are significant and positive drivers of growth of income in all the models. Results suggest that higher the infrastructural support in the state more is the growth in income from agriculture.

Cropping pattern has been controlled through share of total cropped area under different groups of crops like cereals, pulses, sugar, oil seeds, fibre etc. Share of area under fibre, sugar and oil-seeds are all significant and positively influence the growth of income from agriculture[12]. In India, cropping pattern has shown structural rigidity till 1980s when food grains were the dominant crop in India. However, post 1980s, there has been an increase in area under other crop like oil-seeds at the cost of area under pulses and coarse cereals (Bhalla and Singh, 1997). A change in cropping pattern is based on a number of factors like agro-ecological conditions, profitability of crops, availability of technology and infrastructure etc. These results in favour of significant impact of fibre, sugar and oil-seeds support findings from studies like Joshi, Birthal and Minot (2006) which concludes that diversification has been a dominant source of growth since the 1980s in Indian agriculture. The impact of diversification becomes clearer in the next sub-section where we identify the differential impact across the sub-phases.

Human capital has been controlled through rural literacy rate and as expected it has a positive impact on growth of income from agriculture. Deviation of actual rainfall from its normal level greater than 10 per cent significantly reduces growth of income from agriculture in all the models and the impact on income growth is proportional to the level of deviation of actual rainfall from normal.

Table 4- Results of beta convergence

Beta convergence: sub-phases

Comparison of growth process across sub-phases has been done using district based spatial weight matrices in Table 5 since district based spatial weight matrix performed the best

[11] At the all India level, from 1966 to 2007, on an average bovines account for approximately 65% of all livestock, and within bovines, animals in milk constitute only approximately 35%.

[12]

across all other spatial weight criteria (Table 4). The results (Table 5) on spatial beta convergence for the sub-phases indicate significant conditional convergence in all the sub-phases.

In the first sub-phase i.e. models 1 and 2, land ownership is the most important income generating input. Fertilizer is significant only if year effects are not controlled (model 1). Among infrastructure, density of surfaced roads is the key growth driving factor in first sub-phase. This phase of green revolution witnessed enormous expansion of area under food-grains especially wheat at the cost of area under other crops and results indicate that share of irrigated area under cereals had a positive impact on income growth. However, area covered under fibre and sugar had negative impact on growth. Spatial rural literacy was a significant driver of growth in this phase. Income growth also had significant spatial dependence as growth in this phase owing to the selective introduction of the new technology was concentrated in certain geographically contiguous states. This phase also witnessed severe to moderate droughts which get reflected in the negative year effects (1968, 1969, 1976).

In the second sub-phase (model 3), growth was dominated by inputs namely land, tractors and livestock. Among infrastructure, density of surfaced roads again had a significant impact on growth like sub-phase one. Area under cereals like sub-phase one, again led to positive growth. Additionally, area under fibre and oil-seeds also contributed positively to growth. This again validates the findings from studies like Bhalla and Singh (1997) that unprecedented changes took place in the 1980s in cropping pattern and area under other crops expanded at the cost of area under pulses and coarse cereals. Although area under wheat and rice continued to increase in this phase and hence share of area under cereals continue to be a significant driver of growth but one case see that area under other crops were slowly gaining importance in explaining growth of income from agriculture. Excessive rainfall had a negative impact on growth. Spatial growth and irrigation were significant drivers of growth in this phase.

In the third sub-phase (model 4), again land ownership significantly affected income growth. Irrigation contributed in this sub-phase. However, here cereals no longer were a significant driver of growth. Rather in this phase, growth was because of fibre crops. Again this validates the pattern which emerged in studies like Bhalla and Singh (1997) and Joshi, Birthal and Minot (2006) that impact of diversification was highest in the 1990s compared to earlier sub-phases. Literacy was a significant driver of growth in this phase. Spatial spill-over in this phase was because of irrigation and income growth of neighbouring states.

Interesting pattern which comes up from the comparison across sub-phases is the consistent spatial dependence of growth of income and significance of key infrastructure like roads, rural literacy and irrigation across all the sub-phases. Reduction in impact of cropped area under cereals over phases and gaining significance of area under other crops provide evidence in favour of higher returns from diversification. Primary driver of growth in the first phase was growth in area under cereals and land ownership while the second phase saw the emergence of impact of mechanization of agriculture and diversification and third phase continued to witness the impact of diversification. Among the spatial factors, rural literacy and irrigation have almost consistently had a significant impact on growth of per capita income in agriculture.

Table 5–Results of beta convergence for sub-phases

Conclusion

Inter-state disparity has been an enduring feature of Indian agriculture possibly due to differences across states in agro-ecological conditions, cropping pattern, input usage, infrastructural support etc. States like Punjab and Haryana in the north have always had a higher level of per capita income while states like Bihar and Uttar Pradesh have been always been poor performers. This persistent inter-state disparity provides an empirical basis to analyse the convergence behaviour of per capita income from agriculture. Studies like Bhide et al (1998) and Ghosh (2006) have explored convergence across states in India using sigma and beta convergence measures and find that state specific factors like human capital, physical capital and rural infrastructure play an important role in driving convergence across states.

The broader literature on convergence for aggregate economy has documented the role of geography in the growth convergence process. Two broad pathways through which geography plays a role on growth of a region are absolute geography, i.e., through geographic factors specific to a region and relative geography, i.e., the impact of a region on its neighbour through spatial spill-over.The role of relative geography in particular, has not attracted much attention in the empirical literature on convergence in Indian agriculture, though absolute geography has been controlled in many of the past studies .

This paper tries to fill this gap in literature and explores the role of relative geography on convergence in terms of income per rural person across states in India between 1967 and 2010. We follow the literature on convergence and use sigma and beta convergence measures which are the two most commonly used approaches for analysing convergence and further incorporate spatial dependence in our estimation strategy. The relative location of states was incorporated econometrically using spatial weight matrices. One of the contributions of the study is comparing different spatial weight matrices and identifying the one which explains spatial dependence across states in the best possible manner. Stetzer (1982), Stakhovych and Bijmolt (2009) Elhorst (2010 b) document that it is of extreme importance that spatial weight matrices are correctly specified as this matrix will eventually define and quantify the spatial dependence across regions. For that, in addition to the conventional state-contiguous, inverse-distance based matrices, district-contiguous and length of state borders shared have also been used in the analysis. These matrices help to differentiate the impact of two contiguous neighbours as the one with higher number of contiguous districts or length of border shared gets a higher weight in the matrix. This weighing scheme ensures that the incorporated spatial effects are proportional to the possibility of spatial spill-over.

Global and local Moran's I-tests using these weights found statistically significant spatial dependence across states. Therefore, ignoring relative spatial location in convergence analysis would lead to model misspecification and hence erroneous conclusions.

For spatial convergence analysis, spatially lagged dependent and independent variables were computed using spatial weight matrices. A dynamic fixed effect model was used to correct the autocorrelation problem in panel data. We find that among all spatial weight matrices district based spatial weight matrix explains spatial dependence across states in the best manner. This is potentially because states are large geographical units and therefore spatial structure at the state level masks the heterogeneity existing within the states. For example districts in the eastern Uttar Pradesh are similar to one another in terms of both agro-climatic conditions and performance to its neighbouring districts in Bihar rather than districts in west Uttar Pradesh which are in turn more similar to those of Himachal Pradesh. The district based spatial weight matrix we use incorporates this heterogeneity within states and homogeneity across states.

Like past studies on Indian agriculture which have used sigma convergence measures, we do not find any evidence in favour of sigma convergence, rather we find that disparity across states have increased over the years. However, on the same lines as findings from Ghosh (2006) we too find evidence in favour of conditional beta convergence both in the entire time period and the sub-phases. We find that irrespective of the criteria used for spatial weight matrices, there is consistent significant spatial dependence across states for all the three sub-phases and entire time period. Further, we find that the significant channels of spatial spill over across states are rural literacy and infrastructure like roads and irrigation. Other state specific factors which significantly drove growth in the entire time period were input usage, physical infrastructure and cropping pattern. We find that there has been a reduction in impact of cropped area under cereals over the three sub-phases and increasing significance of area under other crops provide evidence in favour of higher returns from diversification. Primary drivers of growth in the first phase were growth in area under cereals and land ownership while the second phase saw the emergence of impact of mechanization of agriculture and diversification and third phase continued to witness the impact of diversification. Among the spatial factors, rural literacy and irrigation have almost consistently had a significant impact on growth of per capita income in agriculture.

The empirical evidence presented here highlights the importance of inputs and infrastructure in convergence in agriculture. Therefore, economic policy measures targeting improvement and expansion of infrastructural support and literacy for example public investments towards irrigation and electricity, roads and rural literacy and input usage can have an important impact in promoting long run agriculture growth and convergence across Indian states. In particular, our findings point towards the significant role of infrastructure and literacy in reducing regional disparity through their spatial spill-over effects.

Some of the limitations of the present study have to be kept in mind while drawing conclusions. A major limitation here is the quality of data availability. It is widely accepted that there is discrepancy in data from government sources on agricultural production, land use etc. because of irregularity of publications and updating the records. Moreover, data on livestock and machinery etc. are not annually available and they had to be interpolated to obtain an annual series. Interpolation potentially might have introduced some errors in the data. Spatial analysis is dependent on spatial weight matrices. Nevertheless, the results confirm spatial dependence in Indian agriculture and point towards channels of intervention which can potentially reduce inter-state disparity.

Abstract

The wheat production has been grown along the years and is one of the most important food grain source for humans. We analyze the productivity of two varieties of wheat planted in a regular sampling grid in an experimental area in south region of Brazil. We considered as explanatory variables the variety of wheat, spike length, average plant height and average number of tillers in 60 days. To model the mean of the wheat productivity we fitted a Gaussian spatial linear model, with different geostatisticals models for the variance-covariance matrix. To asses the influence of some observations we considered local diagnostics techniques based on Cook's approach. We considered appropriate perturbation scheme in the response variable. Then, we have substantial information to select the final model.

Keywords: Geostatistical; Maximum Likelihood; Spatial Variability; Precision Agriculture.

1 Introduction

Wheat (*t*riticum spp.) originated in southwestern Asia. According to Curis (2002), wheat was one of the first domesticated food crops and for 8000 years has been the basic staple food of the major civilizations of Europe, West Asia and North Africa, whilst is grown on more land area than any other commercial crop and continues to be the most important food grain source for humans. World wheat production increased dramatically during the period 1951-1990, although the expansion of the area sown to wheat has long ceased to be a major source of increased wheat output (CIMMYT, 1996). In Brazil the production is concentrated in south region.

The wheat grain is used to make flour for bread, pasta, pastry, etc. Wheat is also a popular source of animal feed, particularly in years where harvests are adversely affected by rain and significant quantities of the grain are made unsuitable for food use (Curis, 2002). It is considered a good source of protein, minerals, B-group vitamins and dietary fiber (Shewry, 2007). Davy et al (2002) has shown that whole wheat, rather than refined wheat, is a good choice for obese patients. Sidorova et al (2012) performed a geostatistical analysis of the spatial variability of the soil properties, the sowing parameters, and the wheat yield in a field experiment under precision agriculture conditions.

We analyze the wheat productivity data and four explanatory variables from an agricultural area in south Brazil. To consider the dependence between observations, the analysis were conducted using geostatistics techniques, where the data are collected at known sites in space, from a process that has a value at every site in a certain domain. To model the mean of the wheat productivity we fitted a Gaussian spatial linear model (GSLM) by maximum likelihood (ML) method given in Section 2. To asses the influence of some observations we considered local diagnostics techniques based on Cook's approach. We considered appropriate perturbation scheme in the response variable as shown in Section 2. The results are presents in Section 3 and some conclusions are given in Section 4.

2 Methodology

Let $\mathbf{Y} = \mathbf{Y}(\mathbf{s}) = (Y_1(\mathbf{s}_1), \ldots, Y_n(\mathbf{s}_n))^\top$ be an $n \times 1$ random vector of an isotropic and stationary stochastic process, that belong to the family of Gaussian distributions and depend on the sites $\mathbf{s}_j \in S \subset \mathbb{R}^2$, for $j = 1, \ldots, n$, $\mathbf{s} = (\mathbf{s}_1, \ldots, \mathbf{s}_n)^\top$. This stochastic process can be written in matrix form by

$$\mathbf{Y}(\mathbf{s}) = \boldsymbol{\mu}(\mathbf{s}) + \boldsymbol{\epsilon}(\mathbf{s}).$$

where, the deterministic term $\boldsymbol{\mu}(\mathbf{s})$ is an $n \times 1$ vector, the means of the process $\mathbf{Y}(\mathbf{s})$, $\boldsymbol{\epsilon}(\mathbf{s})$ is an $n \times 1$ vector of a stationary process with zero mean vector, $\mathrm{E}[\boldsymbol{\epsilon}(\mathbf{s})] = \mathbf{0}$, and $n \times n$ covariance matrix $\boldsymbol{\Sigma} = [C(s_u, s_v)]$. The mean vector $\boldsymbol{\mu}(\mathbf{s})$ can be written as a spatial linear model by $\boldsymbol{\mu}(\mathbf{s}) = \mathbf{X}(\mathbf{s})\boldsymbol{\beta}$, where, $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)^\top$ is a $p \times 1$ vector of unknown parameters, $\mathbf{X} = \mathbf{X}(\mathbf{s}) = [\mathbf{x}_{j1}(\mathbf{s}) \ldots \mathbf{x}_{jp}(\mathbf{s})]$ is an $n \times p$ matrix of p explanatory variables, for $j = 1, \ldots, n$.
The matrix $\boldsymbol{\Sigma}$ is symmetric and positive defined, where the elements $C(\mathbf{s}_u, \mathbf{s}_v)$ depend on the Euclidean distance $d_{uv} = ||\mathbf{s}_u - \mathbf{s}_v||$ between points $\mathbf{s}_u$ and $\mathbf{s}_v$, sometimes $C(\mathbf{s}_u, \mathbf{s}_v)$ is also denoted by $C(d_{uv})$ or $C(d)$. The covariance matrix structure which depends on parameters $\boldsymbol{\phi} = (\phi_1, \ldots, \phi_q)^\top$ as given in Equation (1) (Uribe-Opazo et al, 2012):

$$\boldsymbol{\Sigma} = \phi_1 \mathbf{I}_n + \phi_2 \mathbf{R}, \tag{1}$$

where, $\phi_1 \geq 0$ is the parameter known as nugget effect; $\phi_2 \geq 0$ is known for sill ; $\mathbf{R} = \mathbf{R}(\phi_3, \phi_4) = [(r_{uv})]$ or $\mathbf{R} = \mathbf{R}(\phi_3) = [(r_{uv})]$ is an $n \times n$ symmetric matrix, which is function of $\phi_3 > 0$, and sometimes also function of $\phi_4 > 0$, with diagonal elements $r_{uu} = 1, (u = 1, \ldots, n)$; $r_{uv} = \phi_2^{-1} C(\mathbf{s}_u, \mathbf{s}_v)$ for $\phi_2 \neq 0$, and $r_{uv} = 0$ for $\phi_2 = 0$, $u \neq v = 1, \ldots, n$, where r_{uv} depends on d_{uv}; ϕ_3 is a function of the model range, ϕ_4 when exists is known as the smoothness parameter, and $\mathbf{I}_n$ is an $n \times n$ identity matrix. The Matérn (Matern, 1960) is a covariance function particularly attractive. Table 1 presents few special cases of the Matérn class of models.

Table 1: Special cases of the Matérn covariance function.

smooth parameter	covariance function	model
$\phi_4 = 1/2$	$C(d_{uv}) = \phi_2 \exp(-d_{uv}/\phi_3)$	exponential
$\phi_4 = 1$	$C(d_{uv}) = \phi_2 (d_{uv}/\phi_3) K_{\phi_4}(d_{uv}/\phi_3)$	Whittle
$\phi_4 \to \infty$	$C(d_{uv}) = \phi_2 \exp(-(d_{uv}/\phi_3)^2)$	Gaussian

Let $\boldsymbol{\theta} = (\boldsymbol{\beta}^\top, \boldsymbol{\phi}^\top)^\top$ be the vector of unknown parameters. The log-likelihood and score functions for the GLSM are given by

$$\mathcal{L}(\boldsymbol{\theta}) = -\frac{n}{2}\log(2\pi) - \frac{1}{2}\log|\boldsymbol{\Sigma}| - \frac{1}{2}(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})^\top \boldsymbol{\Sigma}^{-1}(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta}), \tag{2}$$

$$\begin{aligned} \mathbf{U}(\boldsymbol{\beta}) = \frac{\partial \mathcal{L}(\boldsymbol{\theta})}{\partial \boldsymbol{\beta}} &= \mathbf{X}^\top \boldsymbol{\Sigma}^{-1} \boldsymbol{\epsilon}, \\ \mathbf{U}(\boldsymbol{\phi}) = \frac{\partial \mathcal{L}(\boldsymbol{\theta})}{\partial \boldsymbol{\phi}} &= -\frac{1}{2}\frac{\partial \, \mathrm{vec}^\top(\boldsymbol{\Sigma})}{\partial \phi} \mathrm{vec}(\boldsymbol{\Sigma}^{-1}) + \frac{1}{2}\frac{\partial \, \mathrm{vec}^\top(\boldsymbol{\Sigma})}{\partial \boldsymbol{\phi}} \mathrm{vec}(\boldsymbol{\Sigma}^{-1}\boldsymbol{\epsilon}\boldsymbol{\epsilon}^\top \boldsymbol{\Sigma}^{-1}), \end{aligned}$$

where $\boldsymbol{\epsilon} = \mathbf{Y} - \mathbf{X}\boldsymbol{\beta}$. From the solution of the score function of $\boldsymbol{\beta}$, $\mathbf{U}(\boldsymbol{\beta}) = \frac{\partial \mathcal{L}(\boldsymbol{\theta})}{\partial \boldsymbol{\beta}} = \mathbf{0}$, the maximum likelihood estimator $\boldsymbol{\beta}$ is given by $\hat{\boldsymbol{\beta}} = (\mathbf{X}^\top \boldsymbol{\Sigma}^{-1}\mathbf{X})^{-1}\mathbf{X}^\top \boldsymbol{\Sigma}^{-1}\mathbf{y}$. The derivatives of first and second-order of the scale matrix $\boldsymbol{\Sigma}$, with respect to ϕ_1, ϕ_2 and, ϕ_3, for some covariance functions are presented in Uribe-Opazo et al (2012), however the score equation for $\boldsymbol{\phi}$ do not lead to a closed-form solution for $\hat{\boldsymbol{\phi}}$. We consider the parameter ϕ_4 as fixed. The criteria considered to choose the geostatistical model for the covariance matrix were the cross-validation (CV), trace of the asymptotic covariance matrix of an estimated mean (Tr) and the log-likelihood maximum value (LMV) (De Bastiani et al, 2015).
Asymptotic standard errors can be calculated by inverting either observed information matrix, $I(\boldsymbol{\theta})$ or the expected information matrix, $\mathbf{F}(\boldsymbol{\theta})$, where $I(\boldsymbol{\theta})$ is $I(\boldsymbol{\theta}) = -\mathbf{L}(\boldsymbol{\theta})$, evaluated in $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$, with $\mathbf{L}(\boldsymbol{\theta}) = \partial^2 \mathcal{L}(\boldsymbol{\theta})/\partial\boldsymbol{\theta}\partial\boldsymbol{\theta}^\top$ and $\mathbf{F}(\boldsymbol{\theta})$ is given by (see Waller & Gotway, 2004)

$$\mathbf{F}(\boldsymbol{\theta}) = \mathbf{F} = \begin{pmatrix} \mathbf{F}_{\beta\beta} & \mathbf{0} \\ \mathbf{0} & \mathbf{F}_{\phi\phi} \end{pmatrix},$$

where $\mathbf{F}_{\beta\beta} = \mathbf{X}^\top \boldsymbol{\Sigma}^{-1}\mathbf{X}$, and $\mathbf{F}_{\phi\phi} = \frac{1}{2}\frac{\partial\, \mathrm{vec}^\top(\boldsymbol{\Sigma})}{\partial \boldsymbol{\phi}}(\boldsymbol{\Sigma}^{-1} \otimes \boldsymbol{\Sigma}^{-1})\frac{\partial\, \mathrm{vec}(\boldsymbol{\Sigma})}{\partial \boldsymbol{\phi}^\top}$.

2.1 Local Influence

One of the purposes of diagnostic techniques is to evaluate the stability of the fitted model in a data set and should be part of all statistical analysis, since influential observations may distort the values of the statistic interest and lead us to misleading results.
In the local influence method, introduced by Cook (1986), a perturbation scheme is introduced into the postulated model through a perturbation vector $\boldsymbol{\omega} = (\omega_1, \ldots, \omega_k)^\top$ ($\boldsymbol{\omega} \in \Omega \subset \mathbb{R}^k$), generating the perturbed model, where $\mathcal{L}(\boldsymbol{\theta}|\boldsymbol{\omega})$ is the corresponding log-likelihood function. The influence measure is constructed using the basic geometric idea of curvature of the likelihood displacement given by

$$LD(\boldsymbol{\omega}) = 2[\mathcal{L}(\hat{\boldsymbol{\theta}}) - \mathcal{L}(\hat{\boldsymbol{\theta}}_\omega)],$$

where $\hat{\boldsymbol{\theta}}$ is the ML estimator of $\boldsymbol{\theta} = (\boldsymbol{\beta}^\top, \boldsymbol{\phi}^\top)^\top$ in the postulated model, with $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)^\top$, $\boldsymbol{\phi} = (\phi_1, \ldots, \phi_q)^\top$ and $\hat{\boldsymbol{\theta}}_\omega$ is the ML estimator of $\boldsymbol{\theta}$ in the perturbed model.
The plot of the elements $|l_{max}|$ versus index (order of data) can reveal what type of perturbation has more influence on $LD(\boldsymbol{\omega})$, in the neighbourhood of $\boldsymbol{\omega}_0$, Cook (1986). Poon & Poon (1999) proposed the conformal normal curvature $B_l = C_l/\,\mathrm{tr}(2\mathbf{J})$, where $\mathbf{J} = \Delta^\top \mathbf{L}^{-1}\Delta$. The conformal curvature in the unit direction with j-th entry 1 and all other entries 0 is given by $B_i = 2|j_{ii}|/\,\mathrm{tr}(2\mathbf{J})$. The plot of B_i versus index can reveal potential influential observations.
To verify if a perturbation scheme is appropriate, Zhu et al (2007) proposed to use the Fisher information matrix of $\boldsymbol{\omega}$ in the perturbed model considering the vector $\boldsymbol{\theta}$ as fixed. In the following Section we give the results for the response variable perturbation scheme.

2.1.1 Perturbation on the response variable

Let consider as perturbation scheme the model shift in mean, i.e. $\mathbf{Y} = \boldsymbol{\mu}(\boldsymbol{\omega}) + \epsilon$, with $\boldsymbol{\mu}(\boldsymbol{\omega}) = \mathbf{X}\boldsymbol{\beta} + \mathbf{A}\boldsymbol{\omega}$ where $\mathbf{A}$, $n \times n$, is a matrix that does not depend on $\boldsymbol{\beta}$ or on $\boldsymbol{\omega}$. In this case $\boldsymbol{\omega}_0 = \mathbf{0}$. Equivalently we can write $\mathbf{Y}_\omega = \mathbf{X}\boldsymbol{\beta} + \epsilon$, with $\mathbf{Y}_\omega = \mathbf{Y} + (-1)\mathbf{A}\boldsymbol{\omega}$, that corresponds to a perturbation scheme of the response vector.
The perturbed log-likelihood is given by

$$\mathcal{L}(\boldsymbol{\theta}|\boldsymbol{\omega}) = -\frac{n}{2}\log(2\pi) - \frac{1}{2}\log|\boldsymbol{\Sigma}| - \frac{1}{2}[\mathbf{Y} - \boldsymbol{\mu}(\boldsymbol{\omega})]^\top \boldsymbol{\Sigma}^{-1}[\mathbf{Y} - \boldsymbol{\mu}(\boldsymbol{\omega})].$$

To select an adequate matrix $\mathbf{A}$ we can use the methodology proposed by Zhu et al (2007). In effect, the score function for $\boldsymbol{\omega}$ in the perturbed log-likelihood function (2.1.1) is given by

$$\mathbf{U}(\boldsymbol{\omega}) = \frac{\partial \mathcal{L}(\boldsymbol{\theta}|\boldsymbol{\omega})}{\partial \boldsymbol{\omega}} = \mathbf{A}^\top \boldsymbol{\Sigma}^{-1}[\mathbf{Y} - \boldsymbol{\mu}(\boldsymbol{\omega})].$$

Let $\mathbf{G}(\boldsymbol{\omega}) = E_\omega[\mathbf{U}(\boldsymbol{\omega})\mathbf{U}^\top(\boldsymbol{\omega})] = \text{diag}[\mathbf{g}_{11}(\boldsymbol{\omega}_1), \ldots, \mathbf{g}_{nn}(\boldsymbol{\omega}_n)]$ be the Fisher information matrix with respect to the perturbation vector $\boldsymbol{\omega}$. A perturbation $\boldsymbol{\omega}$ is appropriate if it satisfies $\mathbf{g}_{jj}(\boldsymbol{\omega}_0) = c\mathbf{I}_n$, where $c > 0$. In our case, we have $\mathbf{g}_{jj}(\boldsymbol{\omega}_0) = c\mathbf{A}^\top \boldsymbol{\Sigma}^{-1}\mathbf{A}$, with $c = 1$. Notice that usually $\mathbf{A}^\top \boldsymbol{\Sigma}^{-1}\mathbf{A} \neq \mathbf{I}_n$. However if $\mathbf{A} = \boldsymbol{\Sigma}^{1/2}$, then $\mathbf{g}_{jj}(\boldsymbol{\omega}_0) = c\mathbf{I}_n$ and so $\boldsymbol{\mu}(\boldsymbol{\omega}) = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\Sigma}^{1/2}\boldsymbol{\omega}$ is a perturbation scheme appropriate, as shown in De Bastiani et al (2015).
Considering the appropriated perturbation scheme for the response variable, where Δ_β is an $p \times n$ matrix and Δ_ϕ is an $3 \times n$ matrix given by

$$\Delta_\beta = \frac{\partial^2 \mathcal{L}(\boldsymbol{\theta}|\boldsymbol{\omega})}{\partial \boldsymbol{\beta} \partial \boldsymbol{\omega}^\top} = -\mathbf{X}^\top \hat{\boldsymbol{\Sigma}}^{-1/2} \quad \text{and}$$

$$\Delta_\phi = \frac{\partial^2 \mathcal{L}(\boldsymbol{\theta}|\boldsymbol{\omega})}{\partial \boldsymbol{\phi} \partial \boldsymbol{\omega}^\top} = -\frac{\partial\, \text{vec}^\top(\boldsymbol{\Sigma})}{\partial \boldsymbol{\phi}} \text{vec}(\boldsymbol{\Sigma}^{-1} \otimes \boldsymbol{\Sigma}^{-1/2})\, \text{vec}(\epsilon \otimes \mathbf{1}^\top).$$

evaluated in $\boldsymbol{\omega} = \boldsymbol{\omega}_0$ and $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$, where $\hat{\epsilon} = (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}})$ and $\mathbf{1}$ is an $n \times 1$ vector of ones.

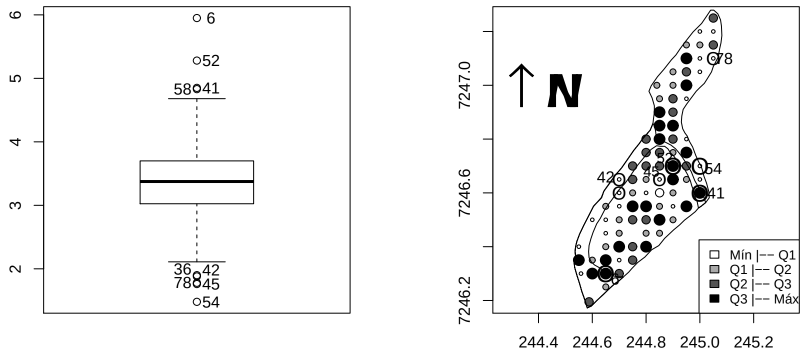
3 Results

The data were collected in 2003 in Cascavel city, south region of Brazil in an area of 22.63 hectares. The climate, according to Kppen is Cfa, temperate mesothermal and super humid. We analyze 84 element samples of two varieties of wheat CD101 and CD103, corresponding to 4.46 ha and 18.17 ha, respectively, collected in a regular grid of $50 \times 50m$. The explanatory variables are: average plant height - `alt60` and average number of tillers - `perfilho60` in 60 days, spike length - `cespigas` and the wheat variety treated as a `dummy` variable (0 or 1). So, $\mathbf{Y}$ represents a vector 84×1.
Table 2 presents a descriptive analysis of the response variable `wheat`, wheat productivity, and the explanatory variables. The wheat productivity mean is $3.372\, t\ ha^{-1}$. The average plant height in 60 days varies from $13.40\, cm$ to $36.60\, cm$. The average number of tillers presents the greatest value for the variance coefficient, however it still can be considered homogeneous. The mean and median of the spike length are the same considering one decimal.

Table 2: Descriptive analysis of response and explanatory variables.

Variable	Min.	1st Quartil	Median	Mean	3rd Quartil	Max.	var. coef.
`wheat`	1.480	3.037	3.375	3.372	3.680	5.950	0.23
`alt60`	13.40	20.65	22.50	23.17	24.62	36.60	0.17
`perfilho60`	0.40	1.200	1.700	1.661	2.100	3.40	0.38
`cespigas`	5.00	6.10	6.45	6.47	6.80	7.90	0.09

Figure 1(a) presents the boxplot for wheat productivity where the observations 06, 36, 41, 42, 45, 52, 54, 58 and 78 are outliers with wheat productivity values of 5.95, 1.90, 4.85, 1.88, 1.76, 5.28, 1.48, 4.83 and $1.78\ t\,ha^{-1}$, respectively. The site of these observartions are highlighted in Figure 1(b).



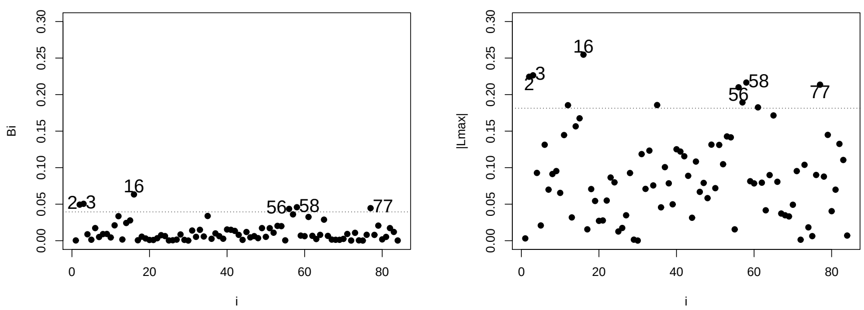
(a) (b)

Figure 1: (a) Boxplot and (b) postplot for wheat productivity samples in a regular grid, $50 \times 50\,m$.

We considered the Matérn family class to model the covariance matrix function. We considered values for ϕ_4 from 0.3 to ∞. According to the criteria LMV, Tr and CV, the choosen covariance matrix function is the value of $\phi_4 \to \infty$, which corresponds to the Gaussian covariance function. According to the likelihood ratio test, all the explanatory variables are significant at a level of 5%. The final choosen model (in parenthesis is given the corresponding asymptotic standard errors) is given by

$$\hat{\boldsymbol{\mu}}(\mathbf{s}_i) = \underset{(1.257)}{0.122}+ \underset{(0.266)}{0.354}\texttt{dummy}(\mathbf{s}_i)+ \underset{(0.024)}{0.069}\texttt{alt60}(\mathbf{s}_i)+ \underset{(0.142)}{0.078}\texttt{perfilho60}(\mathbf{s}_i)+ \underset{(0.146),}{0.188}\texttt{cespigas}(\mathbf{s}_i)$$

with spatial parameters estimates given by $\hat{\phi}_1 = 0.000(0.4058)$, $\hat{\phi}_2 = 0.548(0.4281)$ and, $\hat{\phi}_3 = 0.0349(0.0001)$. Figure 2 presents B_i versus index and $|L_{max}|$ versus index plots where observation #16 is detected as the most potential influent. Non of the observations pointed out where identified in the boxplot given in Figure 1(a).



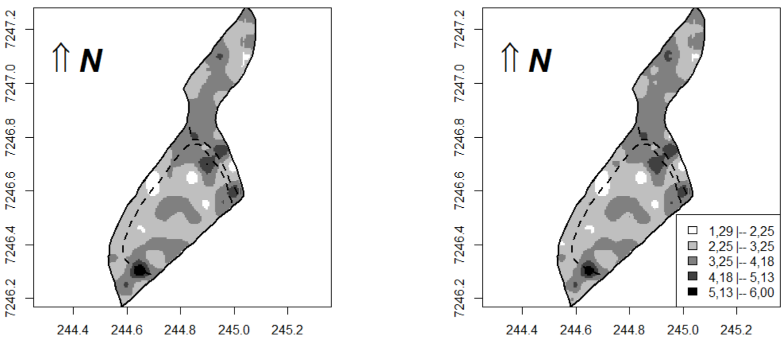
(a) B_i versus index (b) $|L_{max}|$ versus index

Figure 2: Local influence plots, (a) B_i versus index and (b) $|L_{max}|$ versus index considering the appropriate perturbation scheme.

We analized the data set without observation #16, and the chosen model for the covariance function remain the Gaussian one. The model is given by

$$\hat{\boldsymbol{\mu}}(\mathbf{s}_i) = \underset{(1.268)}{0.255}+ \underset{(0.276)}{0.307}\texttt{dummy}(\mathbf{s}_i)+ \underset{(0.024)}{0.070}\texttt{alt60}(\mathbf{s}_i)+ \underset{(0.151)}{0.083}\texttt{perfilho60}(\mathbf{s}_i)+ \underset{(0.146),}{0.175}\texttt{cespigas}(\mathbf{s}_i)$$

with spatial parameters estimates given by $\hat{\phi}_1 = 0.000(0.2323)$, $\hat{\phi}_2 = 0.560(0.278)$ and, $\hat{\phi}_3 = 0.040(0.0002)$. We can note a decrease on the estimate of the asymptotic standard error for $\hat{\phi}_2$.
Figure 3 shows the maps with all observations and without observation #16 where we can note a slightly difference between the maps in the north area. We have information to select the model considering all the observations as the final model.



(a) with all observations (b) without observation #16

Figure 3: Mean wheat productivity maps considering the model (a) with all observations (b) without observation #16.

Figure 3 shows the maps with all observations and the scenarios mentioned above. The maps constructed by kriging with external drift present well defined zones. Note: there is a slight difference between the maps in the northern area. A difference between the varieties CD101 and CD103 was also noted.

4 Conclusions

We proposed a measure based on the likelihood displacement to assess the stability of the likelihood function, using the perturbation on the response variable. We applied the methodology to a data set of wheat productivity collected in south region of Brazil. The spatial linear models enabled us to verify the spatial dependence between the wheat productivity data in the study area, according to the two varieties and plant attributes.
The maps constructed allowed us to estimate the wheat productivity in the study area, allowing us to create management zones with low or high productivity with the purpose of unifying similar areas, apply localized inputs and then maximize the the profit reducing the environment impact. It was observed the deletion of potential influential observations according to Zhu, caused changes in the parameters estimates that define the spatial dependence structure. Then, we have substantial information to select the final model considering all the observations.

ABSTRACT

Dairy is a key investment sector for the Government of Malawi. The strategies proposed to develop the sector have been three: (1) reinforcement of the formal supply chain (i.e., farmers delivering milk to milk bulking groups and these to processors, who pasteurise it and transformed into a number of dairy products); (2) generation of mini dairies (i.e., micro-processing of milk delivered to a milk bulking group); (3) selling directly raw milk to consumers. The purpose of this paper is to explore the aforementioned strategies in terms of the sector economic growth and food security. To study them a spatial multimarket model was constructed for the Malawian dairy sector using census data and milk collection data, which considers milk production in the three regions (North, Central and South), the different processors, consumers and the interaction with the informal market. The results from the simulation indicate that strategies (1) and (3) have more possibilities in terms outcomes than strategy (2). The paper also explores potential roles for the Government and donors.

Keywords: Dairy sector, Malawi, multimarket model.

1. Introduction

Dairy is a key investment sector for the Government of Malawi, and donors such Belgium, Japan, USA and the UK have also been committed to its development. Several value chain analyses (IMANI Consultants, 2004; CYE Consult, 2009; Kawonga et al, 2012; M-Livestock Consultants, 2013) have discussed strategies to improve the dairy sector performance and raise its contribution to poverty alleviation and food security. The strategies discussed by the aforementioned analyses have been three: (1) reinforcement of the formal supply chain (i.e., farmers delivering milk to milk bulking groups and these to processors, who pasteurise it and transformed into a number of dairy products); (2) generation of mini dairies (i.e., micro-processing of milk delivered to a milk bulking group); (3) selling of non-pasteurised of good quality milk directly to consumers.

The purpose of this paper is to explore the impact that the aforementioned strategies could have on the sector economic growth and food security. This is motivated by the fact that the three strategies may have different effects on the smallholder agriculture (more than 80 per cent of the dairy production in Malawi is in the hands of smallholder farmers) and they imply different roles for government policy and governance of the dairy sector. To study the aforementioned alternatives a spatial multimarket model was constructed for the Malawian dairy sector, which considers milk production in the three regions (North, Central and South), the different processors, consumers and the interaction with the informal market in each region. Multimarket models have a long tradition in partial equilibrium modelling and particularly in policy evaluation in agricultural sectors (Braverman and Hammer, 1986 and Sadoulet and De Janvry, 1995 for a review of models). They provide a way to represent the most important markets affected by a policy, leaving aside other markets where the effects of the policy would be negligible. An example of their use in an African dairy market can be found in Kaitibie et al. (2010), where it is used to study the effect of the policy change in the Kenyan dairy sector.

The results indicate that assumptions of strategies (1) and (2) may be flawed. Moreover, there is enough production of milk for the formal market to operate at full capacity; however, the major constraint is the demand for dairy domestic products given the low purchasing power of most of the population. Micro dairies suffer from two problems: first, efficiency in the pasteurisation of milk in comparison with processors, and second, the fact that they cannot offer higher prices to farmers (at least initially) because of they are concentrated on low value added products. Due to the latter, they cannot expand the supply of affordable of milk products for the population. Strategy (3), whilst has the potential of expanding the supply of low price milk to consumers, and therefore, improve food security, requires figuring out how to ensure that good quality milk is delivered to consumers.

The structure of the paper is as follows: it starts with the description of the multimarket model used to simulate the development strategies and the data. The next section presents and discusses the results of the model and the final section provides the conclusions.

2. A multimarket model of the dairy sector

Let us consider the following partial equilibrium model for the Malawian dairy sector. The starting point of the model is the production of milk, which to simplify will be considered to come either from the native zebu or from other breeds (these include exotic breeds or mixed breeds). Hence, the supply of milk from zebus (Y_i^Z) from region i, where i=North (N), Central (C), and South(S). The total production of milk from zebus is given by equation (1).

$$(1) \qquad Y_i^Z = y_i^Z \cdot V_i^Z$$

Where y_i^Z is the milk yield per zebu in region i and V_i^Z is the number of zebus in region i. It is assumed in the model that all the milk coming from the zebus is consumed in the farms (i.e., it is not marketed). Therefore, this is presented in equation (2):

$$(2) \qquad C_i^Z = Y_i^Z$$

Y_i^Z can therefore be considered as milk going/consumed to the informal market. The next step is to characterise the supply of milk produced by non-zebu cows (Y_i^{NZ}). This is given by equation (3), which is analogous to equation (1).

$$(3) \qquad Y_i^{NZ} = y_i^{NZ} \cdot V_i^{NZ} = y_i^{NZ}\left(P^N, P_I^N, W^F\right) \cdot V_i^{NZ}$$

Where y_i^{NZ} is the milk yield per non-zebu cow in region i and V_i^Z is the number of non-zebus cows in region i. It is hypothesised that the yields are a function of the average price paid by the i MBGs (P^i), the price paid by the informal market in region i (P_I^i), and the price of inputs (W^F). The number of non-zebu cows is assumes to be exogenous, as in the past it has depended on donors, Government policy or the pass on programme.

In the Northern region it will be assume that all the milk from non-zebus will go to the milk bulking group (MDFA) (B_N), i.e., (4):

$$(4) \qquad B_N = \phi_N \cdot Y_N^{NZ} = \phi_N\left(P^N, P_I^N\right) \cdot Y_N^{NZ}$$

Where ϕ_N is the proportion of the production of milk from non-zebus in the North, which is a function that depends on P^i and P_I^N. Note that $\phi_N < 1$ because the remaining part goes to the informal market. All the milk collected in the North and pasteurised by MDFA is assumed to be sold within the region. This is given by (5):

$$(5) \qquad YP^{MDFA} = \alpha_{MDFA}\left(B_N\right)$$

Where α_{MDFA} is the proportion of the milk collected by the North milk bulking group for MDFA that is being pasteurised. It is expected that this proportion to be lower than 1 due to losses.

In the case of the Central region, the amount of milk that goes to the milk bulking groups which deliver to processor j (B_C^j) is given by (6):

$$(6) \qquad B_C^j = \phi_C^j \cdot Y_C^{NZ} = \phi_C^j\left(P_C^j, P_I^C\right) \cdot Y_C^{NZ}$$

Where ϕ_C^j is the proportion of the production of milk from non-zebus that goes to processor j in the Central region and j=Lilongwe Dairies (LD-1), Suncrest Creameries (SC-2), Dairibord Malawi (DM-3), Sable Farming (SF-4), MDI (MD-5). Similar nomenclature is used for the prices paid to farmers by processor j (i.e., P_C^j). Note that not all the ϕ's will be greater than zero as some of the dairy processors do not collect milk in the Central region. In addition, the sum of the ϕ's sums less than one, since part of the produced milk will find its way to the informal market. P_I^C is the price prevalent in the informal market.

The equation of the milk going to milk bulking groups in the South is similar to the Central region and given by (7):

$$(7) \qquad B_S^j = \phi_S^j \cdot Y_S^{NZ} = \phi_S^j\left(P_S^j, P_I^S\right) \cdot Y_S^{NZ}$$

The quantity of milk pasteurised by the processors (YP^j) is given by equation (8):

$$(8) \qquad YP^j = \alpha_j\left(B_C^j + B_S^j\right)$$

Where α_j is the proportion of the milk collected in MBGs for processor j that is being pasteurised. Note that α_j is lower than 1 because some of the milk is lost, and also the processors use part of the collected milk to other purposes (e.g., chambiko, liquid yoghurt, yoghurt, ice cream).

The total supply of pasteurised milk in region i (CP_i) is given by (9):

$$(9) \qquad CP_i = \sum_{j=1}^{J_i} s_i^j \cdot YP^j$$

Where s_i^j is the share of the production of pasteurised milk from processor j that it marketed in region i, where J_i is the number of processors selling in region i. Finally, note that the total consumption/purchases of pasteurised milk, can be in some cases understood as residual demand, are given by equation (10):

$$(10) \qquad CP_i = C_i - CM_i - CI_i$$

Where C_i is the total consumption of milk in region i, CM_i is the total consumption of powder milk and CI_i is the total consumption of unpasteurised milk coming from the informal market. It is assumed in the model that whilst processors can sell in several regions, the informal market can only sell milk within its region. Note that the actual consumption of pasteurised milk depends on the retail price set for the product. This price, although suggested by processors, is ultimately set by retailers as shown in Akaichi et al. (2013). Therefore, the price paid by consumers, i.e., the retail price in region i, (P_i^R) is given by (11):

$$(11) \qquad P_i^R = P_i^{W,j} \cdot \left(1 + m_i^j\right)$$

Where m_i^j is the retail marketing margin set by retailers up over the basis of the prices proposed by processor j $P_i^{W,j}$. Given the above expressions, the total size of the informal market (I) is given by (11):

$$(12) \qquad I = \sum_{i=N}^{S} Y_i^Z + (1 - \phi_N) \cdot Y_N^{NZ} + \left(1 - \sum_{j=1}^{6} \phi_C^j\right) \cdot Y_C^{NZ} + \left(1 - \sum_{j=1}^{6} \phi_S^j\right) \cdot Y_S^{NZ}$$

The total milk marketed to the formal sector is equal to (13):

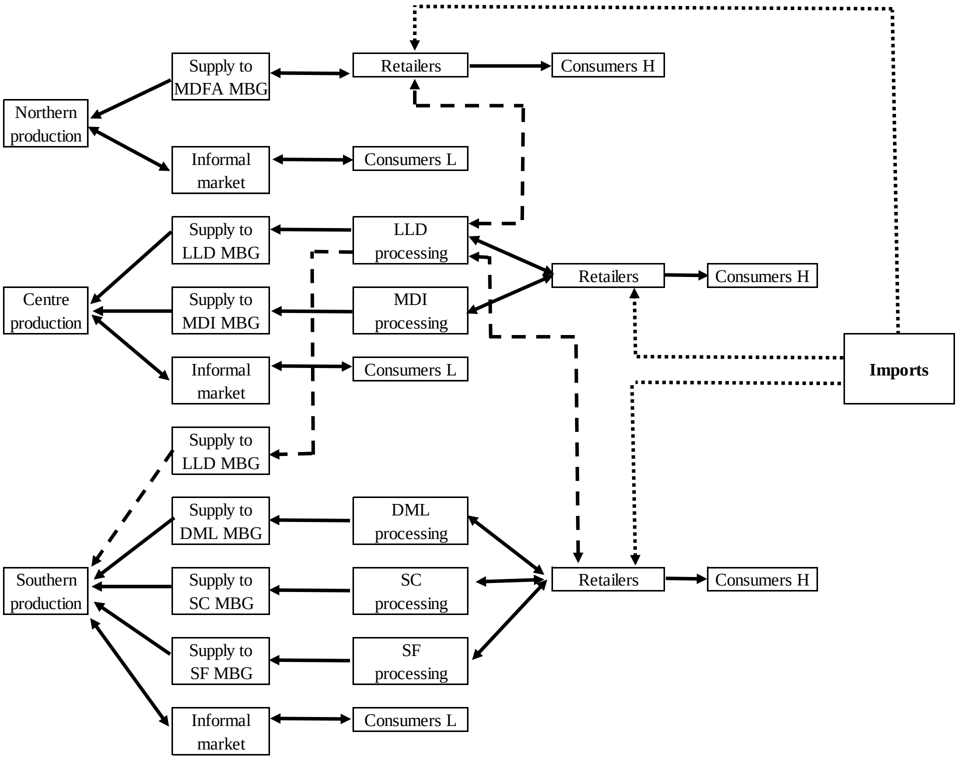
$$(13) \qquad M = \phi_N \cdot Y_N^{NZ} + \sum_{j=1}^{6} \phi_C^j \cdot Y_C^{NZ} + \sum_{j=1}^{6} \phi_S^j \cdot Y_S^{NZ}$$

Let us consider that the plant of capacity (i.e., engineering plant capacity) of processor j is equal to PC^j, then the observed idle capacity of processor j, as a ratio of the plant capacity, can be expressed as PC^j (13):

$$(14) \qquad IC^j = \frac{\left(\phi_C^j \cdot Y_C^{NZ} + \phi_S^j \cdot Y_S^{NZ}\right)}{PC^j}$$

The structure of the model presented in equations (1) to (14) is represented by Figure 1. Three features are important to highlight: The first one is related to the different types of consumers. These are those that demand milk of high quality (H), which comes from the formal sector (i.e., processors and retailers) and/or from imports; and those that consume raw milk from the informal market. The key difference between both groups is there income (i.e., their purchasing power is different). Moreover, given the country's poverty level, the group that demands milk type L is much larger than the one that demands milk type H.

Figure 1. Overall structure of the model



The second feature is that Lilongwe Dairies, which is the most important processor in terms of volume, processes milk in the Central region; however, it collects milk from the South and Central region and they sell their products all over the country (their operations outside the Central region are represented by dashed lines). The third feature is the fact that retailers' imports are destined to consumers who demand high quality, and therefore, imports compete with domestic processors products.

The data used for the model were compiled from a number of sources (Revoredo-Giha and Toma, 2016). The information on production, were from the livestock census carried out by the National Statistical Office of Malawi. The information was broken down by Zebus (meat purpose animals) and Non-zebus (dairy animals), which is the adding up of pure breeds and crosses. The distribution of the total milk produced was from the information provided by the Malawi Milk Producers Association (MMPA), the Central Milk Producers Association (CREMPA) and the Shire Highland Milk Producers Association (SHMPA) (South region).

3. Results and discussion

The full model was implemented in a MS Excel Workbook and solved and simulated with the aid of Visual Basic routines. The results are presented in Table 1, which considers the baseline result (2014 situation) and three discussed strategies/scenarios: strengthening the formal sector ("Formal market"); micro processing ("Micro dairies"); and selling directly raw milk ("Raw milk market"), which presented below:

Table 1: Results from the simulation

Summary of variables	Baseline 1/	Development strategies					
		Strategy (1) Formal market		Strategy (2) Micro dairies		Strategy (3) Raw milk market	
		Result	Change 2/	Result	Change 2/	Result	Change 2/
Total non-zebu production of milk (tonnes)

Average wholesale price (Kwachas/ltr) 5/							
North	194.0	200.8	3.5	213.4	10.0	--	--
Centre	181.7	199.1	9.6	206.0	13.4	--	--
South	200.3	220.7	10.2	272.6	36.1	219.8	9.7

Note:
1/ Corresponds to the 2014 situation.
2/ Change with respect the baseline.
3/ Raw milk comes from the informal market and is consumed in rural areas and by 80% of the urban population.
4/ In the case of strategies 2 MBGs operate as microprocessors and strategy 3 MBGs do not collect milk only check quality.
5/ Processors' price.

3.1 Strengthening the formal sector

The column "Formal market" in Table 1 presents the results for strengthening the formal sector. As shown in the Table, producers are encouraged to deliver more milk to the processors through higher prices. The milk collection increases by about 50 per cent.

The higher prices paid by processors not only increase the collection of milk by MBGs but also encourage a rise in the total production of milk in the three regions. Production in the South increases the most with respect to the baseline (14.1 per cent). This compensates the reallocation of milk from the informal to the formal market such that the milk destined to the informal market still grows.

The growing in the production of milk implies that the per capita consumption of raw milk and processed milk (from domestic origin) will increase (note that the high socioeconomic group in urban areas also consumes imported dairy products). In the case of the raw milk, this is due to the fact that surplus milk will go the informal market. Note that wholesale prices of processed products will increase due to the rise in the cost of the milk (processors are paying a higher price for it); however, it could be expected that not all of this cost will be passed to urban consumers (they make the demand for processors) due to the fact that the expansion of production will reduce the average fixed costs, which are currently high due to idle capacity. It is important to point out that under this scenario it being assumed that the additional production by processors will be sold at high prices (if not in the domestic market, probably abroad in the neighbour countries).

A potential role for Government and donors under this scenario is to improve the public infrastructure (e.g., roads, energy), which certainly would provide positive externalities and reduce the operational costs of the dairy processors. Although, not simulated, this could bring an expansion of the domestic dairy industry.

3.2 Micro processing

Under this scenario the mini dairies will compete with processors on the supplies of milk. As explained, all the farmers-managed MBGs are assumed to become micro dairies. It is important to note that under the assumption that they will only produce pasteurised milk (low value added product) these MBGs cannot afford to pay high prices to farmers for the raw milk. However, as they slightly increase the payments to farmers, there is a small rise in the milk collected by those MBGs (about 7 per cent).

The scenario also shows that processors increase substantively their collection from traders' MBGs due to their higher prices. This is needed due to the fact that otherwise they have an enormous increase in their idle capacity, which was estimated in 30 per cent in the baseline scenario. Nevertheless, as shown in Table 1, their collection is down due the loss of the farmers' MBG. This situation affects particularly Dairiboard Malawi, which depended to great extent of farmers' MBGs for their milk collection. It is highly probably that under this scenario, processors will decide not to produce anymore pasteurised milk and they just concentrate on products with more value added. This (and also the fact that the change in situation will increase their costs) is expressed on the rise in their wholesale price. In the medium term, there is the possibility that processors will expand the number of MBGs under traders in order to capture more milk.

Under this scenario, it is expected that the consumption of the per capita milk will decrease in both the raw milk and the processed milk market. The decrease in the raw milk market is because the product micro dairies is pasteurised milk, which is more expensive than raw milk and can only be afforded by the more affluent group. It should be mentioned although it is not capture in the model that there is the implicit assumption that the micro dairies will successfully make the transition from collecting milk to processing and marketing it. This is a very important assumption as experience shows in the case of the Bumbwe cooperative, which stopped operating in 2012 due to low margins, management problems and the inability to satisfy food safety standards (M-livestock consultants, 2013). For this scenario to succeed Government and donors will require significant investment not only on the facilities but also on training (including business management) to ensure the sustainability of the enterprise.

3.3 Selling directly raw milk

The results of this scenario show that farmers' MBGs will stop collecting milk but will be in charge of controlling milk quality, whilst traders' MBGs will continue supplying processors. In this sense, the scenario has commonalities with the micro dairies scenarios. Under this scenario, farmers would be selling directly raw milk avoiding the cost of pasteurising (milk will be boiled by households). Urban households, who can afford it, will probably substitute pasteurised milk by imported dried milk and the remaining of the urban population will consume raw milk.

Processors are under this scenario to focus on dairy products with greater value added, which as in the previous scenario will increase wholesale prices. Furthermore, as show in Table 1, milk collection for processors will concentrate in the South of the country (assuming that in the short term no additional MBGs in the hands of traders are established). Due to the fact that the prices for selling milk are lower it is expect that the aggregated production of milk will decrease, except in the South, where could be expect to remain at similar levels as in the baseline. Note that prices paid to farmers in the South are higher because processors will concentrate their milk collection there at high prices. In addition, under this scenario the amount of milk sold raw increases, and therefore, the per capita consumption of milk of poor urban and rural population will also rise; whilst the per capita consumption of processed milk from domestic origin will decrease. This scenario shows a trade off between economic growth (via production of greater value added) and production destined to massive consumption (food security).

A role for the Government and donors under this scenario is to create the conditions to ensure that the quality of the milk that is sold is good and safe. Given the potential size of the informal market, this could be a laborious and expensive task. The lessons from the Kenyan process will be important under this strategy.

4. Conclusions

The results from the simulation indicate under the first scenario that if processors are able to increase the prices paid to farmers in order to expand their milk collection, it is possible to expand both the amount of milk going to processed products together with the sales of raw milk (this is due to the fact that milk production reacts to prices). Under this conditions, market prices of dairy products (i.e., wholesale prices) are expected to increase due to the higher milk prices paid by processors but probably not as much as the increase in milk prices due to the reduction in processors' average fixed costs (i.e., due to the fact that there is a reduction in their idle capacity). The increase in the milk prices paid by processors is expected to raise the price of milk in the informal market (if the former is a reference or indicator for the latter) and therefore make milk less affordable in the informal market.

Under the second scenario, micro dairies, the situation indicates that production will remain basically the same except than in South due to the higher price paid by processors to traders' MBG to collect more milk. Micro dairies, which are an aspiration for farmers' MBG, will in the short term only be able to produce pasteurised milk, which has low value added and therefore pay farmers a low price for their milk. This will imply that production in the North and Central regions, will in the best case situation, remain the same (assuming that the micro dairies operate properly, which might be given past experiences, not very probable) and showing growth in the South.

The third scenario, allowing the selling of raw milk, it is similar to the second scenario, the difference is that farmers' MBG will only have the role of supervising the quality of milk; therefore, the price paid of raw milk will expected to be lower. Due to this, the production of milk might be expected to decrease in the North and Central regions and increase in the South. The amount of raw milk consumed is, as expected, found to increase. The scenario will therefore imply a substitution of pasteurised milk for raw milk at lower prices. This could improve food security of those consuming raw milk.

Overall, what strategy should Malawi follow in terms of dairy development? The results from the exercise indicate that either the development of the formal sector or the following the Kenyan approach have possibilities, since micro dairies would require a potential high investment and will bring a very uncertain outcome. It is important to note that given the size of the informal market, selling directly raw milk to consumers is an option that it is already present. This means that the current situation is something in between the first and the third scenario. In this context, probably the role of the Government and donors should be to ensure that the raw milk that it is sold in the informal market it is of good quality and the formal dairy sector benefit with improvement of infrastructure (particularly roads and electricity power), which will reduce their costs.

ABSTRACT

Spatial interactions are essential drivers of price transmission mechanisms and may significantly affect any food policy's outcomes. However, spatial aspects seem to be generally overlooked when analyzing price transmission. This paper attempts to fill this gap by highlighting the usefulness of spatial interaction and models for market integration analysis. A Spatial Dynamic Panel Data model is presented and applied to Niger's millet market. Empirical results show that (1) the millet market is partly integrated, (2) locally traded commodities (millet and sorghum) are linked by a cross-commodity price transmission, (3) most imported cereals prices, which for Niger is maize and rice, did not affect the millet market, and (4) no cross-regions price transmission occurred for the millet market.

Keywords: Spatial econometrics, panel data, agricultural commodities, market integration, Niger.

1. Introduction

In recent years, agricultural products have undergone huge price variation in international markets. Such variation in world markets is not without effect on local markets. The extent of these shocks vary across countries as some are more dependent on international markets than others. A number of factors determine the degree of price transmission in a country, such as trade flows, transactions costs, trade policies, availability of price information across markets, and installed infrastructures. For example, if domestic products dominate the local markets, price transmission will be less severe than in markets where foreign goods dominate local goods. In addition,

[1]A.goundan@cgiar.org
[2]M.tankari@cgiar.org

transaction costs (transport, margins, risk premium, cost of information), distance, quality of infrastructure and trade barriers reduce price transmission by limiting trade flows.

Price transmission analysis measures how well different spatially separated markets are connected. If markets are perfectly integrated, price signals are transmitted from a selected location to other locations. This implies a price adjustment in response to existing excess supply and demand conditions in other locations of the integrated area.There is extensive theoretical and applied research on the mechanisms of price transmission. As applied studies often focus on policy implications, a large portion of the literature deals with methodological improvements in the fields of price transmission analysis. Therefore, various approaches can be found in the literature. The first studies began using correlation coefficients of prices to test market integration between spatially separated markets (Jones, 1972). Other research employed regression based models (Monke and Petzel, 1984), or time-series analysis techniques such as dynamic regression (Ravallion 1986)and cointegration analysis (Baulch 1997). Furthermore, a number of studies have proposed nonlinear approaches (Meyer and Cramon-Taubadel 2004, Greb et al. 2013).The common feature of these approaches is that they are mainly based on time-series analysis.

Since price transmission occurs between different locations, it is essential to include spatial interactions in price transmission models. The failure to take this fact into account may bias the results of an analysis. For example, Lesage (1999) stated that, due to spatial dependence and heterogeneity, Gauss-Markov assumption is violated. Spatial econometrics that successfully model those issues and draw appropriate inferences is a straightforward solution for price transmission analysis. Unfortunately, this tool seems to be rarely used in price transmission analysis. To the best of our knowledge, Keller and Shiue (2007) presented the only research that used the spatial econometric approach to study market integration for China’s rice market.

Spatial features are accordingly important as they influence the degree of market integration. In addition,the price dynamic in a given location is influenced by its neighboring prices (Keller and Shiue 2007).LeSage and Pace (2009) pointed out five reasons to include spatial features (spatial autoregression) in a regression model: (a) a time-dependence motivation; (b) an omitted variables motivation; (c) a spatial heterogeneity motivation; (d) an externalities-based motivation; and (e) a model uncertainty motivation. Interestingly, these motivations are relevant in market integration analysis.Therefore, the main aim of this paper is to add to the literature by highlighting the usefulness of the spatial econometrics approach for price transmission analysis.

The remainder of this paper continues as follows. Section 2 presents the dynamic spatial panel framework. Section 3 provides the results of the application of the proposed frameworkto millet market in Niger. The final section is devoted to conclusion and policy implications.

3. Methodological framework

An appealing spatial econometrics models for price transmission analysis is the Spatial Dynamic Panel Data (SDPD) model proposed by Lee and Yu (2010). This framework allow three types of interactions in price transmission. First, temporal dependency is taking into account. Previous price is allowed to affect the following period price level in a specific location. This is particularly what time series modeling do. Second, endogenous interaction effects is also integrated. The price level in a specific location is assumed to be impacted by adjacent locations price level. This is an interesting characteristic of our framework since separated markets are connected through trade flows and price information. Third, exogenous interaction effects is also integrated. While exogenous variables are present in the price transmission model, our framework is able to account for the observed exogenous variables in adjacent locations.

Let Y_t^k be the vector of price for *N* locations at time *t* for commodity *k* and X_t stand for exogenous variables, which could be the price of other products or weather variables. The SDPD setup is:

$$\boldsymbol{y}_t^k = \tau \boldsymbol{y}_{t-1}^k + \rho \boldsymbol{W} \boldsymbol{y}_t^k + \eta \boldsymbol{W} \boldsymbol{y}_{t-1}^k + \boldsymbol{x}_t \theta + \boldsymbol{W} \boldsymbol{x}_t \beta + \boldsymbol{\mu} + \alpha_t \boldsymbol{l}_N + \boldsymbol{v}_t (1)$$

This model is known as a dynamic spatial Durbin model (Debarsy et al., 2012). $\boldsymbol{\mu}$is a vector spatial fixed effects, α_t stands for time fixed effects, while $\boldsymbol{l}_N$ is a vector of ones. $\boldsymbol{W}\boldsymbol{x}_t$is the exogenous interaction effects term, $\boldsymbol{y}_{t-1}^k$ is the lagged of the dependent variable in time, $\boldsymbol{W}\boldsymbol{y}_t^k$ represents the contemporaneous endogenous interaction effects, $\boldsymbol{W}\boldsymbol{y}_{t-1}^k$ is the lagged endogenous interaction effects.

Based on the proprieties of model 1, it can be classified into three different cases depending on the value of $\boldsymbol{\tau} + \boldsymbol{\rho} + \boldsymbol{n}$. According to Lee and Yu (2010), model 1 is stable if this value is less than one, cointegrated if it equals one and explosive otherwise. To estimate model 1, we followed Yu et al. (2008), Lee and Yu (2010), and Yu et al. (2012), who used a bias-corrected quasi-maximum likelihood (BC-QML) estimator. This method produces consistent parameter estimates when the model is stable. However, when this stability condition is not satisfied, a data transformation is needed to consistently estimate model 1 using BC-QML. In fact, when the stability condition is not satisfied, Lee and Yu (2010) and Yu et al. (2012) proposed the spatial first-difference transformation of model 1 using the matrix (**I-W**) where **I** denotes the N x N identity matrix. See Elhorst (2014) for more details.

To interpret the effect of a change in an explanatory variable in this SDPD framework, one has to compute the reduced form of (1), which is presented

$$\boldsymbol{y_t} = [(\boldsymbol{I} - \boldsymbol{\rho W})^{-\boldsymbol{1}}(\boldsymbol{\tau I} + \boldsymbol{\eta W})]\boldsymbol{y_{t-1}} + (\boldsymbol{I} - \boldsymbol{\rho W})^{-\boldsymbol{1}}[\boldsymbol{x_t \theta} + \boldsymbol{W x_t \beta})] + (\boldsymbol{I} - \boldsymbol{\rho W})^{-\boldsymbol{1}}[\boldsymbol{\mu l_N} + \boldsymbol{\alpha_t l_n} + \boldsymbol{v_t}] \quad (2)$$

The short-term impacts of a change in a specific explanatory variable $\boldsymbol{x_i}$(or the lagged endogenous variable) on the dependent variable can be computed as:

$$\frac{\partial \boldsymbol{y}}{\partial \boldsymbol{x}_i} = [(\boldsymbol{I} - \rho \boldsymbol{W})^{-1}(\boldsymbol{x}_i \theta + \boldsymbol{W} \boldsymbol{x}_i \beta) \quad (3)$$

$$\left.\frac{\partial \boldsymbol{y}}{\partial \boldsymbol{y}_{t-1}}\right] = [(\boldsymbol{I} - \rho \boldsymbol{W})^{-1}(\tau \boldsymbol{I} + \boldsymbol{\eta W})] \quad (4)$$

The results of (4) are named the convergence effects (impact of the lagged endogenous variables). These partial derivatives (3) and (4)are*N*x*N*matrixes. As noticed in Debarsy et al. (2012), diagonal elements of equation (3) are different for each cross section, and off-diagonal elements differ from zero and the matrix is nonsymmetric. This model is richer than the traditional linear model. The average of diagonal elements represent own-partial derivatives (called direct effects), meaning the impactof a change in the selected explanatory variable in location *i*on the dependentvariable in this location.The average of the off-diagonal elements (cross-derivative elements) of (3)-(4) is thus labeled indirect effects and showsthe response of the dependent variable in location*i* to a change in explanatoryvariables in any of the other locations.

In price transmission framework, direct effects of (4) gives the extent of price transmission across years in the same region. It is to say how a price change for a selected market (millet, rice

…) in a location affects futureprices for this market in this location. The indirect effects of (4) shows the response of price in a region to a previous price change in any of the other regions. Therefore, price transmission analysis in our framework helps to know if a price shock originated from one location is transmitted only inside this location or to neighboring locations. Thus,price transmission has two components: intra-region price transmission and cross-regions price transmission. When price of substitute commodities were used as explanatory variables, a cross-region and cross-commodities price transmission can be examined. Such situation is examined in this study, which analyzed millet's market integration accounting for sorghum, maize and rice prices. One issue here is that these price series are clearly endogenous. The price of sorghum may affect the price of millet and vice-versa or both prices may be affected by unobserved factors.In this paper, we addressed this issue byusing the average of m[3] previous observations of the prices of sorghum, maize and rice.

4. Millet's market price transmission in Niger

In this section, the SDPD model was applied to analyze price transmission on cereals market in the eight regions of Niger (Agadez, Diffa, Dosso, Maradi, Niamey, Tahoua, Tillaberi and Zinder), with a special focus on millet, which is the most consumed cereal (food) in Niger (FAO, 2009). The attention paid to the millet market is justified because this cereal represents 78 percent of cereals consumption and 62 percent of food consumption in Niger (FAO, 2009). In addition, the millet consumed in Niger is totally produced locally (USDA, 2016). According to USDA database, around 2 percent of sorghum consumption are from imports, while maize and rice's consumption depend mainly on imports with more than 80 percent of demand satisfied by imports.

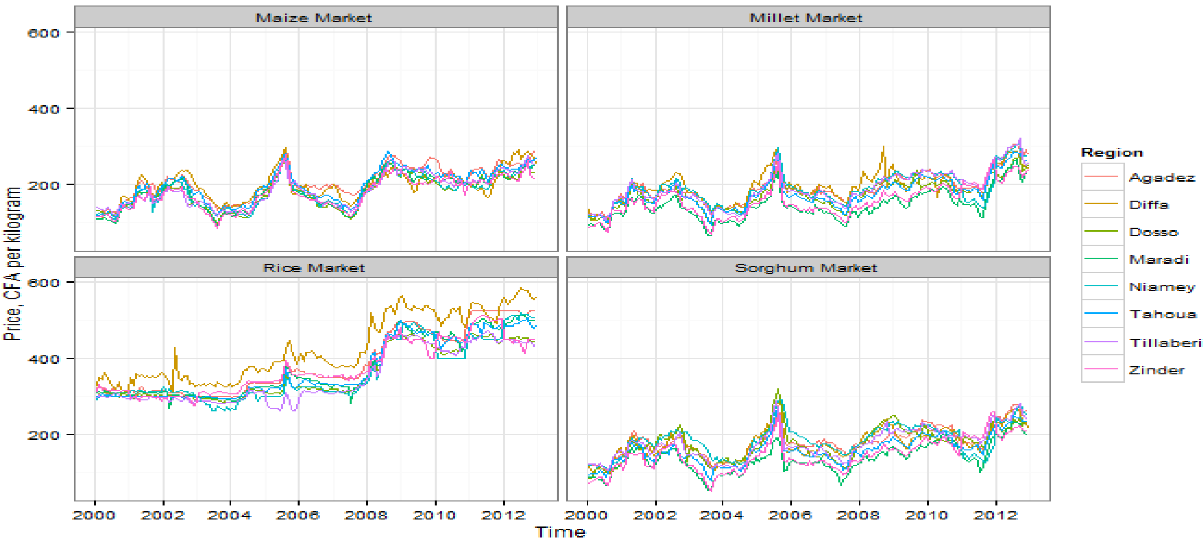

Figure4.1*Trends in Niger cereals prices, 2000–2012*

Source: SIMA, 2013

[3]We also used the average of the three, four, and five previous months

Price series used in this study were provided by the Niger's System of Agricultural Market Information (SIMA). Established in 1989, SIMA is a specialized service of the government of Niger, which is operated by the Ministry of Trade and Private Sector Promotion. The main mission of SIMA is to collect, process, and disseminate information about agricultural markets for better decision making by policy makers. Prices used here concerned monthly retailer prices over 2000-2012 (per kg price level in local currency, CFA) for the main cereals consumed in Niger, namely millet, sorghum, maize and rice. The dynamics of various cereals prices considered are depicted in Figure 4.1.

Table 4.1 presents the results of price transmission analysis on Niger's millet market when accounting for other cereal prices. The results, as stated in the table's heading, are related to the spatial first-difference of model (1) since the latter is found unstable. Due to space constraints, we don't present nor discuss the results of the direct estimation of model (1) here. For these details and others, the interested reader is referred to the *Discussion Paper* version of this study (Goundan and Tankari, 2016).

Column (1) of Table 4.1 reports the estimation results of the spatial first-difference of model (1), columns (2) to (4) show the results for the direct, indirect and total effects of explanatory variables as formulated in section 3. The t-statistics of the derived effects are obtained by carrying out a Monte Carlo simulation experiment over the estimated parameters.

Only four parameters over the nine estimated are significant (column 1). They are the first three parameters related to the endogenous variables and the one related to sorghum as own region's sorghum price observed at current period. The temporal lagged millet price seems to have a positive and significant correlation with its next period level (**0.68**). The second and third parameters correspond to cross-region millet price transmission. They are both significant with different signs. The contemporaneous millet price of adjacent locations has a positive impact (**0.28**) while its lagged term has a negative (**-0.23**).This fact may lead a neutral indirect effect (to be confirmed by results in columns 2 to 4). The last significant parameter equals **0.09,** which means sorghum price could have a positive direct effect on the millet price. Other parameters are not significantly different from zero. These results have to be confirmed by results in columns 2 to 4.

Note: The numbers in (.) are the asymptotic t-statistic.

The convergence effect, the effect due to the temporal or spatial lag of the dependent variable, here the millet price, showed a positive and significant direct effect (**0.68)** and a non-significantindirect effect. The direct convergence effect means that there is a price transmission over time of **68**percent for Niger millet market. An increase in the previous price of millet is transmitted to its current level for about 68 percent. This parameter is the price transmission elasticity of millet price from one period to the next. Since the indirect convergence effect is not significant, this 68 percent price transmission is only a region specific price transmission. There is no cross-regions price transmission in Niger millet market. Concerning the impact of the price of millet's substitute commodities (maize, sorghum, and rice), we found that a change in the price of maize or rice had no direct nor indirect impacts on the millet price. Conversely, an increase of the price of sorghum significantly increased the price of millet. In fact, the direct effect of sorghum price is significantly positive and equals **0.10.** This means that a change in the price of sorghum is transmitted to millet price for about 10 percent. This finding could be seen as evidence of the fact sorghum is a substitute for millet.

Two interesting findings are from these results. First, there is no cross-regions price transmission for millet market in Niger. This means that a price change in one location had likely no effect on price level in other locations. Many reasons could be given to explain such situation. Among them, we found (1) high transportation cost, (2) malfunctioning transport service (lagged transmission), (3) imperfect substitution of goods, (4) lack of price information, and (5) installed infrastructures (Badiane and Shively 1998, Ghosh 2011, Rashid et al. 2008, Minot 2010). Even though each of these factors could explain the inexistence of price transmission across regions, transport-related factors and infrastructure would be the most important factors in Africa in general and Niger specifically. Limited road infrastructure is available in Africa. Therefore, transports costs are high compared to other regions of the world (Macchi and Raballand , 2009; Teravaninthorn and Rabelland, 2009). Due to a lack of adequate infrastructure, the transportation of commodities took too much time. This situation could constitute a caveat for price transmission since traders cannot access readily available price information.

Second, only sorghum, a locally produced and consumed cereal (less than 2% of imports), affects the price of millet. Maize and rice, which mainly depend on imports, have no impact on millet market. Even though each of the aforementioned cereals were natural substitutes, their availability on local markets and the associated prices would determine consumers' choices. Millet and sorghum, which are locally produced and consumed, are likely to be the first choices of the population. Results also confirmed that Niger's top cereal imports, rice and maize, are not substitutes for locally traded commodities such as millet and sorghum. In the local market, exception to rice, these cereals have similar prices and dynamics (Figure 4.1). Therefore, the inexistence of price transmission from maize to millet is likely due to availability and consumers behavior. For rice, this could be explained by the price gap—rice price is about 2 to 4 times the price of millet (SIMA, 2013)— and the fact that in many West African countries, rice is considered a luxury good, and is generally only consumed during special events (FAO, 2009).

5. Conclusion

Price transmission is an important research topic from a scientific and policy perspective. The recurring commodity price spikes, especially the recent food price crisis, have revived the debate on the issue of market integration and best policy response. Price transmission occurs from one period to another and between separate locations. This study is one of few that suggest the use of a dynamic spatial econometrics framework for the analysis of price transmission and thus the integration of markets. As an application, the SDPD model has been used to analyze the price transmission on the millet market. Our results revealed (i) a cross commodities price transmission between locally traded commodities (millet and sorghum), (ii) no significant price transmission between locally traded cereals (millet and sorghum) and regionally, or internationally traded cereals (rice and maize), and (iii) nosignificant spillover or diffusion effects (cross regions price transmission) for cereals market. These findings have some policy implications. Since absence of cross regions price transmission (market integration) is due to poor infrastructures and institutional facilities, government of Niger should strategically invest in appropriate infrastructures that will improve cereal markets integration. Millet and sorghum are essential for food security in Niger, and given the fact they are segmented from most imports cereals, it would be interesting for government to promote their production, which may be a good resilience strategy for consumers. In addition, storage facilities development can reduce their post-harvest losses and allow a better food availability in the country.

ABSTRACT

Mexico's staple crops such as corn, kidney bean, wheat and sorghum are present throughout the country, therefore, it is important to identify their distribution patterns and estimate their area every agricultural cycle. For that purpose, we identify the areas that concentrate 90% of the planted area per state, then, we select samples by means of statistical and environmental criteria. Along with the field work, we acquire satellite imagery. Before the classification process, it is necessary to apply geometric and radiometric corrections and identify the crop mask. Ground truth, obtained from the field work, serves to analyse spectral signatures, histograms and scatter plots of crops or other land cover. Maximum likelihood is the classification method used and, in order to improve the agricultural parcels geometry, a post-classification is applied. Prior to the publication of these results a Kappa analysis is implemented, the results accuracy is regularly above 85%. The general results show, for the agricultural year 2015, an estimation of 5 897 499 hectares for corn, 1 545 766 for kidney bean, 1 884 748 for sorghum and 810 840 hectares for wheat.

1. Introduction

Mexico’s population growth and the increase of foreign demand for agricultural productshave resulted in a biggerrequest of farmingresources for this country. So, the knowledge about the amount of production and its localization increases in relevancy. Because of this, to get timely and reliable information about the sown area for the crops of interest in favour of the agri-food security at a national scale becomes essential.

Remote Sensing (RS), Statistics, *Geographical Information Systems* (GIS) and *Global Positioning Systems* (GPS) provide accurate information about the elementsalong the Earth's surface. Through RS, information about the land cover can be achieved without being in direct contact with it (Chuvieco, 1995). Statistics provides sampling methods applied to the natural communities, GIS processes contribute with the data analysis and output generation (Gómez y Barredo, 2005) and using the GPS technology, any object can be geographically located.

Traditionally, agricultural surfaces were estimated using methods which didn't include precision parameters. Nowadays, they are obtained through the *Area Frame Method*, where sown areas can be estimated using statistical sampling and RS (Ambrosio y Alonso, 1993; Gallego, 1995).Since the 90's decade, in Mexico, it has being planned to get the farming statistics through anAreaFrame, agricultural stratum collection and use of RS. In 2004, collegiate organizations of the *Ministry forAgriculture, Livestock, Rural Development, Fishery and Food Supply* (SAGARPA because of its name in Spanish) launched the *National Surface, Production and Efficiency Estimation Plan*, and, based on this, the *Agri-food and Fishery Information Service* (SIAP, because of its name in Spanish) adopted, in 2007, part of the European Union's *Monitoring Agriculture with Remote Sensing* (MARS) method, to generate the geo-referenced crop areas.

The MARS methodstates a sampling strategy for the evaluation. It is a stratified random area sampling, in which (i) the sampling frame is part of the territory, supported by topographical maps, (ii) the sampling unitsare 700 meters long per side squares and (iii) the stratification criteria is the land use, considering from 6 to 10 stratum or land use types (Gallego y Delince, 1991a in Deppe, 1998). The relative accuracy of this method has being estimated as 1.53 for wheat and 1.31 for barley. For the rest of the principal crops, accuracy has resulted similar (Gallego y Delince, 1991b in Deppe, 1998).

Mexican variety of ecosystems causes a heterogeneous agricultural development. Because of this, the method to estimate the crop surface has being adjusted through RS, considering the MARS method principles (Gallego, 1995). Specifically, SPOT sensor imagery is used, which has being used for diversepurposes (Valdez, González y De los Santos, 2006; Aguilar et al, 2012).

Considering all of these, we have set the objective of estimating, at national level, the area for crops of interest through Remote Sensing.

2. Method

Figure 1presents a general overview ofthis method. It consists of the following stages: sampling design, fieldwork, satellite images acquisition, digital image processing and supervised classification. It was performed for thetwoagricultural cycles considered in México: spring-summer (PV because of its name in Spanish; from April to October) and autumn-winter (OI because of its name in Spanish; from November to March).

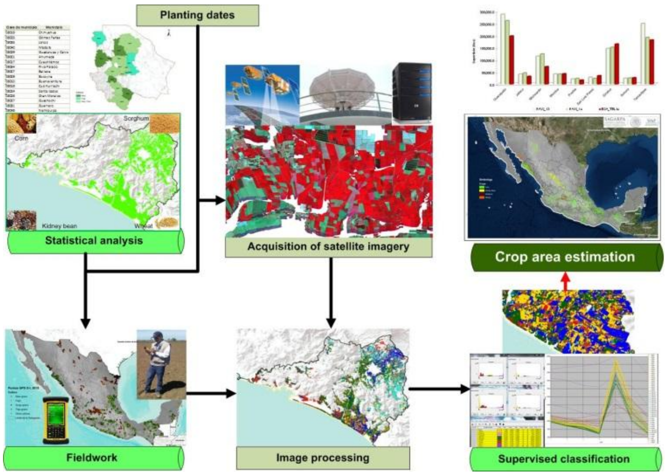

Figure 1: *General overview of the method*

2.1 Sampling Design

The sampling universe was the list of municipalities (4,475) in the Web Agriculture and Livestock Network (RAW, because of its name in Spanish) database. It contains information at national, state and municipality level about sowing and harvesting progress corresponding to both cycles, for irrigation and seasonal regimes. Specifically, the reported information for 2014 was used.

The sampling method is targeted, stratified by conglomerate in a single stage and systematized with a distribution proportional to the whole of the sowed surface for each conglomerate. It is targeted because the information is obtained in sampling units which the field technician assumes as representative. It is stratified by the land use and crop type; and it is conglomerated by the geographical location of each federal entity. It is considered as in one stage because the primary sampling unit for each conglomerate is the municipality, and the sampling unit is a geographical point registered inside an area sowed of the crop of interest. It is systematized because the basic units are organized from most to less sowed surface, so the bigger amount of the sampling units will be placed where most of the sowed surface is located, in a proportional distribution.

2.2 Sampling Selection and Calculation

For each strata (corn, kidney bean, sorghum and wheat) and federal entity, the municipalities which together represent 90% of the sowed surface, are selected. The sampling space for each municipality considered 3% of the sowed surface. The MARS method (Gallego, 1995) was modified as a response to the specific heterogeneity and crop diversity conditions and the available resources. The number of sampling points was determined with the following formula:

$$n = \frac{Z^2 pqN}{(N-1)\varepsilon^2 + Z^2 pq} \tag{1}$$

Where

n= Number of points.
Z= Confidence level (90%).
p= Positive variability (90%).
q=Negative variability (10%).
N= Population size.
ε= Accuracy error (15%)

2.3 Fieldwork

22,573 GPS points were considered for the 2015 exercise, being 17,805 for the PV cycle and 4,768 for the OI cycle. Table 1 presents their distribution.

Table 1:*Stratified samplingdistribution*

Cycle	Corn		Kidney Bean		Sorghum		Wheat	
	Surface (ha)	Points	Surface (ha)	Points	Surface (ha)	Points	Surface (ha)	Points
PV	172,232	11,855	39,564	3,317	24,651	1,989	2,625	644
OI	30,673	2,435	5,584	1,007	22,676	569	19,430	757
Total	202,905	14,290	45,148	4,324	47,327	2,558	22,055	1,401

Once the number of samples was defined for each crop and municipality, the sowing dates are consulted. Considering this, field work and the acquisition of satellite images are scheduled, which is planned to be when crops are in flowering and fruiting(Fernandez, Gepts y López, 1986).

Each GPS point should be 50 m inside the plot, being each one about 1 km far from the nearest. Each plot should be at least 0.5 ha big. The information collected at each pointwas: crop, crop's height (in meters), approximated property's surface, phenological stage, variety, water regime, percentage of ground covered by the crop, weed percentage, sinister, north, south east and west bordering crops, and 2 geo-referenced pictures.Besides local particularities, from July to September, for the PV cycle; and from January to March, for the OI cycle, have resulted the adequate months for the fieldwork.

2.4 Satellite Image Acquisition

Considering the sowing dates, the satellite image acquisition is requested to the *Mexico Receiving Station* (ERMEX because of its name in Spanish), which is the Mexican facility for the management of the SPOT images. For this study, they should be ortho-rectified, a maximum cloud cover of 10% and an incidence angle range of 20° to 25°.In the PV cycle, there were used 1,475 images, and in the OI cycle 1,064 images were used.

2.5 Digital Images Processing

In order to perform the supervised classification, the digital levels (DL) of the image should be expressed in reflectance values. For this, a radiometric correction should be performed.

As long as the surface estimation should be focused on the agricultural area, the satellite images were cut with the geographical delimitation of said areas, which SIAP has available (Figure 2).

a) b)

Figure 2: *Satellite image before (a) and after (b) cutting of non-agricultural areas*

2.6 Supervised Classification

A supervised classification is performed to the satellite images, supported by the fieldwork, to get the above stated classes, including the “other coverings” one (other crops, highways, roads, canals and water bodies). The band configuration to make this identification is false color, which is obtained by placing the near infra-red, red and green bands in the red, green and blue order, which is the 4,3,2 combination for SPOT 6/7. These bands are chosen because they have the greater original variance content (Chuvieco, 1995).

The training phase is fundamental in the supervised classification. In it, several factors should be considered, since they influence in the reflectance for each selected band. For example, this can result in a category expressed in several spectral classes, two or more categories expressed in a single spectral class, or several categories expressed in several classes. For each training field, homogeneous samples or variable surfaces for the same category are sampled. Each one of these should be composed of a number of pixels between 10m and 100 m for each category (Jensen, 1986& Mather, 1987 in Chuvieco, 1995), considering the physical variations of the Earth surface.

These variations are evaluated through a spectral signature and a separability analysis. The advantage of the spectral signature analysis is to highlight the pixels that belong to a certain category, according to the parallelepiped decision rule. Meanwhile, the separability analysis calculates the statistical distance between signatures, which can be used to determine the best group of elements that will be used in the classification.

In the assignation phase, using the maximum likelihood method each element is assigned to a category assuming it has a normal distribution. Considering this, knowing the mean and standard deviation for each category, the probability of association to it can be estimated. The post classification process consists in a generalization according to the variability of the categories, according the neighbor ones and, if applicable,integrates them. When there are isolated pixels, they are assigned to the dominant category. Also, when a pixel is smaller than 0.25 ha, it is assigned to the neighbor category.

To evaluate the classification, 3% of the field samples are used in a confusion matrix, which expresses the conflicts between classes. Due to its configuration, it can be identified what was correctly classified according to what was sampled in the fieldwork, and mistakes of classifying what is not present in field or elements in reality which are not represented in the classification. The proportion of the correctly classified points and the overall is the reliability of the map (Chuvieco, 1995).

3. Results

In the 2015 exercise, geo-referenced information was sampled for 25,392 plots, being 18,157 for the PV cycle and 7,235 for the OI cycle (Table 2).

Table 2: *Plots sampled during 2015*

Cycle	Corn	Kidney Bean	Sorghum	Wheat
PV	12,690	2,528	2,511	428
OI	3,450	807	1,020	1,958
Total	16,140	3,335	3,531	2,386

About the separability analysis, the "other crop", "forest", "soil" and "protected agriculture" are easily distinguished form the crops of interest. Separability between the crops of interest defines that it is easily identifiable from sorghum, sorghum from wheat and kidney bean from sorghum. In order to validate the sowed surface for the crops of interest, 3% of the points of each one were used. They were 2% more than those stated by Congalton (1988b) in Chuvieco (1995).

Based on the fieldwork information, agriculture coverage, satellite images and these processed, the spatial distribution of the sowed surface of the crops of interest is presented. Specifically about the PV cycle, corn is present almost in all the agricultural area of the country, principally in the Transversal Volcanic System, meanwhile kidney bean has is more present in Zacatecas and Durango, and sorghum and wheat are dominant principally in Tamaulipas, Sinaloa and Guanajuato.

This evaluation assigned correctly 484 of 542 GPS points (Table 3). Corn and sorghum were confused, because in their development stage they have a similar spectral behavior. Also corn and kidney bean were confused, that is because, especially in the central and southern part of the country, they are sowed associated. Other factor that affect is the continuous presence of clouds. The overall reliability of this cycle is of 89.3%

Table 3: *Confusion matrix for the PV cycle*

	Map class	Corn	Kidney bean	Sorghum	Wheat	Total	User's accuracy	Commission error
Field class	Corn	366.0	21.0	9	0	396.0	92.4	7.6
	Kidney bean	4.0	50.0	0	1	55.0	90.9	9.1
	Sorghum	15.0	3	61.0		79.0	77.2	22.8
	Wheat	3	2	0.0	7.0	12.0	58.3	41.7
	Total	388.0	76.0	70.0	8.0	**542.0**		
	Producer's accuracy	94.3	65.8	87.1	87.5			
	Omission error	5.7	34.2	12.9	12.5			

For the OI cycle, corn was located principally in Sinaloa, wheat in Sonora and Baja California, sorghum in Tamaulipas and kidney bean is relatively low in presence.

The classification for the OI cycle assigned correctly 201 GPS points of the 215 of the total (Table 4). As happened in the PV cycle, corn still presents confusion with kidney bean and sorghum. The reliability of this classification was of 93.5%. This is because most of the agriculture is of irrigation regime and also this classification has improved because there were fewer clouds in the images.

Table 4: *Confusion matrix for the OI cycle*

	Map class	Corn	Kidney bean	Sorghum	Wheat	Total	User's accuracy	Commission error
Field class	Corn	98.0	1.0	2	0	101.0	97.0	3.0
	Kidney bean	5.0	20.0	0	0	25.0	80.0	20.0
	Sorghum	3.0	0	30.0	2	35.0	85.7	14.3
	Wheat	0	1	0.0	53.0	54.0	98.1	1.9
	Total	106.0	22.0	32.0	55.0	**215.0**		
	Producer's accuracy	92.5	90.9	93.8	96.4			
	Omission error	7.5	9.1	6.3	3.6			

Based on the analysis of these results, the surfaces inTable5 were obtained. It can be appreciated that the PV cycle has more sowed surface, since all the country is benefited by the rainy season, from May to August.

Table5: *Estimatedsowedsurface*

Cycle	Sowed Surface (Millions hectares)			
	Corn	Kidney Bean	Sorghum	Wheat
PV	5.0	1.1	1.2	0.2
OI	0.9	0.2	0.7	0.7

4. Discussion and Conclusions

The results obtained by the modified MARS method and those obtained by a traditional agriculture surface estimation are presented inTable 6. In the PV cycle, the difference is 0.1 ha (1.3%) and for the OI cycle is 0.2 ha (8%).

Table 6: *Estimated surfaces by both methods*

	Surface (Million Ha)	
Method	PV	OI
Modified MARS	7.5	2.5
Traditional	7.4	2.3
Difference	0.1	0.2

Both methods were different in the estimated amount of surfaces. These differences may have being caused by the physical configuration of the terrain or the specific parameters the sensor had at the moment the image was taken.

The use of a method supported by RS and Statistics provides various benefits to the agricultural land estimation, such as the possibility of performing it on big surfaces. Also, due to the stock images, comparisons along time can be done. Also, the possibility of coordination between the dates of the fieldwork and capture of the satellite image allow a more detailed estimation. In this scenario, the satellite information will match to that reported in the RAW, so some specific variations can be ignored.Applying specific statistical methods, the sampling process presents a concrete focus. In this way, integrating the RAW information will provide important improvements to the sample design.

It is important to establish that merging the benefits of the incorporation of these two disciplines, big optimizations of economical and human resources will be achieved. Although, it has to be considered that this innovations is in a development stage and it has to be subject to different evaluation process.

ABSTRACT

Small photographs.

Keywords: Land cover area estimation, High resolution satellite images, Area frame sampling.

1. Introduction

The Land Monitoring Service of the EU (European Union) Copernicus programme (land.copernicus.eu) includes High Resolution Layers (HRL) that provide information on specific land cover characteristics produced from 20 m resolution satellite imagery. The main 5 themes covered are: imperviousness, (sealed soil), tree cover density and forest type, permanent grasslands, wetlands and water bodies. Pixels of 20 by 20 m are aggregated into 100 by 100 m grid cells for final products. The imperviousness layer was the first one to be produced in 2006-2008. New imperviousness layers have been produced for 2009 and 2012. They cover the 33 Member States of the European Environment Agency (EEA) and 6 associated West-Balkan countries representing a total of 6 million km². Some countries are missing at the time of drafting this paper (Spain, Greece, Cyprus and the French overseas regions are missing). The imperviousness HRL captures the spatial distribution of artificially sealed areas, with a degree 1-100% is produced using an automatic algorithm based on a calibrated normalised difference vegetation index (NDVI). The methodology was described by Gangkofner et al. (2010) for the 2009 update and by Lefebvre et al (2013) for the 2012 update. Similar methods have been also applied in the USA for the development of the National Land Cover database (Xian et al. 2011). A density threshold of 30% was used to derive a 0-1 mask. In Europe, it is currently estimated that artificial areas represent less than 5% of the total EEA39 (Büttner et al. 2012) and impervious surfaces only represent a subset of this area. Because of this relatively low share, commission and omission errors may be high even when the overall accuracy of the layer is apparently good.

2. Sampling Scheme.

Similar products are provided by the National Land Cover Database of the Conterminous United States (Wickham et al. 2013) and a recent study from Hansen et al. (2014). Wickham et al. (2013) applied a stratified random sampling approach using the land cover classes as strata. For the European Imperviousness layer, a similar approach was applied but based on a stratified systematic sampling approach using the LUCAS sampling frame (Gallego and Delincé 2010) targeting also imperviousness changes for which relatively low accuracies are reported, in part because the area increase occupies a very small proportion of the total land area. Using the LUCAS based approach improves traceability and sample sharing for assessing several products. Estimation domains are countries or groups of countries with an area greater than 90,000km². In each domain 6 strata were determined as follows:

- Commission 2006-2009-2012: Imperviousness Degree 30-100% in 2006-2009-2012. This category is divided into two strata defined by intersection with the CORINE Land Cover (CLC) artificial and non-artificial classes.
- Omission High Probability 2006-2009-2012: Imperviousness Degree 0-29% & CLC impervious classes 2006-2009-2012
- Omission Low Probability 2006-2009-2012: Rest of the area 2006-2009-2012
- Commission Change 2006-2009: all changes
- Commission Change 2009-2012 : all changes

A sample of 20,164 PSUs (primary sampling units) was selected. PSU were squares of 100 m × 100 m. It was decided to select a minimum of 50 PSU per stratum in each of the 23 zones. In each PSU a grid of 5 x 5 Secondary Sample units (SSUs) with a 20 m step is selected and photo-interpreted on orthophotos (figure 1). If a point falls on the boundary of an impervious element, a shifting rule is applied so that roughly half of the points in this situation are classified as impervious.

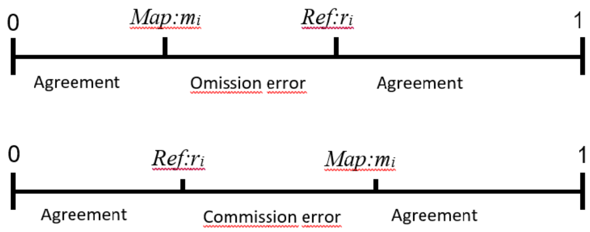
Figure 1: *Example of PSU with a grid of points.*

3. Thematic accuracy.

The usual validation scheme for land cover maps or satellite image classification is based on confusion matrices that assume sharp categories (Congalton and Green, 1999): each point is allocated to one single category as well as each validation unit. When both validation data and product under validation are continuous, a confusion matrix approach can be used by applying a threshold to produce a mask. For the Copernicus imperviousness layer, a threshold of 30% had been foreseen. However better alternatives can be found in the modelling literature to deal with quantitative products (Wilmott, 1981, Legates and Mc Cabe, 1999, Duveiller et al., 2016). Agreement indicators for quantitative parameters have been also widely used in the remote sensing literature (Ji and Gallo, 2006, Silván Cárdenas and Wang, 2008, Meroni et al., 2013).

Among the indicators that have been proposed, we have chosen to quantify the disagreement at the PSU level as the difference between the map value m_i and the reference r_i. If the map value is larger than the reference value for a PSU, it will contribute to the commission error, but it will contribute to the omission error if the oposite happens (Figure 2).

Figure 1: *Commission and omission errors with continuous data between 0 and 1.*



The commission φ and omission ψ errors would be computed as:

$$\varphi = \frac{\sum_i w_i\, pos(m_i - r_i)}{\sum_i w_i\, m_i} \qquad \psi = \frac{\sum_i w_i\, pos(r_i - m_i)}{\sum_i w_i\, r_i} \qquad (1)$$

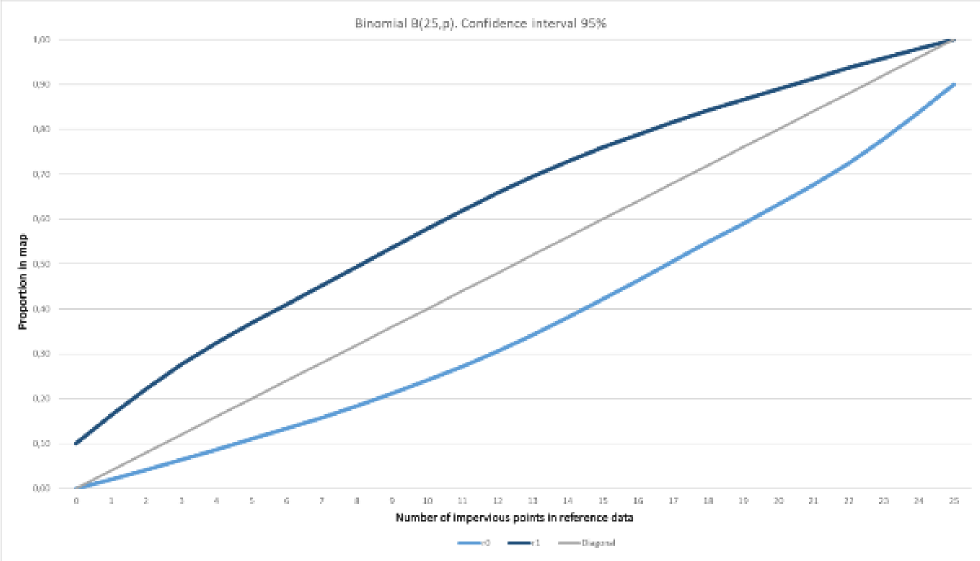
and the overall accuracy $$\theta = \frac{\sum_i w_i\, (min(r_i, m_i) + min(1 - r_i, 1 - m_i))}{\sum_i w_i} \qquad (2)$$

where w_i is the extrapolation weight (inverse of the sampling probability) and $pos(x)$ is the positive part. With these criteria we have a commission error of 21.9% and an omission error of 40.2%, even if the overall accuracy is 98.4%. Part of the disagreement between reference comes from the incomplete information on the cell for our reference data: if we assume that the map and the reference data are in perfect agreement, there would be still a difference between m_i and r_i because the spatial support is different: m_i refers to the whole PSU while r_i refers to a sample of points inside. Our r_i has a probabilistic distribution that we can approximate by a binomial B(25, p_i) with a somewhat lower variance due to the systematic sampling. This has an impact on the expected commission and omission errors. One possible way to take this into account is delineating a confidence band under the null hypothesis $m_i = p_i$ (figure 3). For any pair (r_i, m_i) inside this band we are not reasonably sure that $m_i \neq p_i$. A possible way to deal with this source of uncertainty is quantifying the commission and omission errors:

$$\varphi = \frac{\sum_i w_i\, pos(m_i - r_{0i})}{\sum_i w_i\, m_i} \qquad \psi = \frac{\sum_i w_i\, pos(r_{1i} - m_i)}{\sum_i w_i\, r_i} \qquad (3)$$

where r_{0i} and r_{1i} are the closest points in the confidence band. With these criteria the commission error is around 10% and the omission error around 20%.

Figure 3: *95% confidence band (r_i,m_i) under the hypothesis $m_{i=}$ p_i.*



4. Area estimation.

A naïf approach for area estimation using classified satellite images is pixel counting or equivalent for classifications that focus on the proportion of a parameter, as it happens in our case:

$$\tilde{A} = \sum_i m_i \qquad (4)$$

The result for this estimator for the zones covered at the moment (excluding Spain, Greece, Cyprus and French overseas territories) is 2.06%, approximately 107,000 km^2. It is well known that this area estimation has a bias that can be very large (Bauer et al, 1978, Houston and Hall, 1984, Czaplewski, 1992) and roughly corresponds to the difference between the commission and the omission errors (Carfagna and Gallego, 2005). A simple reasonable idea may be correcting the bias with the difference between the commission and omission errors computed on a confusion matrix. Unfortunately it is still frequent that remote sensing practitioners compute confusion matrices on the basis of a purposive set of units instead of a proper probability sample. In the scientific literature purposive samples have nearly disappeared thanks to the effort of a number of authors (Congalton and Green, 1999, Stehman, 2009, Olofsson et al., 2014), but they are still frequent in reports of projects carried out for various institutions and remain unpublished. We can simulate a purposive sample using our sample by omitting the weights in equations (1). We would get table 1 that suggests us reducing the estimate by approximately the difference between 26.6% (apparent commission error) and 20.8% (apparent omission error) to obtain an estimate just above 100,000 km^2. If we apply the correct weights we get the confusion matrix in table 2, in which we find that the omission error (40.7%) is much higher than the commission error (21.9%). The figures of the confusion matrix can be interpreted as area in km^2 and we can obtain an area estimation by adding something that is close to the difference (40.7-21.9)%. A better estimate is obtained by simply adding the difference between the off-diagonal terms: 107,000+57,000-23,200 ~ 140,000 km^2, i.e the 2.74% of the territory.

Table 1: *Unweighted confusion matrix.*

		Map Impervious	Other	Total	Omission error
Reference	Impervious	4280.4	1124.1	5404.5	**20.8%**
	Other	1553.3	13041.2	14594.5	
	Total	5833.7	14165.3	19999	
	Commission error	**26.6%**			

Table 2: *Weighted confusion matrix.*

		Map Impervious	Other	Total	Omission error
Reference	Impervious	82859	56981	139840	40.7%
	Other	23232	4961592	4984824	
	Total	106091	5018573	5124664	
	Commission error	21.9%			

The most reasonable principle is combining the two sources of information we have: more accurate data on a sample and less accurate but nearly-exhaustive information from the image classification (i.e. the imperviousness layer we are validating). We have given above a coarse view on starting with remote sensing based estimates using reference data on a sample. The opposite approach is more frequent: a sample-based estimate modified using the co-variate provided by a classified image. At the first step of this approach we compute an estimate of 139.800 km^2 with a coefficient of variation of 3%. The estimate is very close to the estimate obtained with a simple correction on commission-omission errors computed from the weighted confusion matrix. The observation of the variances by stratum, not reported here, suggests that major improvements can be obtained by applying a Neyman allocation in the future.

A better estimator is generally obtained combining the more accurate data on a sample (reference data) with less accurate exhaustive data obtained from satellite images. If both data are quantitative, the standard technique to do so is the regression estimator (Cochran, 1977). For the impervious areas in 2012 in the zones considered for the Copernicus validation, table 3 reports the naïf estimator obtained directly from the image-derived values, the stratified sampling estimator from the reference data and the stratified regression estimator. Just by chance the overall regression estimator for the study area nearly coincides with the extrapolation from the reference data (139,800 km^2) with a coefficient of variation of 2.77%. This means that the relative efficiency is around 1.17, a rather modest value.

Table 2: *Different estimates of impervious areas in 2012 (in km^2).*

5. Conclusions.

The direct area estimation by pixel counting in a classified image, or equivalent approaches, is known to have a bias because commission and omission errors. We have illustrated with the example of the estimation of impervious areas in Europe that a simple correction of bias using a confusion matrix gives acceptable results if the confusion matrix has been properly weighted with the inverse of sampling probabilities. In exchange if these weights are ignored, the correction can be completely wrong and even "correct" the estimates in the wrong direction. In our example the bias of the naïf (direct) estimation of impervious area from classified satellite images is above 20%, even if the overall accuracy of the classification is above 98%. This observation has an implication on the use of remote sensing for area estimation that is not new, but is worth reminding:

- the risk of bias in direct area estimation from classified images is particularly strong if the targeted classes occupy a small proportion of the geographic area.
- Bias correction with a sample of more accurate and approximately unbiased data requires applying the correct weights from the sampling plan.

ABSTRACT

The aim of this paper was to collect research regarding the analysis of land use and land cover changes (LULCC) made with the different approaches and methodologies in the last few years on the Italian territory. The LULCC can be analysed using both cartographic and inventory approaches. The latter, in particular, provide estimates of the accuracy of the sampling strategy adopted , allowing objective and scientifically sound comparisons of the estimates at different times. The possibility to assess the statistical accuracy and the possibility of frequent updates, suggest the inventory approach as a valid and reliable instrument for the LULCC assessment. The evaluation of LULCC and the selection of a reliable and accurate approach usable as a standard for

a large series of experiences, plays a primary role as a support for future land use planning. In this perspective, the Italian Inventory of Land Use has been further implemented during last years to better understand LULCC, their causes and possible effects on ecosystem services, thus offering a valuable support for future land use planning.

Keywords: Land Use, Land Cover, Multitemporal analysis, Inventory, monitoring

1. Introduction

Since the Industrial Revolution, and particularly after the World War II, the socio-economic dynamics have strongly exacerbated the land use and land cover changes (LULCC), particularly in Developed Countries, such as e.g., Italy. LULCC alter the ecosystems' structure, functionality, as well as their capacity to provide goods and services supporting human wellbeing (e.g., Foley et al., 2005). Furthermore, it is now evident that rapid changes in ecosystems, especially if driven by human activities, significantly affect the ecological resilience (Vizzarri et al., 2015). Monitoring LULCC and assessing the related impacts on resilience and Ecosystem Services (ES) are crucial to support adaptive governance, as well as to evaluate the effects of the currently implemented actions on sustainability. Consequently, the development and implementation of new methodologies and approaches to face these needing represent active and stimulating fields of research (e.g. Vizzarri et al. 2015).

Cartographic and inventory approaches are used for LULCC analysis, through applying different methodologies and nomenclatures strictly according to their aims and scopes (Corona, 2010). For example, land use inventories aim to provide statistically sound estimators of land-use proportions and related changes for a given time-span in a study area. This need is satisfied by applying different sampling strategies aimed at maximizing statistical accuracy and data reliability, while minimizing sampling costs and duration. Otherwise, for mapping, the demand is for a graphical depiction of attributes location within a study area, which is useful for the spatially-explicit investigation of certain phenomena. The choice of the most appropriate approach is not then an easy task, since it is related to different aspects, such as time, costs, objectives and data reliability. In this context, the aim of this contribution is to briefly present some recent outcomes and methodological remarks obtained by testing, improving and implementing the Italian Land Use Inventory (IUTI from the Italian acronym of *Inventario dell'Uso delle Terre d'Italia*) at national or regional scale in Italy. The manuscript is divided into four main sessions describing *i*) the characteristics and main aspects of IUTI; *ii*) the LULCC affecting the Italian landscape during the last 20 years; *iii*) the maximisation of the informative power of IUTI through integrating inventory and cartographic approaches, as well as LU and LC meanings; and *iv*) some final comments and remarks.

2. The Italian Land Use Inventory (IUTI)

IUTI has been promoted and implemented by The Italian Ministry of Environment and Protection of Land and Sea in the framework of the Extraordinary Plan of Environmental Remote Sensing as a key instrument of the National Registry for forest carbon sinks (Marchetti et al., 2012). The Italian territory was covered by a network of 1,217,032 quadrats of 25 ha, in a way that each quadrat contained at least a portion of this territory. Hence, in accordance with the protocol of tessellation stratified sampling (TSS), a point was randomly selected in each quadrat (Fattorini, 2014). The large sample size adopted in IUTI was due to the need for estimating LULCC with adequate statistical accuracy, even estimating small changes that are likely to occur during brief temporal intervals (Corona et al. 2012a). The sample points were photo-interpreted on high resolution imagery available for the years 1990, 2000 and 2008 to estimate LULCC over the time. Those points that fell outside the Italian territory were classified in an additional class (i.e. "outside area"), while the others were classified in 9 LU classes divided into 3 hierarchical levels. The analysis of LU and LC changes is based on the construction of a transition matrix, also known as a cross-tabulation matrix (Pontius et al. 2004) (e.g., Table 1 shows the Italian transition matrix from 1990 to 2008).

		2008

	Total	9,653,216	10,056,141	3,114,765	144,376	1,874,449	1,991,200	518,586	2,140,903	655,040	30,148,676

Table 1: *Transition matrix of the changes which occurred in LU from 1990 to 2008 in Italy.(Source: Marchetti el al., 2014a).*

Additionally, during 2013, the IUTI database was updated using a 1% subsample within the whole national territory (about 13,000 sample points), thus obtaining an estimation of the LULCC trends for that year. For reducing the sampling efforts, the one-per-stratum stratified sampling (OPSS) has been adopted. The results from Fattorini et al. (2015) showed that in front of a reduction of the on-screen classification effort of 100 times, the RSE estimates increased by approximately 10 times. In absolute terms, these results are then rather encouraging, because the largest LU classes show RSE estimates invariably smaller than 3%, while the smallest ones show RSE estimates always below 9% (Pagliarella et al., *in press*).

3. LULCC in Italy during last decades

IUTI allows to identify and quantify in a quick way and at low cost the key dynamics characterizing the landscape changes, including their impact in ecological and functional terms. At national scale, several studies have shown that, during the last 50 years, the Italian landscape has been deeply marked by industrialization, urbanization, agricultural and livestock intensification, mostly in downhill and plains. On the contrary, mountain areas are currently affected by land abandonment and spontaneous forest revegetation. Summarizing, the most important LULCC in Italy, during the last decades, were: (i) urban growth and soil sealing; (ii) loss of arable lands, meadows and pastures; and (iii) natural reforestation (e.g., Falcucci et al., 2007). In particular, forest regrowth (+1.7% of the Italian territory), primarily occurred at the expense of croplands in the hills, pastures and grasslands in the mountains; the shrinkage of arable lands (-4.2% of the Italian territory) is due to urban growth in lowlands, conversions to permanent crops in hills (mainly orchards and vineyards) and natural reforestation in mountain areas; urban area increased by 1.6% with a total coverage of settlements reaching 7.1% of the whole Italian territory in 2008. Preliminary results of the updating process in 2013, show a decreased rate of annual variation, if compared with that from the first monitoring period (1990-2008) (Sallustio et al., 2015a). Considering the first two changes (natural reforestation and land abandonment), IUTI showed that in Italy they are following a latitudinal gradient as shown in table 2. In fact, the decreases in arable lands, meadows and pastures are more marked descending from North to South (Sallustio et al., 2015a). Moreover, it is worthy to note that the loss of arable lands primarily occurs on agricultural land uses marginal in economic terms, despite it is very important from an ecological perspective (see e.g., biodiversity and cultural landscapes conservation) (Marchetti et al., 2014a). Furthermore, Marchetti et al. 2013 showed that the trends registered at national scale in Italy are not very different from those observed within the National Parks. These findings are particularly important to deeper understand to what extent the policy instruments and regulations are currently used and implemented in these areas to address conservation issues.

	North			*Centre*			*South*			*Italy*

Table 2: *Forest dynamics occurred in Italy and in the three macro-regions between 1990 and 2008. Values are expressed as surface (ha) and relative values (%) with respect to the total surface of each macro-region. (Source: Sallustio et al. 2015a).*

The urban growth is one of the most worrying LULCC in Italy, and occurs especially at the expense of arable lands and croplands in general (approximately 75%, Marchetti et al., 2012). In particular, land take occurs in lowlands and gentle slope territories, which are usually attractive for brick and mortar investments (Marchetti et al., 2014a). Moreover, this phenomenon is still also affecting regions with negative demographic balance (e.g., Basilicata, Calabria, Liguria and Molise), with a subsequent increase of their per-capita built-up area (Sallustio et al., 2013).

Using two different definitions of mountain (statistical and juridical) and comparing the LULCC occurred during the same time-span even on the entire national territory and within the National Parks, Sallustio et al., (2015b) highlighted the importance of using a clear and unambiguous definition of the study area to obtain reliable results able to effectively support a certain policy, strategy or plan (the one related to mountain areas in the specific case). In particular, they found that LULCC are very similar (for type and magnitude) both in the statistical mountain and Protected Areas case, despite they appear quite different according to the "statistical mountain" definition, and the whole national territory. This finding turned out to be an essential need also for future policies and management strategies, such as those related to the oncoming Common Agricultural Policy.

4. Beyond IUTI: how to maximize the informative power at low costs?

The lack of data and funding sources limits the research activities, and encourages researchers to optimize the freely available data, as well as maximize their informative power. This section shows the results of the two works carried out by using IUTI data to integrate inventory with cartographic approach, as well as LU with LC meaning.

4.1 The integration of inventory and cartographic approaches

Sallustio el al. (2015c) proposed and tested a method to quantify land take dynamics associated with urban growth, and estimate their effects in terms of carbon stock loss. Specifically, a method used for urban forest coverage assessment over Italy (Corona et al., 2012b) was implemented in order to estimate urban patch abundance and average size. This approach is based on integration between the inventory and cartographic approaches to estimate not only the extension of a given LU or LC class, but also the number and average size of the patches. The sampled urban patches were then used as inputs for the assessment of change in carbon loss, both in biophysical and economic terms, through using the InVEST model (Tallis et al., 2013). Analyses were performed in two very different study areas in central Italy, such as the province of Rome, the most populated and urbanized area in Italy, and the Molise region, the least dense and urbanized area in Italy. The main results are reported in Table 3, in which it is possible to appreciate the satisfactory level of accuracy of the estimates.

Study area	Year	$\hat{N}$	$se_{\hat{N}}$ (%)	$\hat{A}$ (ha)	$se_{\hat{A}}$ (%)	$\hat{\bar{a}}$ (ha)	$se_{\hat{\bar{a}}}$ (%)
Molise Region	1990	2449	10.1	9000	5.2	3.68	7.6
	2008	3455	8.5	12,850	4.3	3.72	6.2
Province of Rome	1990	10,763	4.9	81,037	1.7	7.53	4.4
	2008	13,989	4.2	109,026	1.4	7.79	3.8

Table 3: *Estimates of number of urban patches (N), urban coverage (A) and urban patch average area (a), and their estimated relative standard errors (expressed in percent).(Source: Sallustio et al., 2015c).*

Despite the low realization and updating costs, the integration of inventory and cartographic approaches is demonstrated to be a reliable estimate, enhancing their information power. Moreover, the possibility to couple such estimates with spatially-explicit tools allows the identification of ES or functions loss due to a certain LULCC of ecosystems' modification, and provides useful information for land use planning.

4.2 The integration of LU and LC inventories

There are both semantic and technical differences between LU and LC measurements. The most common definitions of LU and LC are those adopted in the Land Cover Classification System by FAO (2000), in which the former is referred to the socio-economic function of a given piece of territory, while the latter is usually related to its biophysical cover that can be directly observed in the field and registered by orthophotos. The confusion between the two concepts has existed in the literature for at least forty years (Anderson et al. 1976), leading to the spread of hybrid classification systems. However, the ability to distinguish or integrate use and cover concepts can represent a challenging opportunity for researchers.

Recently, Sallustio et al. (2016) presented an example of LU and LC inventories integration applied to the Molise region. Changes in LU and LC were evaluated from 2000 to 2012 using the IUTI sample points. The analysis was performed using both the original LU classification and through a new classification system addressing the LC. The sampling points were classified through a visual interpretation of aerial photographs for both LU and LC in order to estimate their surface and changes over time. The results demonstrated that a comparison between the two classification schemes provides an understanding of the causes of their misalignment. In fact, the aggregation proposed in table 4 indicates a good correspondence between the LU and LC estimates only for *Arable lands and Orchards, vineyards and nurseries*, whose differences are not significant. In the other cases (e.g., *Forest lands and forest plantations*, *Settlements and artificial lands*, and *Other lands*), the differences between the LU and LC estimates are highly significant. In the case of *Forest lands*, for example, such difference is 2.16%, mainly due to the LU parameters of classification used, such as the height of mature trees, the crown coverage, the extension and the minimum width of the woods (FAO, 2000), which are neglected by the LC classification.

	LU classes	**LC classes**	**LU (%)**	**LC (%)**	**LU (ha)**	**LC (ha)**	**absolute differences (%)**	**absolute differences (ha)**	**significance**
Forest lands and forest plantations	1.1- 1.2- 2.2.2	33	35.23	33.06	161,525	151,600	2.16	9,925	0.00001(*)

Table 4: *Comparison of the estimates achieved for LU and LC aggregated categories in 2012, their differences and their corresponding significance. (Source: Sallustio el al., 2016).*

The combined use and interpretation of the LU and LC estimates are helpful for deeper analysing and understanding the processes and dynamics occurring within a certain study area. For example, from the repartitioning of the sampling points classified as *Settlements* among the LC classes for the Molise region, Sallustio et al. (2016) found that 31.9% of them fall in unsealed (permeable) classes. This value gives insights on the density and compactness of urban areas. In fact, the higher is the degree of the unsealed surface, the higher its degree of permeability, corresponding to more scattered and fragmented urban areas. The extension of this permeable surface in urban areas offers a great potential to enhance and implement urban green spaces to improve the people wellbeing (Haase et al. 2014). The comparison of the estimates from the two classification systems may constitute a quick and effective instrument able to provide essential information to support land use planning.

5. Final remarks

The evaluation of LULCC and the selection of a reliable and accurate approach usable as a standard for a large series of experiences, plays a primary role as a support for future land use planning. This turns to be extremely important to make the future-oriented management guidelines coherent with the bioeconomy bases and to frame other key questions for sustainable development policies, like the set-up of environmental-economic accounting systems (Marchetti et al., 2014b).

ABSTRACT

Land use and land cover change accounts for about 80% of the global cost of land degradation, and one fifth of the land degradation that took place globally between 1982 and 2006 occurred in Africa south of the Sahara. We map the land cover of the three Savannah Regions of Northern Ghana twenty years apart (1994 – 2014) using remote sensing data, and subsequently employ spatial regression analysis to examine the relationship between long-term land cover change and current total value of harvest and maize productivity. Through the construction of a unique dataset combining information from georeferenced household surveys, remote sensing, and other secondary data sources, we propose a method to observe the relationship between landscape-level transformation and household-level outcomes. We find that areas that are currently cultivated or urbanized but were green vegetation in 1994 show higher agricultural production and productivity than areas currently cultivated or urbanized that were previously bare land. This suggests that the expansion of crop land into degraded areas with poor quality soils may not yield the expected positive gains, thus threatening the sustainability of agricultural production upon on which millions of poor smallholders rely.

Keywords: Land cover change, agricultural productivity, spatial regression, spectral analysis.

1. Introduction

The world population is expected to reach nine billion people by 2050 (United Nations 2009), requiring a steady growth in the production of food, feed and bioenergy sources for its subsistence (FAO 2011). This evolution is expected to put significant pressure on the natural vegetation and cropland on which millions of poor people rely heavily for their livelihood, therefore increasing the vulnerability of households living in rural areas (Biggelaar et al. 2004; Berry et al. 2003). Poverty, in turn, prevents farmers from investing in the measures necessary to protect the natural resource base, creating a poverty-environment vicious circle (Bremner et al. 2010; Bhattacharya et al. 2006; MEA, 2005; Perrings 1989; IPCC 2000; Wood et al. 2004). This negative spiral of poor livelihoods and resources degradation is further magnified by factors such as imperfect market and institutional failures (Duraiappah 1996).

About 40% of the global land surface is devoted to cropland and pastures, and in sub-Saharan Africa the rate of agricultural expansion has been steadily increasing over the period 1961-2005 (Foley et al. 2005; Nkonya et al. 2012). At the same time, about 65% of Africa's arable land is too degraded for sustainable food production, posing serious challenges for supporting the growing population that depends on it (Montpellier Panel 2014). This threat could be especially severe in arid and semi-arid environments, such as the semi-arid savannah region of West Africa (Pinstrup-Andersen and Watson 2010).

Existing literature on household welfare shows a strong spatial dimension in livelihood strategies, whose understanding is crucial to properly design effective poverty-alleviating policy interventions (Ayadi et al. 2009; Benson et al. 2005; Minot et al. 2003; Okwi et al. 2007). Yan et al. (2009) show how the transition of cultivated land into infertile soil, taking place in China following the dramatic urban expansion, significantly reduced overall agricultural productivity. Wiebe (2003) further discusses how the negative effects of land degradation on crop yields tend to be particularly important in areas with already high poverty rates, thus underlining the strong interdependence between household welfare, agricultural activity, and land cover dynamics.

Spatial analysis has been previously proposed to study these linkages (Bremner et al. 2010; Berry et al. 2003; Dasgupta et al. 2003; Dang 2014; Gyawali et al. 2004; Nkonya et al. 2008). Nevertheless, while the understanding of the spatial patterns of land cover changes and welfare has significantly improved during the last decade (Ayadi and Amara 2008; Okwi et al. 2007; Paraguas and Kamil 2005), empirical evidence on this relationship remains limited and seldom complemented with socioeconomic analysis (Barrett and Carter 2013; Galford et al. 2013; Mali 1998; Turner 2002).

The focus area of this paper is northern Ghana, comprising o Upper East, Upper West, and Northern regions. This area covers 40% of the nation's surface, while 80% of its population relies primarily on agriculture. These three regions also show the lowest levels of welfare in the country and, in contrast with the rest of the country, poverty rates have been increasing over the past years (Diao et al. 2007; World Bank 2011). Finally, the area is also highly affected by land degradation as a result of unsustainable farming practices due to the dominant bush-fallow rotation system, the removal of natural vegetation cover, and urbanization (Braimoh and Vlek 2005; Diao and Sarpong 2007; FAO 2000; World Bank 2007). These characteristics render the three regions under study particularly vulnerable to the poverty-environment vicious cycle, therefore understanding the underlying dynamics at play would be crucial to suggest interventions to break the cycle. The paper starts by describing the changes in land cover that occurred between 1994 and 2014. Next, it shows a spatial regression analysis that examines the link between long-term land cover change and current rural livelihoods, after controlling for regional trends in poverty and population over the period. Results show that households living in natural cover areas in 1994 that turned into productive areas in 2014 are associated to higher harvest value and maize yield than households currently living in productive areas that were previously bare land. This finding suggests that expanding crop cultivation to relatively low fertile soils may not lead to sustainable agricultural production, and that once land becomes degraded it is very difficult to reverse the process. While this study shows that crop cultivation in areas previously covered by vegetation bear positive effects on production, the loss of natural resources is likely to be detrimental in the longer term that goes beyond what is captured by this analysis. Results bear important policy implications calling for enhanced investments in land conservation practices in the regions - including reforestation -, and for sustainable intensification in areas already under cultivation.

The novelty of the study lies in the ability to combine household-level analysis with geo-spatial information at the landscape level to examine the interdependence between land cover change and rural livelihoods. The methodology used to derive the land classification is also new. First, it takes advantage of the georeferenced boundaries of 278 plots collected at the household level to precisely derive the 2014 cropland distribution for the entire northern Ghana. Second, it uses spectral prediction out of sample to recover the complete land cover distribution two decades ago (1994).

The rest of the paper is organized as follows. Section 2 outlines the conceptual framework; Section 3 describes and summarizes the data. Section 4 outlines our identification strategy and Section 5 discusses regression results. Finally, Section 6 concludes.

2. Conceptual Framework

There is a vast literature describing the spatial concentration of poverty in clusters of indigence (Ayadi and Amara 2009; Benson et al. 2005; Demombynes et al. 2002; Lanjouw et al. 2013; Minot and Baulch 2005), which – especially in Sub-Saharan Africa - are often located in rural areas where subsistence farming constitutes the main livelihood strategy (Amarasinghe et al. 2005). While transient poverty is mainly caused by temporary shocks, chronic poverty depends on the scarcity of productive assets (Barrett 2005), which in the case of subsistence farmers are mostly constituted by the natural capital embedded in the land they cultivate (Dasgupta and Deichmann 2003; Okwi et al. 2007). Therefore, the characteristics of the land-cover define the potential for agricultural production and productivity of the communities that inhabit it, and their evolution influences the dynamics of household welfare (Ikefuji and Horii 2005).

In order to study these linkages, our framework considers three main land-cover classes on the base of their contribution to livelihoods. The first class is defined as the *natural* cover and is composed of forest, water sheds, shrubs, and savannah. It represents the area that has not been transformed by human action. The natural cover is not only a source of fodder, fuel, food, and timber for the adjacent communities, but has also an important role in the farming systems' regenerative processes as well as constituting a stock of genetic resources for future agricultural needs (Alavalapati 2003; Sunderlin et al. 2008). Natural resources therein are non-exclusive and all the members of the community can benefit from them (Shackleton et al. 2007).

The second class is defined as the *productive* cover and is composed of cropland and urban areas. This land type is shaped by human action and constitutes the location where most of the economic activity takes place. Cropland is devoted to agricultural production and livestock breeding while urban areas host the industry and services activities.

Finally, the third class is defined as the *degraded* cover and is composed of bare soil. The process of land degradation describes the dissipation of soil nutrient content that can either be the product of human activities such as overexploitation, or the result of natural phenomena such as climate change. Degraded land is neither productive nor a source of natural capital and thus do not supply any resource for livelihoods (De Sherbinin 2002; Reynolds 2001).

The three land cover classes create nine possible land cover trajectories between 1994 and 2014. Table 1 summarizes them and reports their expected effect on household livelihoods.

Table 1: Land cover changes between 1994 and 2014 and expected impact

Land cover in 1994	*Land cover in 2014*	*Livelihood trend*
Natural	Natural	Same
Natural	Productive	(+/-)
Natural	Degraded	(-)
Productive	Productive	Same
Productive	Natural	(-/+)
Productive	Degraded	(-)
Degraded	Degraded	Same
Degraded	Productive	(+)
Degraded	Natural	(+)

We expect the likelihood of the changes to be heterogeneous, with certain trajectories observed more frequently than others (Lambin et al. 2003; Mustard et al. 2004; Vitousek et al. 1997). In particular, we expect two trajectories to be dominant in northern Ghana. The first is the change from natural cover to productive cover and subsequently to degraded land (mostly caused by human action) (Braimoh and Vlek 2005; Braimoh 2009; Wood et al. 2004). The second is the change from natural cover to degraded land directly (mostly caused by natural factors). On the other hand, we expect the emergence of natural cover from the other two classes to be quite rare, especially in the absence of appropriate conservation practices in place.

In terms of the relation between land cover changes and livelihoods, we expect the shift from natural cover to productive cover to improve household production and productivity up to a certain point, beyond which the increased scarcity of natural resources will start to impact livelihoods negatively (Coomes et al. 2011). For this trajectory to be sustainable, there needs to be a positive tradeoff between the loss of natural capital (biodiversity stock, carbon stock, etc.) and the economic effects of enlarged productive areas (Chhabra et al. 2006). Indeed, the objective of sustainable intensification is to create a balance between productive land and natural stock in order to allow the system to regenerate itself and to avoid overexploitation leading to land degradation (Cao et al. 2012; United Nations Department of Economic and Social Affairs 2012). The change from natural vegetation or productive cover to degraded land is expected to cause a deterioration of livelihoods (Berry et al. 2003; Bhattacharya and Innes 2006; Diao and Sarpong 2011), while the cultivation of land that was previously degraded is expected to improve livelihoods to a certain extent but still result in low productivity, because of the infertile nature of the soils. (Yan et al. 2009). It is also worth noting that these relations could be non-linear and be influenced by a number of economic, environmental, and institutional factors (Wiebe 2003). Finally, since the analysis is based on just two data points, we are not able to account for possible trend reversals that may have happened in-between.

3. Data

3.1 Land Classification

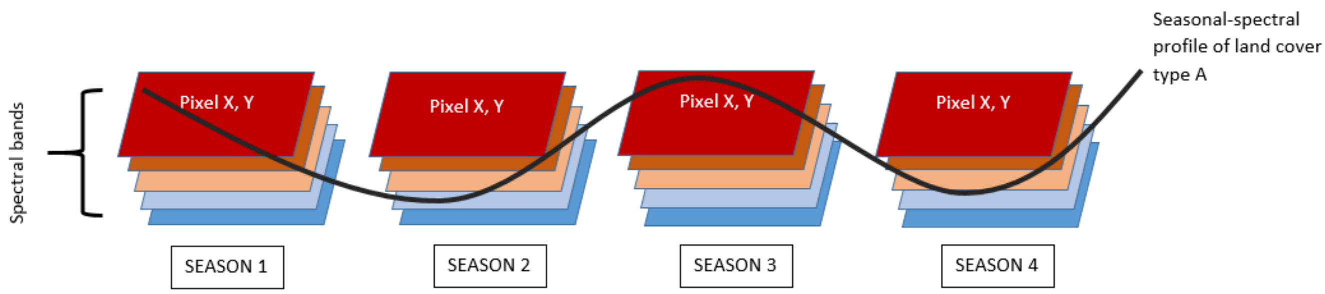
The analysis is based on a unique dataset combining primary data from a georeferenced household survey, micro-data from secondary sources (Ghana Living Standards Surveys -GLSS-), satellite imageries, and census information.

First, we produced two land cover classification (for 1994 and 2014) using Landsat images from USGS (Landsat 5 and Landsat 8) that cover the entire northern Ghana[1]. The year 1994 is selected as the baseline because prior to the 1990s the quality of satellite imageries was significantly lower, making it difficult to identify different land cover types at an adequate resolution. Furthermore, while 1991/92 and 1995 were characterized by some abnormally intense floods (Codjoe and Owusu 2011), 1994 can be considered as a normal year in terms of climatic conditions such as rainfall and temperature. This year is also chosen to match the household survey data year.

The classification is obtained by assigning one of the seven land cover classed defined by FAO to each 30 meter by 30 meter pixel within the images (Campbell 1987). The seven classes are bare soil, crop land, forest, savannah, shrubs, urban settlements, and water bodies. However, the land cover types can look very different from the satellite imageries depending on the time of the year when the picture was taken. For example, cropland changes drastically between the growing and the harvest season while waterbody varies significantly in size between the rainy and dry season. For this reason, each classification is based on four images that capture seasonal variation[2] and, within each image, on several spectral bands that are sensitive to the detection of the different spectral properties of all the seven land cover types.

To produce the land cover maps, the algorithm used calibrates the spectral properties of each land type in comparison to the others. For this reason, the images have to be overlaid with a sufficient number of external ground-truthing points identifying the exact locations where each type can be found. This allows to define and calibrate seven spectral profiles and to apply them to the entire surface. Figure 1 summarizes the identification process.

Figure 1: *Diagram for the identification of land cover types*



The ground-truthing points for cropland are identified with the georeferenced boundaries of 278 plots collected in the household survey, while the ones of the remaining six land cover types are identified

[1] The code of the selected tiles is the following: Path194, Row53; and Path195, Row 53

[2] Since cloud-free good quality images are unavailable for the four seasons in both years, one year time lag (before and after the selected year) has been also considered.

through Google Earth. In total, about 200 ground-truthing points for each land cover type are collected across the three administrative regions, of which two thirds are used to train the system while the remaining one third is used for validation of the final products.

The maximum likelihood classification algorithm is applied to produce the 2014 classification (Johnson and Dean 1988). The latter considers both variance and covariance of the classes across the ground-truthing points and apply them to the remaining pixels. Under normality assumption, a class can be characterized by mean and covariance. Given these two characteristics, the probability of each cell to belong to any class is computed and each cell is assigned to the class showing the highest probability. The final classification is then validated and cross checked with Google Earth as well as shared with local partners for feedback.

This methodology, however, cannot be directly applied to the 1994 images because historical ground-truth data are not available (Mosteller 1977; Richards 1986). For this reason, the 1994 images are analyzed through unsupervised classification methods using the IsoData classification algorithm. The latter clusters pixel observations into groups based on their reflectance values of the multiple spectral bands (Tou and Gonzalez 1974). Since different land covers exhibits their own unique spectral properties, the IsoData unsupervised classification algorithm investigates each pixel's spectral properties and groups them based on similarities. In a second step, the Maximum Likelihood Classification matches the spectral profiles identified in the 2014 with the spectral properties of 1994, to identify the same classes. Appendix Figure A1 and Figure A2 summarize the results of this land classification exercise, suggesting a reduction in shrubs and grassland and an increase in crop and bare land across the three regions.

In order to evaluate the quality of the 2014 land cover map, an accuracy assessment of the prediction is needed. We thus take the 1/3 ground-truthing points that were not used to train the algorithm to perform a statistical accuracy assessment for the entire classification as well as for the assignment of the individual classes. The accuracy matrix is provided in Table 2. The land cover classification results shows satisfactory accuracy rates[3]. The overall accuracy is over 70%. The urban, forest and waterbodies have the highest accuracy among all the land cover types (above 90%), while the rest of the classes have accuracy around 60%. Although cropland is usually recognized as one of the most difficult classes to identify, in our case it has higher accuracy rates than other vegetation types. This could be explained by the higher precision of the ground-truthing points from plot GPS coordinates than the ones based on the visual interpretation of Google Earth photos. Given the relatively high degree of land cover seasonality in northern Ghana and the possibility of land cover misclassification, we considered two years and grouped land cover types into homogeneous clusters.

Table 2: *Accuracy Matrix of the 2014 Land Classification*

		Ground Truthing class							
	Landcover types	Cropland	Forest	Grassland	Shrub	Bareland	Water	Urban	User accuracy
Land Classification 2014	Cropland	861	26	185	106	106	26	146	59.1
	Forest	-	596	-	-	40	13	-	91.8
	Grassland	146	93	728	331	93	-	40	50.9
	Shrub	40	199	225	1,152	185	13	159	58.4
	Bareland	13	13	26	66	331	-	119	58.1
	Water	-	53	-	-	-	887	-	94.4
	Urban	15	-	-	-	20	-	1,497	97.7
	Producer accuracy	80.1	60.8	62.5	69.6	42.7	94.4	76.4	70.8

[3] The producer accuracy indicates the probability of the reference pixel being correctly classified and is a measure of omission error. It is used to indicate how well a certain area can be classified. The user accuracy is a measure of commission error. It indicates the probability that a pixel classified on the map actually represents that class on the ground.

3.2 Household Data

We take advantage of the detailed geo-referenced, socioeconomic household and community Ghana Africa RISING Baseline Evaluation Survey (GARBES)[4] data collected in northern Ghana in 2014 to construct two measures of household livelihoods – maize yield and value of harvest - as well as several socioeconomic controls, including land holding, soil quality on-farm, and two indices of non-agricultural wealth and access to basic services[5]. Furthermore, spatial data matched to the household GPS coordinates were also included among the controls: market access (measured by travel time to the nearest town of 50 thousand people) and elevation, proxies for agricultural potential.

Finally, we construct region-level welfare indicators based on two waves of GLSS (1998/99 and 2012/13) to control for regional-level poverty trends as well as district-level population changes based on two waves of census data[6] (2000 and 2008) to capture broad economic trends.

3.3 Matched Spatial and Household Data

Regarding household-land cover mapping, a land cover type can be assigned to the geo-referenced sample households in a number of ways. One way is to assign a class based on the class of the 30 meter by 30 meter pixel in which the household is located. Alternatively, different buffer zones can be defined around the pixel in which the household is located. When using a buffer zone, as we did in this paper, a decision needs to be made about the size of the buffer zone as well as how to assign a land class to households when there are multiple classes within the buffer zone. A wider buffer zone has the advantage of better representing the environment affecting the livelihoods of the household, especially given that the average walking distance to the closest plot reported in the surveys was of 30 minutes.

On the other hand, the wider the buffer zone chosen, the larger the number of overlapping pixels among households (and villages), and the smaller the variation in land cover changes in our sample. For comparability, we considered four buffer zones based on 9 pixels (p) (3 pixels wide and 3 pixels high around the pixel in which the household is located), 25p (5px5p), 49p (7x7), and 81p (9x9). A summary of the share of each land cover class is shown in Appendix Figure A3. Cropland, savannah/shrubs, and bare land were the three most dominant land cover types in 1994, while, cropland, savannah/shrubs and urban are the three dominant land cover types in 2014.[7] These patterns are consistent regardless the buffer zone considered. Therefore, the empirical analysis is restricted to the 25 pixels buffer zone. We then regroup the initial 7 land cover types into the three defined classes (natural, productive and degraded land) resulting in nine land cover changes (summarized in Table 1). A summary of the re-classified land cover types and changes is provided in Figure 2.

---

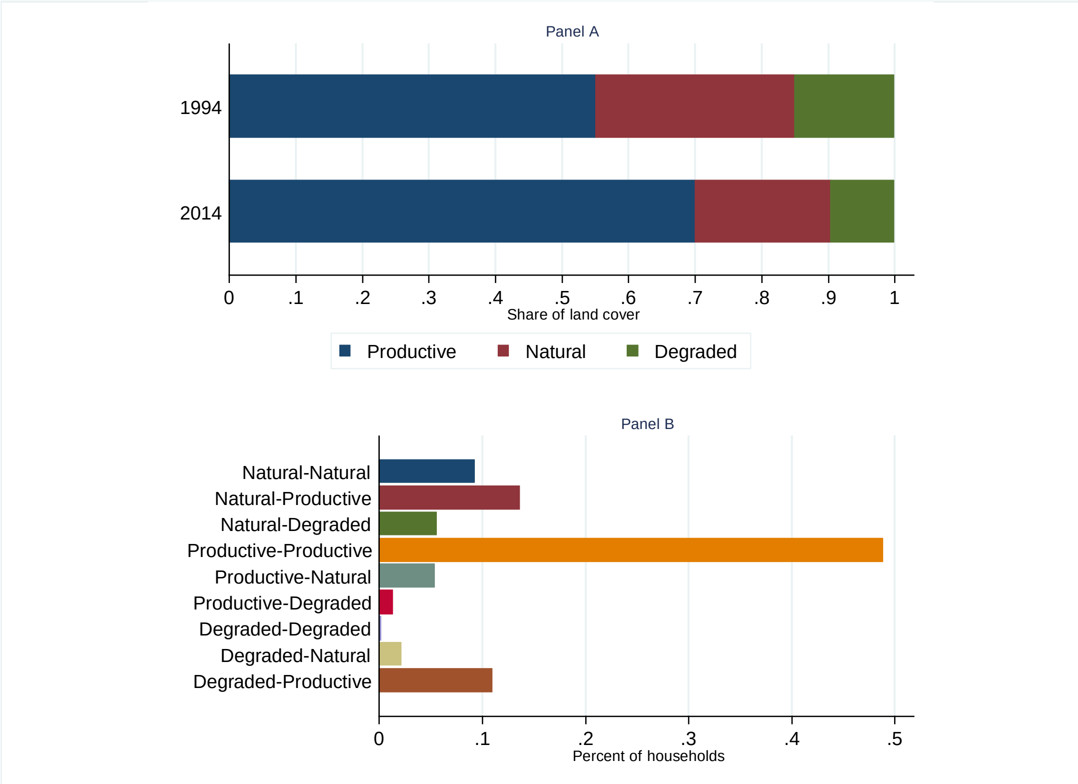
[4] Detailed about the program can be found here. Africa Research In Sustainable Intensification for the Next Generation (Africa RISING) Baseline Evaluation Survey in Ghana (GARBES) gathered detailed socioeconomic data from 1285 households residing in 50 communities in the Upper East, Upper West, and Northern regions.

[5] The indices are constructed using factor analysis (principal-component factor method) following Filmer and Pritchett (2001). The non-agricultural wealth index is constructed based ownership of various non-agricultural household durable assets and dwelling condition while access to basic services index is constructed based on self-reported travel time to get to selected infrastructure (such as asphalt and all-weather roads) and various services (such as weekly and daily market places and bus stops).

[6] Data are available from IPUMS International (Minnesota Population Center 2015) https://international.ipums.org/international/

[7] Shrubs and savanna are difficult to distinguish from google earth resulting in possible measurement errors.

Figure 2: *Re-classified land cover types (level and change) (25 pixels)*

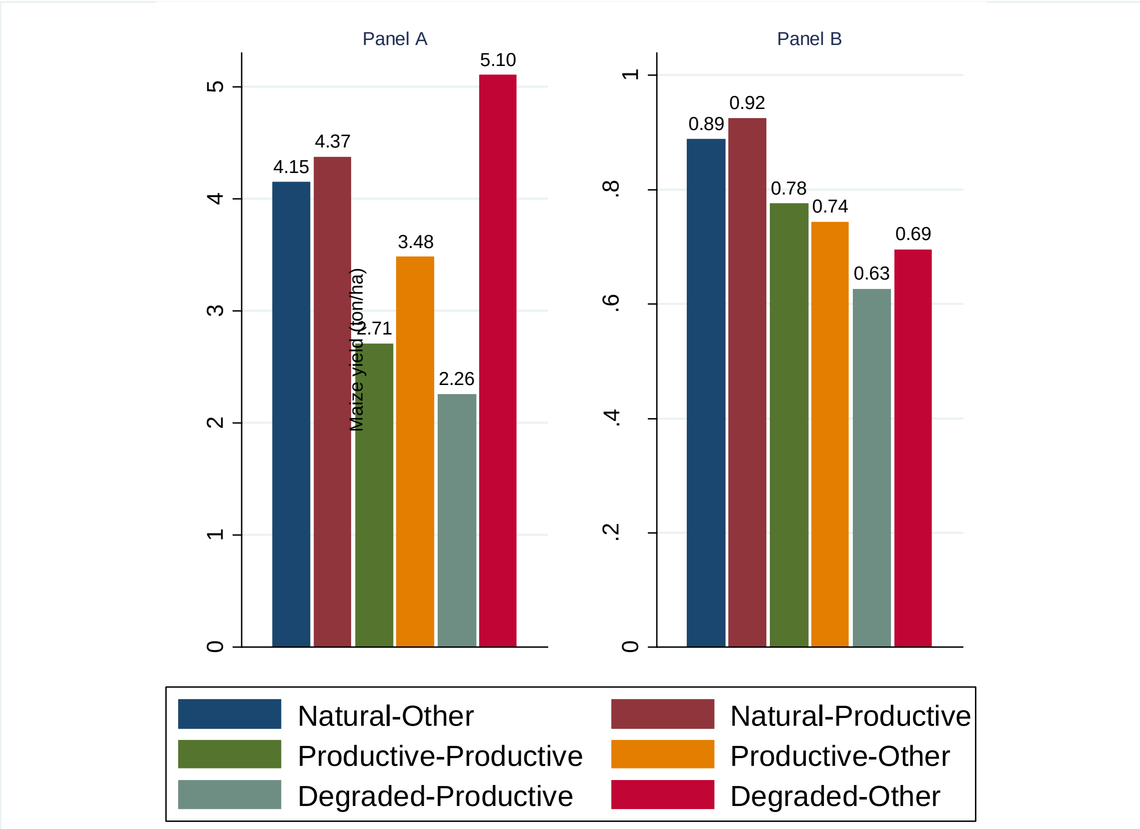


Productive cover accounts for more than 50% of land area in 1994, and reaches 70% in 2014. On the contrary, both natural cover and degraded land appears to have declined during the reference period, more so in the former case (Figure 2, panel A). Panel B summarizes the share of households in each of the nine possible land cover trajectories. About half of the households surveyed in 2014 reside in an area that that was crop land or urban in both 1994 and 2014 (Productive-Productive). Dominant are also land cover changes from natural cover to productive land (Natural-Productive) and from bare land to productive land (Degraded-Productive) (Figure 2, panel B).These patterns are indicative of the rapid expansion of extensive agriculture that is becoming more and more dominant in the landscape, to the point that farmers are starting to cultivate on less fertile soils that were previously bare land.

Given the relatively small sample size for some of the trajectories, and in the interest of improving precision of the estimates, we made further re-grouping of the land cover trajectories for the subsequent analysis. First, Natural-Natural and Natural-Degraded are grouped into one class (Natural-Other) that represents about 14% of the sample. Second, Productive-Natural and Productive-Degraded are grouped into one class (Productive-Other) representing about 7% of the study sample. Third, Degraded-Degraded and Degraded-Natural are grouped into one class (Degraded-Other) associated with 2% of the study sample. Figure 3 summarize our two measures of livelihood in 2014 - value of harvest and maize yield - by land cover trajectories for the 25 pixels buffer zone.

Setting aside the Degraded-Other trajectory (given the small sample size of 2%), households who live in areas with Productive-Productive and Natural-Other trajectories have the highest harvest and maize yield while those who live in areas that used to be bare land but turned into cropland or urban land scored the lowest harvest value and maize yield. A descriptive summary of the other socioeconomic variables used in the empirical analysis is shown in Appendix Table A1.

Figure 3: *Land cover change and welfare (25 pixels)*



4. Identification and Spatial Correlation

Agriculture is the main source of livelihood for more than 80% of the population in northern Ghana. As such, household welfare is highly correlated with agricultural production, which in turn depends on the characteristics of the landscape. Since our outcome variables (harvest value and maize yield) are likely to have a spatial dimension, modeling them without accounting for it would produce biased and inconsistent estimates (Paraguas and Kamil 2005). In addition, the spherical disturbances assumption of the ordinary least squares (OLS) would be violated if the model disturbances are spatially correlated. Finally, our pixel-based indicators of land cover change are expected to be spatially correlated as well, since by construction the buffer zones of neighboring households partially overlap.

To empirically test the existence of spatial correlation, we perform the Moran's I test (Moran 1950) of positive correlation between each of the suspect variables (the two outcome measures and land cover change variables) and its spatial lag[8]. The value of Moran's statistic ranges between –1 and + 1, with

[8] For a given (n x1) vector X, its spatial lag is computed by averaging the values of the variable for "neighboring" units and Moran's I (I) statistic is given by $\frac{n}{\sum_i \sum_j w_{ij}]} * \frac{\sum_i \sum_j w_{ij}(X_i - \bar{X})(X_j - \bar{X})}{\sum_i (X_i - \bar{X})^2}$ where n is the number of observations, w_{ij} parameterizes the distance between i and j, $\forall\, i, j$ and $w_{ij} = 0$ if $i = j$ and $\bar{X}$ is the mean of X. In this paper, w_{ij} is given by $1/d_{ij}$, where d is the haversine distance between households i and j, defined based on the latitude and longitude coordinates of i and j.

values near -1 (1) suggesting high negative (positive) spatial autocorrelation and values near zero implying minimal spatial autocorrelation. Under the null of no spatial autocorrelation, Morain's I has an asymptotically normal distribution with expectation $(-1/n-1)$.[9] A summary of Moran's tests (Jeanty 2010) in Appendix Figure A4 (for the two outcome indicators of rural livelihood) and Figure A5.a - Figure A5.c (for the land cover trajectories) shows the presence of positive spatial autocorrelation. Autocorrelation coefficients for the outcome variables range from 0.05 to 0.07, while those of the land cover change measures range from 0.08 to 0.19.

To explore the link between land cover changes and livelihoods while accounting for these identification challenges, we follow a nested approach and specify a spatial first-order autoregressive model (Drukker et al. 2013; Drukker and Prucha 2013; Kelejian and Prucha 1998; LeSage 1999), which also adds spatially-lagged values of land cover change as follows.

$$\mathbf{y} = \rho\,\mathbf{Wy} + \sum_{k=1}^{5} \beta^k \boldsymbol{LCC}^k + \sum_{k=1}^{5} \phi^k \mathbf{W}\boldsymbol{LCC}^k + \boldsymbol{\Lambda}'\mathbf{Z} + \boldsymbol{\varepsilon} \qquad (1)$$

$$\boldsymbol{\varepsilon} = \lambda\,\mathbf{M}\boldsymbol{\varepsilon} + \mathbf{u} \qquad (2)$$

Equation 1 is a cross-sectional model of livelihoods (measured by harvest value and maize yield) with $\mathbf{y}$ representing an $nx1$ vector and n representing the number of study households in GARBES; $\boldsymbol{LCC^k}$ is a column vector for one of the five land cover trajectories summarized in Section 2, with the sixth one - Degraded-Productive - used as a reference category; $\mathbf{Z}$ is an nxp matrix of conditioning variables where we control for progressively increasing number of household- and landscape-level covariates such as household demography, regional-level poverty trends and district-level population trends; $\boldsymbol{\varepsilon}$ is an $nx1$ vector of error terms allowed to be spatially correlated (as shown in Equation 2); $\boldsymbol{Z}$ is an nxk matrix of household-level socioeconomic covariates; $\mathbf{W}$ is an nxn spatial weighting matrix with elements w_{ij}, parameterizing the distance between households i and j, $\forall\, i, j$ and $w_{ij} = 0$ if $i = j$; $\mathbf{Wy}$ and $\boldsymbol{WLCC}^k$ are the (first order) spatial lags of the column vectors $\mathbf{y}$ ($= \sum_{j=1}^{n} w_{ij} y_j$) and $\boldsymbol{LCC}^k$ ($= \sum_{j=1}^{n} w_{ij} LCC_{ij}^k$), respectively.

Equation 2 models the disturbance terms as a spatially weighted average of the disturbances of the other study households; $\mathbf{M}$ is an nxn spatial weighting matrix with elements m_{ij} with $m_{ij} = 0$ if $i = j$ [10], $\mathbf{M}\boldsymbol{\varepsilon}$ is a spatial lag of $\boldsymbol{\varepsilon}$; and $\mathbf{u}$ is an nx1 vector of errors assumed to be independently and identically distributed. The parameters ρ and λ are the spatial lag and spatial error terms to be estimated[11], along with $\boldsymbol{\beta}$ (the main parameters of interest), $\boldsymbol{\Phi}$ and $\boldsymbol{\Lambda}$. A statistically significant $\widehat{\rho}$ suggests lag dependence in poverty while a significant $\widehat{\lambda}$ indicates spatial error correlation. We estimate Equations 1 and 2 using maximum likelihood (ML) (Drukker et al. 2013; Jeanty 2010) and, based on Lagrange Multiplier tests (Paraguas and Kamil 2015), we reject (could not reject) the null that $\widehat{\rho}$ ($\widehat{\lambda}$) is zero. In the next section, therefore, we present ML estimates of from Equation 1, and report Huber-White standard errors.

[9] See Wont and Lee (2005) for additional details on Moran's I test.

[10] $\mathbf{W}$ and $\mathbf{M}$ can be the same or different (for example, $\mathbf{M} = \mathbf{W}^2$). The analysis herein uses the same spatial weighting matrix ($\mathbf{W}$) for $\mathbf{y}$ and $\boldsymbol{\varepsilon}$. As is commonly done (for the sake of comparability of spatial weighting matrices with different parametrization of distance), $\mathbf{W}$ a row-standardized ($\mathbf{W}^*$) such that $\mathbf{W}^*\mathrm{x}\boldsymbol{T} = \boldsymbol{T}$, where $\boldsymbol{T}$ is an $nx1$ vector with elements $t_{ij} = 1\ \forall\, i, j$.

[11] See Kelejian and Prucha (2004, 1998) for assumptions and conditions about the spatial weighting matrix, the estimated autoregressive parameters, and the spatial lag variables and Drukker et al. (2013) for applications in Stata software.

5. Results

Table 2 shows estimates of the effect of land cover change on harvest value based on 25 pixels buffer zone. We use different specifications, where we first control for just land cover change and progressively control for household socioeconomic variables, agricultural inputs, region-level population and poverty (trends as well as initial levels), and finally elevation and market access (as measures of agricultural potential). Households living in areas that changed from natural cover in 1994 to productive cover in 2014 are associated higher harvest value than those who lived on a degraded land that turned into productive. The difference amounts to about 1,000 GHC ($950 in 2011 PPP terms). As mentioned, a shift from natural cover to productive cover is expected, at least in the short term, to improve the wellbeing of smallholder farmers who primarily rely on agriculture for their livelihood. The welfare of households associated to the Degraded-Productive change could be relatively low given the initial infertility of the soil, particularly unsuitable for agricultural production.

Similar effects appear when looking at the relationship between land cover changes and maize yield (Table 3). Households who reside in areas characterized by Natural-Productive change, with a Natural cover in both years, or with a Natural cover in 1994 and Bare land in 2014 (Natural-Other change) all appear to attain higher maize yield, relative to households in areas characterized by Degraded-Productive change, although the latter association is not significant in the more parsimonious specification (Table 3, column 6). These results seem to confirm that initial conditions matter, and that the land cover twenty years ago can be a good proxy for soil fertility today. Areas covered by vegetation in 1994 are generally suitable for agricultural production, while areas initially degraded are hard to restore.

Parameters of control variables show the expected sign, are generally significant, and consistent across different specifications. Total land area operated by the household is positively associated with harvest value, while it does not seem to be associated with maize yield. This results is consistent with several studies that have documented inverse land size-productivity relationship (Sen 1966; Deolalikar 1981; Carter 1984; Barrett 1996). Female headship, distance to basic services, and soil erosion are all negatively associated with agricultural production and productivity, while household size, non-agricultural wealth, and agricultural inputs (use of hired labor and irrigation) show a positive correlation with the outcome variables.

6. Conclusion

The livelihoods of households living in northern Ghana are strongly interdependent with landscape characteristics. Population and welfare dynamics in these regions are affected by the changes in land cover that modify availability and ecosystem services of natural capital, while in turn exerting pressure on the natural resource base. Therefore, understanding these linkages is crucial to design welfare-improving policies for local communities aimed at restoring the environment over the long term.

By combining remote sensing data with geo-referenced household surveys we propose an innovative methodology to observe the interlinkages between changes in landscape and household livelihoods. We show how GPS information on parcels' location collected in household surveys can contribute to refine land cover classification procedure compared to more traditional ground-truthing approaches. In addition, we demonstrate how unsupervised classification methods can be used to map land cover in northern Ghana in 1994, bypassing the need of historical ground-truthing points. Finally, we employ a spatial regression analysis to examine the links between historical land cover change and current rural livelihoods, as proxied by maize yield and harvest value, while controlling for spatial correlation.

Through mapping of land cover distribution across northern Ghana in both 1994 and 2014, we observe a large expansion of land devoted to crop cultivation over the last twenty years, which mainly replaced natural vegetation areas. Bare land has also increased, even though at a lower extent than cultivated areas. This is likely caused by practices of agricultural extensification rather than intensification. Regression results show how households located in areas that turned from natural (forest, shrubs, savannah, or water bodies) to productive covers (cropland and urban areas) over the last twenty years are associated higher crop production and productivity today, relative to those living in current productive areas that were previously degraded (or bare land). These findings suggest that land initial conditions matter for agricultural production and livelihoods, and that the cover type twenty years ago seems to be a good proxy for soil fertility today. Our study confirms that degraded bare soils are very difficult to restore as well as render fertile and productive again. Therefore, our findings call for effective conservation practices aimed at restoration of the soil nutrient content that prevents land degradation.

It is worth noting that the observed positive impact of the natural-productive change may vanish in the long term, when the increased scarcity of natural resources will begin to play a detrimental role for local livelihoods. Furthermore, the overexploitation of cultivated areas that prevent the regeneration of soil nutrients will lead to additional degradation over the long run. In recent years these concerns are indeed the driving force behind the increased focus on the need to sustainably intensify the smallholder agricultural sector, in order to balance the trade-off between productive land and natural stock, allowing a self-regenerating system. The medium-to-long term effects of different land cover changes merit further consideration beyond the scope of this study, spurring further research.

Area estimation by integration of line transect sampling and multi-source remote sensing data

Wu Bingfang, Zhang Miao, Li Mingyong, Zheng Yang
Key Laboratory of Digital Earth Science,
Institute of Remote Sensing and Digital Earth,
Chinese Academy of Sciences, Beijing 100101, China
Keywords: Crop area estimation, line transect sampling, multi-source remote sensing

DOI: 10.1481/icasVII.2016.g42e

Abstract:

Background and methodology:

Crop area estimation is one of the key components for agricultural statistics. Crop identification is a basis for area estimation for long time. Plenty of methods and algorithms for crop classification have been developed or improved during the last three decades. However, Pixels in remote sensing data do not always correspond to a single crop type or field. Mixed pixels are commonly found in agriculture regions with small crop fields and always impact crop classification accuracy. Therefore, remote sensing based crop classification without ground survey is not sufficient.

To overcome the shortcomings of area estimation based on classification, a crop planting and type proportion method (CPTP) (Wu and Li) was developed for CropWatch to estimate crop acreage, which crop planting proportion was derived from optical satellite data and crop type proportion was derived from GVG transact sampling survey. GVG surveying system which integrated a GPS receiver, a video camera, and a GIS analysis system was invented and developed to survey the crop type proportion along transact sampling lines. Crop area for each crop type can be calculated using the following equation:

Crop area = Arable land area * cropped arable land fraction * crop type proportion

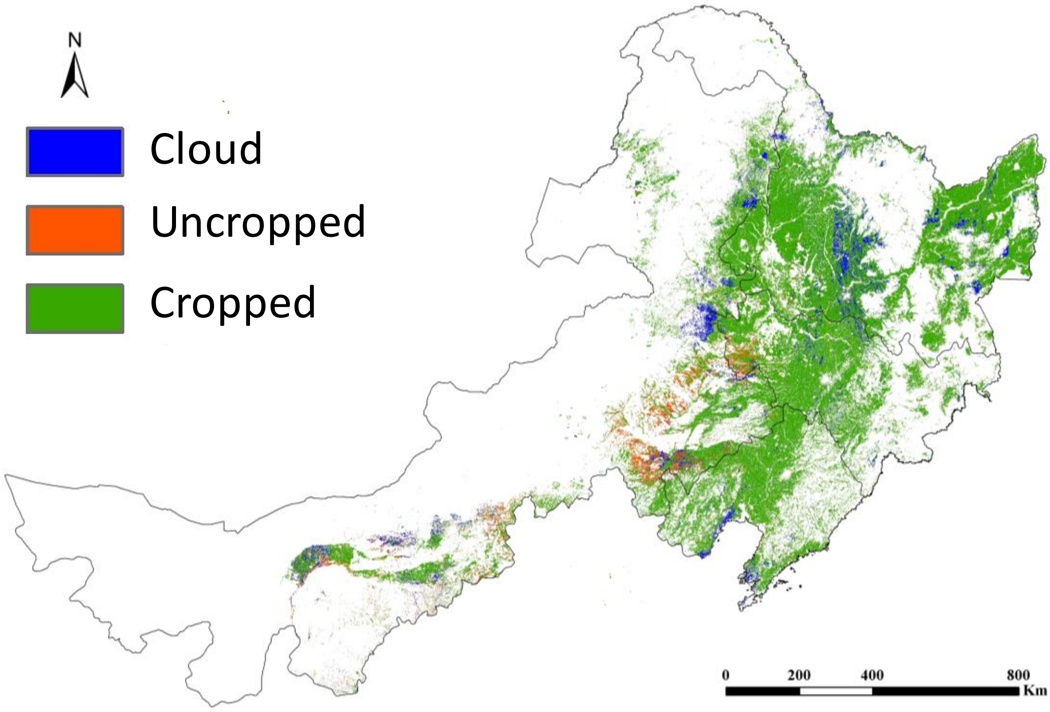
The four provinces – Heilongjiang, Jilin, Liaoning, and Inner Mongolia were selected as the study area. Field sampling was carried out from August 1st to 15th according to the sampling frame. Arable land area was derived from the arable land mask extracted from ChinaCover 2010 (a 30m resolution land cover dataset for whole China). The objective of this research is to use multi-source satellite data to overcome the impacts by cloud covers to improve the accuracy of cropped arable land fraction.

Images from China High resolution Earth Observation satellite (GF-1), China Environmental Satellite (HJ-1), Landsat 8 as well as Sentinel-2 Satellites were acquired during the summer crop growing season. Decision tree was applied to all the images for cloud extraction, cropped and uncropped arable land separation. Independent field samples were used for classification accuracy assessment based on the derived confusion metrics.

Results:

1.Cropped and uncropped arable land separation

Classification results showed that total arable land area is 35617.3kha, of which 94.2% is cropped; 93.5% of upland and 99.3% of paddy fields in the study area are under cultivated. Uncropped fields mainly locates at southeastern Inner Mongolia, Chifeng and Tongliao.



The independent validation results show high accuracy in separating cropped and uncropped arable land. Accuracy assessment in Inner Mongolia presents slightly lower than that in Heilongjiang province. The overall classification accuracy for Inner Mongolia and Heilongjiang was 97.8% and 99.3%, respectively.

Table 1 Accuracy of cropped and uncropped arable land mapping from confusion metrics

Province	Cropped arable land		Uncropped arable land	
	Producers' accuracy	User's Accuracy	Producers' accuracy	User's Accuracy
Inner Mongolia	97.3%	99.8%	99.3%	92.9%
Heilongjiang	99.2%	99.9%	99.6%	97.6%

2.Cropped arable land fraction

Crop type proportion for each county was estimated based the 39025 collected field photos, and was then interpolated and aggregated to crop type proportion zone, and provinces. Crop type proportion for the four provinces in 2015 and 2016 was compared. (Table 2). The proportion of maize in Inner Mongolia and Heilongjiang in 2016 is lower than that in 2015, while that in Liaoning and Jilin is slightly higher. The proportion of maize in Inner Mongolia was 40.99%, down by 3.12% compared with the same period of last year. Correspondingly, the proportion of soybean increased by 2.2% and that of spring wheat increased by 0.94% in Inner Mongolia. The proportion of maize in Heilongjiang was 45.61%, down by 0.42% and the planted proportion of rice, soybean and spring wheat was increased by 0.57%, 0.25% and 0.06%, respectively. The proportion of maize in Liaoning Province (54.84%) increased by 1.93%, while that of rice and soybean decreased by 12.23% and 3.52%, respectively. The proportion of maize in Jilin province increased by 0.5%.

Table 2 Crop type proportion for the four provinces in 2015-2016 (%)

Province	Maize		Rice		Soybean		Spring wheat		Other crops	
	2015	2016	2015	2016	2015	2016	2015	2016	2015	2016

Inner Mongolia	44.11	40.99			8.41	10.61	9.21	10.15	38.27	38.25
Liaoning	52.91	54.84	13.42	12.23	4.47	3.52			29.21	29.41
Jilin	62.64	63.14	13.06	14.29	5.62	5.78			18.68	16.78
Heilongjiang	46.03	45.61	26.55	27.12	22.53	22.78	1.28	1.34	3.61	3.15

3.Crop area inter-annual variation

Table 3 Estimated crop area for the four provinces in 2015-2016 (Kha)

Province	Maize		Rice		Soybean		Spring wheat	
	2015	2016	2015	2016	2015	2016	2015	2016
Inner Mongolia	3258.6	3036.5			621.2	786.1	680.7	751.7
Liaoning	2572.5	2587.2	652.3	577.1	217.2	166.0		
Jilin	3446.6	3494.4	718.7	790.9	309.3	320.1		
Heilongjiang	5180.6	5077.2	2987.7	3019.1	2536.2	2535.8	144.3	149.6
Sub total	14458.3	14195.3	4358.7	4387.1	3683.9	3808.0	825.0	901.3

In terms of planted area, maize in Inner Mongolia decreased by 222.1 thousand hectares, and maize area in Heilongjiang Province was down by 103.4 thousand hectares from 2015. At the same time, maize area in Liaoning Province and Jilin Province increased by 14.7 and 47.8 thousand hectares, respectively. In total, 262.9 thousand hectares (about 394.4 million mu) decrease of maize area in the four provinces was observed.

Soybean acreage in the four provinces totaled at 3808.0 thousand hectares, an increase of 124.2 thousand hectares, of which Inner Mongolia soybean acreage increased by 164.9 thousand hectares, while soybean acreage in Liaoning Province decreased by 51.2 thousand hectares. Soybean planted area in Jilin increased by 10.8 thousand hectares, while Heilongjiang soybean area in Heilongjiang is almost same as the 2015.

Discussion and conclusions:

The changes in decreased maize area are mainly due to the policy changes released by China Ministry of Agriculture which reduce the subsidy for maize cultivation. It is expected that maize area in the four provinces will decreased by about 700 thousand hectors. However, the decreased maize area in 2016 is estimated at 262.9 thousand hectors, indicating that only 40% of expected reduction of maize planted area was achieved. Soybean area increased by 76.3 kha in the four provinces which leads to a slightly increase of soybean planted area nationally in 2016, the first inter-annual increase in more than a decade.

By integration of images from multiple wide swath sensors, sufficient data source can be acquired for cropped and uncropped arable land mapping. Even though, there are still some pixels invalid due to the continuous cloudy weather over the area. In the future, the integration of optical and SAR data could potentially improve cropped and uncropped arable land mapping accuracy.

Crop type proportion sampling used in this research is still time-consuming, labor intensive and costly. Crowd Sourcing Geographic Data will dramatically improve the efficiency and the GVG APP will be upgraded to allow any user to upload the field photos.

MODELLING FOOD, NUTRITION AND AGRICULTURAL MARKETS: UNDERSTANDING DATA NEEDS AND DISCOVERING NEW OPTIONS TO MEET THEM

Session Organizer
B. Schmidhuber | FAO | Rome | Italy

ABSTRACT

This session will be organized around two major streams of interest. The first will focus on needs and challenges, the second will try to identify efficient solutions that allow data practitioners to live up to these challenges. 1. What are the needs? Analysts and model builders in the area of food , agriculture and nutrition have long been struggling with a number of large and persistent challenges. These challenges arise from the ever greater data needs for ever more complex modelling tasks, the need to combine data of different provenances into a consistent overall framework, to update existing series fast and efficiently, to document their specificities and, more generally, to maintain a comprehensive metadata archive. Without finding practical solutions to these challenges, modelling and data analysis more generally, will become increasingly burdensome and the associated costs may put valid and important modelling tasks into jeopardy. Eventually, this could undermine the general commitment to evidence-based decision making. 2. How can we live up to the challenges? The second part of the session will focus on concrete solutions and specific tools to address the challenges. It will take stock of existing tools and solutions and focus on synergies, "share-ability" and interoperability to address the needs of a broader community of data analysts and modellers. It will look at communalities between solutions, present platforms to share data and modelling code and, if and where possible, identify common solutions to common problems. Importantly, it will try to match the supply from data providers with the demand from data users. Contributions will be sought from practitioners in the following area: Partial (agricultural) and general equilibrium modellers, designers of statistical data warehouses, developers of apps, tools, and software sharing platforms. On the supply side, contributions will be sought from FAOSTAT, the FAO Statistical Data Warehouse (SDW), the UN, the World Bank, the IMF, and selected national authorities such as USDA. On the demand side, modellers and data analysts will present both their demands and their own solutions, which often reflect a lack of relevant supply. These include, inter alia, contributions from GTAP, AGLINK/COSIMO, ENVISAGE and MIRAGE.

ABSTRACT

Pork is the main meat for Chinese consumer, the price of hogs has a significant impact on the price of agricultural products and the Consumer Price Index(CPI), and it has always been the focus of the government and the academic community to stabilize the price of hogs. In this paper, we use the intermediate consumption survey data from National Bureau of Statistics of China, by using the machine learning algorithm, to predict the price of hogs in each provinces in the first half of year 2016.The result of this research would be used to lay the foundation for more accurate and efficient policy control and market regulation.

Keywords: hog prices, intermediate consumption survey, machine learning algorithm

1. INTRODUCTION

Pork is the main meat for Chinese consumers. In 2015, The production of pork reached 54.87 million tons, about 41 kg per person ,accounting for about 65% of the total output of meat. In recent years, The hog price fluctuates frequently. On the one hand ,the producers may face more risks in the market, on the other hand, the quality of people's lives would be affected. Therefore, The hog price controlling mechanism for stabling the hog prices and reducing the volatility of the hog prices become a hot topic for government, the society and the scholars.

Most studies on the mechanism for producing hog price at home and abroad focus on: Effects between supply and demand, Production costs, the level of money supply, the international market price transmission, the scale of production and epidemic disease etc. The main research methods include Cobweb Theorem, Vector Autoregression (VAR) ,Neural Networks(NN), Grey System etc., based on the analysis of the seasonal, cyclical and trend fluctuations in the price of Hogs. For example, Ying Qi, Jie Li (2007) considered that the relationship between supply and demand, the deviation of production decisions, the cycle of hog production, Consumption habits of the residents are the main causes of hog price volatility. By using the method of Co integration analysis, with the monthly data from 2002 to 2006,Fang Wang (2009) found out that the long term influence factors of pork price, sorted by impact strength, are the price of corn, piglet, hogs and pork. Feng Luo et al. (2009) indicated the long-term equilibrium relationship between the Chinese and the international prices of agricultural products by using the Co-integration Analysis and Impulse Response Function ,with the data from 2003 to 2008 . LiXiang Zhang et al. (2011) found the high degree of integration in the hog chain market by using the Co integration Analysis to study the price data of corn, feed, piglets, pig and pork, from January 2003 to July 2010, and the prices of Piglets and hogs are the core of the whole chain by the Granger Causal Relation Test. YongBo Ma (2011) considered the price volatility of agricultural products mainly came from the supply, cost-push, the money supply and international agricultural price transmission and so on. GuoChang Xin(2013) found the supply of cattle products can provide a stronger affect on the prices than the demand did, and the supply, demand, production costs, the price of alternatives, macro-control can cause significant different affect on the hog price by path, intensity and period.

Since the 1990s, the scale production of poultry breeding industry have developed rapidly in China, the marketable fattened stock from the scale-producing units(units that have the size of the marketable fattened stock more than 1000) accounts for about 17% of the total amount of the marketable fattened stock. In recent years, the yield of Chinese pork goes up periodically , there were inflection points once every 5-8 years. In the last 15 years, the inflections occurred in the year of 2007,2011 and 2015.

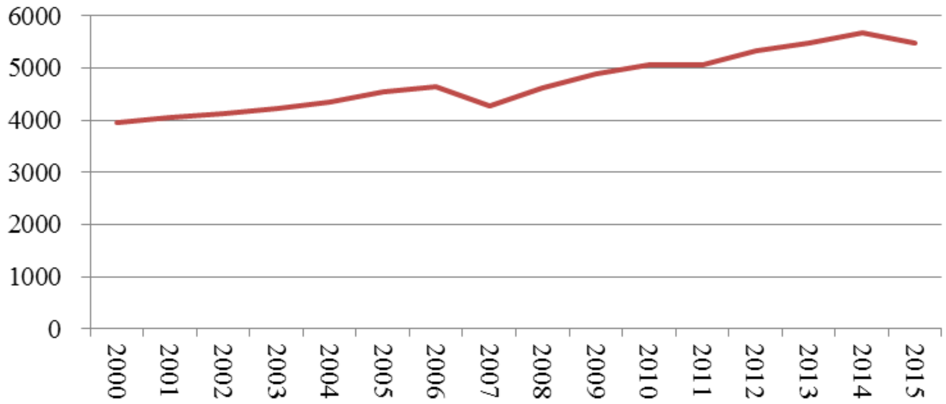

Figure 1: *The yield of Chinese pork,2000-2015 (Unit: 10,000 tons)*

The hog price presents the obvious periodicity and seasonality. From a monthly point of view, the price is usually lower from April to May and higher from January to February. Viewed annually the hog market price has a fluctuation cycle of 3-5 years, and recently the cycle became shorter.

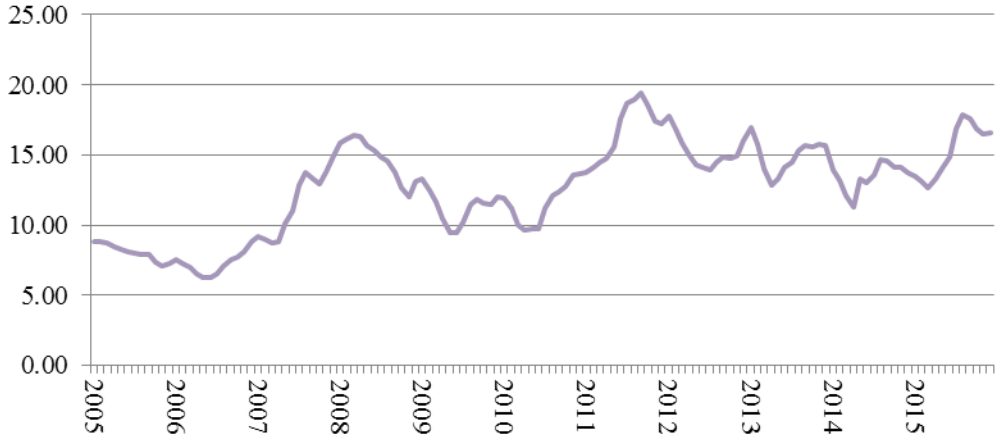

Figure 2: *The Chinese Hog market price,2005-2015 (unit: yuan / kg)*

There are four surveys related to hog in the Rural Division of the National Bureau of Statistics of China including the animal husbandry production survey (quarterly), the agriculture, forestry, animal husbandry and fishery output survey (quarterly), the agricultural products price survey (quarterly or monthly) and the intermediate consumption survey (semiannually). The relevant statistical indicators include the amount of output, slaughter and feeding; the output value and added value; the producer price and the market prices; the feeding costs, costs of piglets, labor costs, operating expenses and so on. In order to adapt to the industrial development of the hog production ,the National Bureau of Statistics continually reforms and improves the statistical investigation system and sampling methods to better reflect the production and development of hog.

2. EMPIRICAL ANALYSIS

2.1 Model Selection

In the study of forming mechanism of the agricultural products prices, the methods of Cobweb Theorem, the VAR model, the neural networks and the grey system all have been widely used and achieved fruitful results. In the empirical study, the quality of data has a significant impact on the results. The study of the hog price has its special difficulties: firstly, with the rapid development of industrialization and the necessity of environmental protection, the picture of hog producing changes rapidly, which makes the analysis of the long-term hog prices become difficult. Secondly, Since the producing and consuming of hogs have the attribute of periodic and seasonal characteristics, the relationships between the hog price and its influencing factors are relatively complex, meanwhile, the function between the hog price and its influencing factors are different on path, intensity and cycle ,there are both the positive and reverse conduction between the hog price and its influencing factors and the transmission intensity is also different. Thirdly, the quality of the data itself affects the results. With the different sources of data and differently processing methods, the scholars may draw different conclusions from the same object. There are a large number of high quality data in NBS. To develop and utilize these data has always been an important issue of our work. There are about 2000 sample units in the intermediate consumption survey of hogs nationwide in China, Each year about 1/5 of the sample units are rotated. There are two surveys for one year, one is held in the first half of the year and the other held in the second half. The interview of the survey covers the main information of each sample unit, including address, the hog slaughter, the sale price ,the piglets cost ,the feeding cost, the fuel cost, the water cost, the electricity cost, the labor costs and so on. It could be theoretically and practically instructive to predict hog price movements by using these data.

On the basis of the represent above, this study based on samples which have many variables and been observed in a short-term period. Considering the characteristics of the data and the applicability of the model ,we decide the research method of this paper is using the data of the intermediate consumption survey, applying the machine learning method (the four models of Decision Tree, Support Vector Machine ,Neural Networks and Random Forest) to construct the forecast model to forecast the price movements of hogs, and then put forward some specific suggestions.

2.2 Variables Selection and Data Processing

To form the index system from the intermediate consumption survey data we preliminarily select the price of hog as the explained variables, and the explanatory variables include the price of purchased piglets, the price of since numerous bred piglet, the price of concentrated feed, the price of crude feed, the price of water fees, the price of electricity fees, the price of gasoline, the price of diesel, the price of coal, the price of hired worker, the price of family labor and the cost of the epidemic prevention.

Table 1: *preliminary selection of variables*

Name	Shortcut	Type
the price of hog	y	explained
the price of purchased piglets	gzx	explanatory
the price of since numerous bred piglet	zfzx	explanatory
the price of concentrated feed	jsl	explanatory
the price of crude feed	csl	explanatory
the price of water fees	sf	explanatory
the price of electricity fees	df	explanatory
the price of hired worker	gg	explanatory
the price of family labor	jg	explanatory
the cost of the epidemic prevention	Fy	explanatory

the price of gasoline	qy	explanatory
the price of diesel	cy	explanatory
the price of coal	m	explanatory

The intermediate consumption survey began in 2002 in the Rural Survey of the National Bureau of Statistics. Taking into account the sample rotation and the characteristics of the hog production in different periods, we selected the data from 2011 to 2015 into the analysis. The objects of the intermediate consumption survey are households or units, considering the sample rotation and the different characteristic of hog production in different regions, we selected the provincial average prices into analysis after comparison. Therefore we get the final analysis data of a total of 10 cycles from 2011 to 2015 and the provincial average prices.

Before carrying out the machine learning method, we need to translate the time series data into the panel data. We tested for the correlation coefficients between the hog prices and all the influential factors in the cycles (T-4,T+4) by applying the Pearson Correlation Coefficient Test. Then we get to a conclusion that the price of purchased piglets, the price of concentrated feed, the price of water fees, the price of electricity fees, the price of hired worker in the period of T-1 have the biggest correlation with the price of hog, while the correlation between the price of self breeding piglets, the price of crude feed, the price of gasoline, the price of diesel, the price of coal, the price of family labor in period T-1 did not correlate significantly with the price of hog. Hence we put a one-cycle-advance on each influencing factor then matched with the hog price to make up the training and testing samples for the machine learning model , and impact factor data of the last cycle was used to predict the hog prices of the coming cycle.

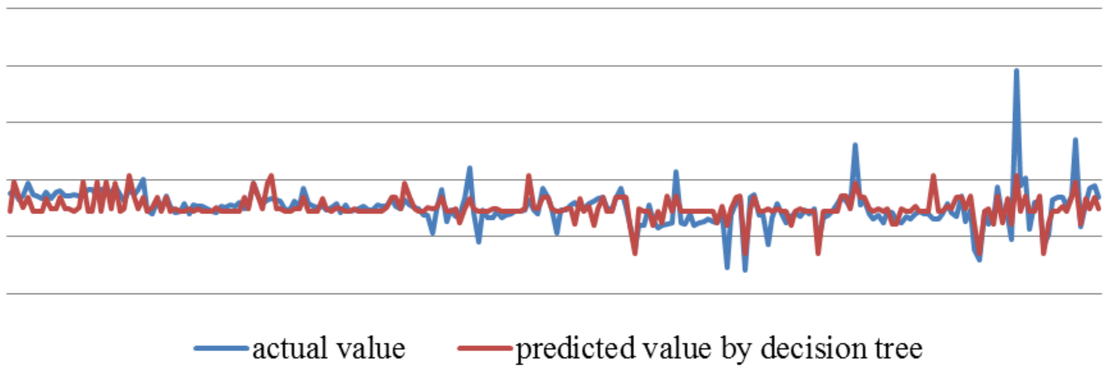
Table 2: *The correlation test between the price of hogs and the T-1 influencing factors*

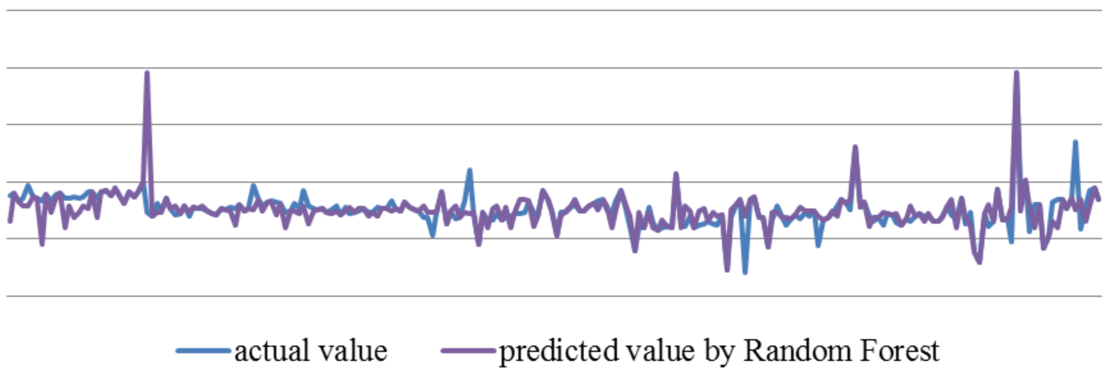
Name	Coefficient	P Value
the price of purchased piglets	0.837	0.0000
the price of concentrated feed	0.867	0.0002
the price of water fees	0.513	0.0307
the price of electricity fees	0.551	0.0312
the price of hired worker	0.732	0.0237
the price of since numerous bred piglet	0.637	0.1017
the price of crude feed	0.523	0.0749
the price of gasoline	0.314	0.2022
the price of diesel	0.350	0.2812
the price of coal	0.211	0.3714
the price of family labor	0.273	0.0747

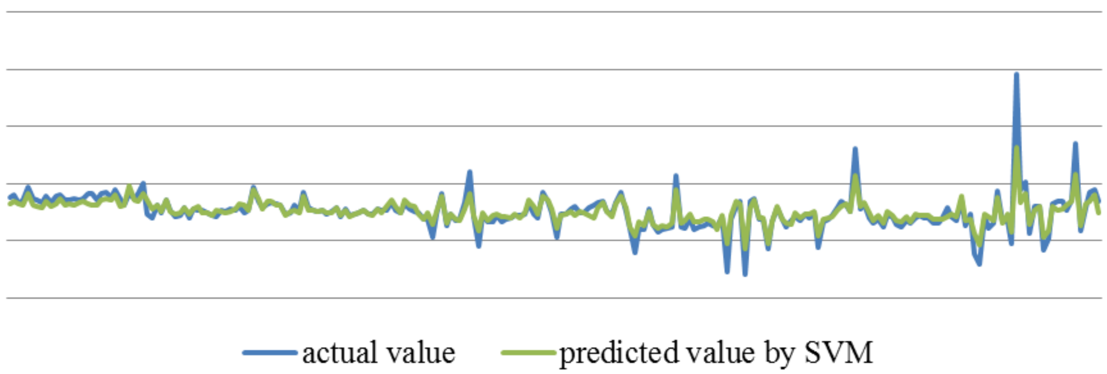
the cost of the epidemic prevention	0.416	0.0814

2.3 Model Implementation

The training and test data are used to model in R3.2.4 by the models of the Decision Tree, Random Forest, Support Vector Machine and BP Neural Networks. The program code is shown in the Appendices. The fitting curves of the four models are shown below.







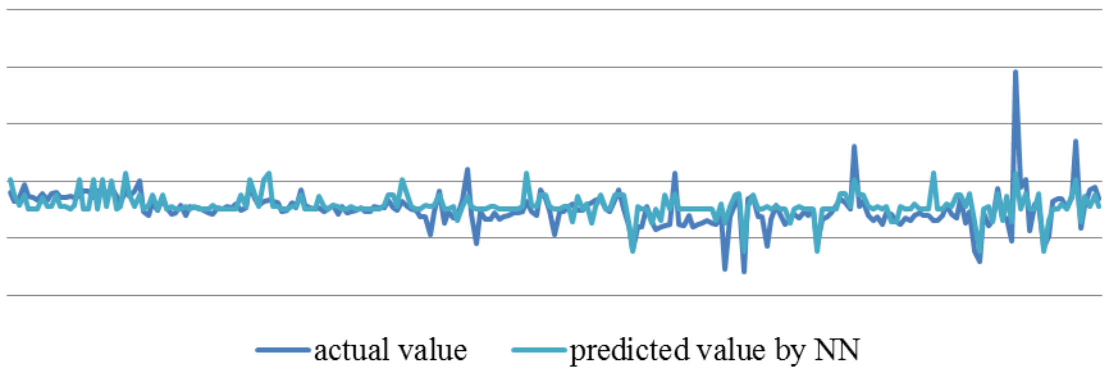


Figure 3: *The fitting curves of the four models*

By applying the 10-fold cross validation, we get the Root Mean Square Errors (RMSE) of the four models decision tree, random forest, support vector machine and BP neural network are respectively 0.2214, 0.0125, 0.3756 and 0.3392.This shows that the four models have good fitting effects and it is feasible by using these models to predict the hog prices, By comparison of the values of RMSE, in these four models, the Random Forest model is relatively better. Finally, we used the 10th period data of the influential factors to predict provincial hog prices in the first half of 2016,then calculated the national price index of the hog which was about 113.7.

3.CONCLUSIONS AND RECOMMENDATIONS

Firstly, this paper shows that it is feasible to use the intermediate consumption survey data such as the cost of piglets, feed, operating and labor etc. to predict the price of live pigs by applying the machine learning algorithm.

Secondly, this paper provides a reference of building a price forecasting model in multi regions and shorter periods with the exploration of forecasting the price of hogs in many provinces and the semiannual.

Thirdly, since the obtainable data is limited, this article has not yet taken the effect of market demand, money supply level, international market price transmission, alternative goods prices, the macro-control policy etc. into scope of study. we will continue to explore the impact of these factors on the price of hog in the next stage.

Finally, by looking into the leading indicators we can forecast the price movements of hogs in advance of one or several cycles. In addition, analysis on the price movements of the different regions with the leading indicators could help to make more accurate and sensitive policy and market regulation.

ABSTRACT

India being a pre-dominantly agricultural country, agricultural crops form the major factors contributing to the Gross Domestic Product (GDP). The author reviews and develops various non-Gaussian as well as non-linear time series models for prices of agricultural crops. The study also aims at predicting future prices, so as to enable the scope of agricultural crops as profitable means of cultivation. Another aspect is to assess the global threats and reasons for the decline in prices in the post liberalization period in India. We also give special emphasis on the external factors consequent to India's adherence to the W.T.O. agreement and suggest some remedial measures to make Indian agricultural sector profitable to the farmers as well as the nation.

In Part1, a detailed analysis of the GATT rules and multilateral agreements, which are relevant to natural rubber and coconut, is done. An insight into the developments in the international market and various policy initiatives during the last decade is done. The need for productivity enhancement, effective production, quality improvement for export competitiveness, steps to be taken for value addition of rubber, etc are pointed out. It is found that the price of coconut oil depends on the prices of other vegetable oils. The coconut industry in the world is always susceptible to the pressure from low oil seed prices and increased availability of cheap oils like palm oil, soybean oil etc. The widespread incidence of coconut mite and root wilt disease as well as recurring drought during recent years affected coconut sector to a great extent. Rather than W.T.O. effects, lack of productivity and adequate market connectivity, outdated trading practices, etc caused havoc in this sector. However, the tea, coffee, pepper, cardamom etc are facing serious problems.

In Part 2, we have developed some non-Gaussian time series models. It was found that most data on agricultural crop prices/indices are marginally non-Gaussian and hence time series models

with non-Gaussian marginal distributions are to be developed for proper modeling. First order autoregressive models are sufficient and parsimonious in modeling agricultural crop prices/indices. Models with marginal distributions like Cauchy, Stable, Linnik, Geometric Linnik, Generalized Laplace, Marshall-Olkin Exponential and Weibull distribution are appropriate in this regard. Non-linear models like AR(p)–ARCH(q) models can best reflect the volatility and changing conditional variances. The best non-Gaussian time series model for agricultural crop prices is one with Generalized Laplacian marginals. Cauchy and Linnik autoregressive models are also satisfactory. With regard to modeling volatility and varying conditional variances with regard to time, ARCH models are more suitable. Only short term forecasts are meaningful as prices depend on various non-random extraneous factors like govt. policies at national and international levels. Also some computer programs are developed for simulating the models and estimating the parameters. In the concluding section, the findings and conclusions are summarized.

Keywords: ARCH Models, ARMA Models, WTO regime, Natural Rubber, Coconut.

1. Introduction

The changed economic order in the context of globalization and liberalization of world trade in agriculture has opened up new vistas of growth. Spices sector is one of the key areas in which India has an inherent strength to dominate the global markets. The world's romance with Indian spices continues unabated. India is the largest producer, consumer and exporter of spices in the world. The present annual production of spices in India is 3.0 million tons from over 2.5 million hectors. About 8.5% of India's export earnings from agricultural and allied products come from spices. India is a significant exporter of spices and plantation produces.

India occupies the 3rd position in production and 4th in consumption and 1st in terms of productivity of Natural Rubber (NR). Of the global production of 71.1 lakh MT India's share is only 6.4 lakh MT in 2002. The annual growth is at the lowest at 0.08%. Kerala accounts for 84% of the rubber production in India. In India about 1.89 million hector of land is under coconut cultivation. At the rate of 6776 nuts per hector India produces about 12822 million nuts a year. Though the share of Kerala state was 56% in 91-92 the share has come down to 48% in 2001 and 2002. The productivity has also come down to 5895 nuts per hector. The major products are coconut oil and coir products. India contributes 25% of the world pepper production with about 3.2 lakh million tons in 2002.

Since agriculture is always at a loss, the area under cultivation of many crops is declining. The productivity of all the crops is showing a slowing trend. It's also a fact that we produce comparatively more but do not realize proportionate revenue from these commodities in the international market. In view of the existing open market approach under the provisions of World Trade Organisation rules coupled with the Regional Trade Agreements it is apprehended that free flow of these commodities from international markets would badly affect the farm economy of the country. Though market access for our commodities to international markets is technically feasible, technical barriers to trade might become an impediment unless they are professionally addressed to at the right time through appropriate mode. Though all these commodities are not covered under the Agreement on Agriculture of WTO, there are GATT negotiations on these.

2. WTO and Agricultural Crops in India: Challenges and Opportunities

The rigorousness of the applicable WTO disciplines increase manifold if they are agricultural products as compared to the 'non-agricultural'. Non-agricultural products in the WTO, are not the same as industrial products and include products and product groups which traditionally or in context of other international agreements/ understandings are agricultural. The prime examples being products like natural rubber, coir, jute and even fishery or marine products. This is so because the WTO Agreement on Agriculture (AOA) applies on a list of products specifically mentioned in the Annex to that Agreement. By default therefore, any product that is not included in the Annex to the AOA, such as those mentioned above, fall within the ambit of the 'general' provisions of GATT and related WTO agreements.

The main agricultural products of concern in this study are: (i)Coconut & products such as copra and coir, (ii)Natural Rubber; (iii)Spices – pepper, cloves and cardamom; (iv)Cashew; (v)Tea; (vi) Coffee.Here we attempt to raise certain issues of concern to India's negotiating position/ options in WTO for these products/ product groups. Identification of possible developmental mechanisms and their examination under applicable WTO disciplines is necessary to throw up crucial development issues that need to be examined and debated. Formulation of a coherent and comprehensive policy structure for the long-term development of supply capacities in India of these products is only possible through such a structured approach.

2.1 Natural Rubber

Kerala holds a share of 92% in Natural Rubber production in India. World trade in natural rubber both in terms of the main suppliers and the main importers or users is very well defined and limited.Thailand, Indonesia,Malayasia, Singapore,Ivory Coast,USA, India constitute the principal suppliers of natural rubber.The principal importers are USA,China,Japan,Malayasia and Korea. Of these China imposes 20% MFN applied Tariffs where as USA, Japan and Malayasia do not impose this tariff.

Other than tariffs, the important WTO disciplines that apply to the trade of natural rubber are the possible non-tariff barriers – in terms of standards and other technical requirements - and the subsidies that may be provided by other exporting countries. Finally, an issue for discussion would be the implications under WTO agreements of possible development measures that the States and Central Government in India may put in place for the development of the industry. It may be verified that tariffs are not the most significant barriers to trade, the applied tariffs in the main markets are fairly low, ranging from 0% to 20%. Since this is also the range for the bound tariffs in these countries, the scope for negotiating the reduction of these tariffs for further improvement in the market access is limited. The present applied tariffs in India, which are amongst the highest in the main producing and exporting countries, is affording the needed protection in the domestic market for the present.

The main issue concerning Natural Rubber in India is the volatility of the international price of rubber, making it difficult to formulate a steady and long term policy. Unlike other major producers like Malaysia, Indonesia and Vietnam, where substantial state support for exports are provided no such structured incentive is provided for rubber exports from India. Governmental attempts at price stabilization has also at best had mixed results and difficult to justify as a continuous policy support mechanism, particularly when the international prices move up. The alternative to market interventions is a sustained and long term WTO compatible development policy for the sector without a specific focus on exports. This would promote a competitive industry in general.

2.2 Issues of concern

Natural Rubber in India is treated as an agricultural product, but in the WTO it is not covered by the disciplines of the Agreement on Agriculture (AOA). A move seeking renegotiation in product coverage will require significant negotiating capital – and just re-designating Rubber as an agricultural product will not allow India the right to enhance the present bound rates. For enhancing the bound rates on several agricultural tariff lines including rice and wheat, India had to negotiate under the Article XXVIII of GATT 1994 and pay significant compensation to the affected countries. This intervention is urgently needed since rubber prices had reached the lowest level of Rs.90/- per kg in the global as well as Indian markets in January 2016.

There is a need for balancing the consumer interest of NR users in India with that of the producers. Therefore, prohibitive import duties will not be supportable in the long run. The solution has to be targeted towards the sustained development of the Rubber industry. In addition to W.T.O. effects, there are various external factors, which influenced the prices of agricultural crops in recent years. As far as rubber sector is concerned the main factors are low productivity and lack of value addition. Non-exposure to export market, devaluation of Indian rupee during 1991 and Asian economic turmoil caused decline in prices. Demise of INRA (International Natural Rubber Agreement), removal of port restrictions and quantity restrictions, accumulated surplus, decline in international price, non-inclusion under AoA and treating NR as a non-agricultural crop, treating NR as an industrial raw material, lack of cost efficiency, slow down in the internal demand of NR since 1996-97 etc had their impacts.

Measures to reduce adverse effects in the rubber sector are inclusion under AoA, enhancing bound rate of tariff and infrastructure strengthening for quality improvement. Promotion of rubber wood, as an eco-friendly plant, giving subsidy for rubber export, providing a level playing field for NR growers, re-categorization of rubber as an agricultural product, imposing antidumping duty etc are some other measures. Procurement and buffer stocking through STC, NAFED etc, Promoting group action through Rubber Producers Societies (RPS), avoiding import of rubber products, providing strategic market information support, enhancing productivity, investment for productivity increase and cost effective production, promoting rubberization of roads, using rubber wood as construction timber, developing value addition techniques, incentives for quality improvement, certification and packaging and transportation and periodic review of market situations are needed.

In the case of coconut, low price of other vegetable oils, minimum level of demand, recurring drought, endemic and epidemic outbreak of pests and diseases etc are the various external factors, which caused the havoc. Dependence on coconut oil driven market alone, middle level trade practices, coconut mite infestation, drastic decline in production and lack of oil market connectivity affected this sector to a large extent. Non-inclusion under AoA and fear of cholesterol in coconut oil had adverse effects.

As remedial measures we should evolve policies focused on competitiveness through higher productivity, reduction in cost of production and better adoption of cultivation practices at farmer's level. It is necessary to find ways and means to put coconut into other alternative uses like tender coconut as soft drink, edible copra, desiccated coconut, coconut cream etc. Value addition and by-product utilization, effective utilization of land through mixed cropping in order to increase productivity and net return, integrated disease management for effective controlling of eriophyid, mite, root wilt disease, leaf rot disease, bud rot disease, stem bleeding disease etc. can help a lot. Post harvest processing methods are to be modernized for ensuring quality. The full economic potential of coconut and related products like coir, shell based handicrafts, etc are to be explored. Regulation of import, readjustment in tariff, promotion of coconut oil as an edible oil, diversification of products, promotion of sweet toddy as a health drink and jaggery making, promotion of tender coconut water as a soft drink, using coconut oil as a lubricant oil are some other steps. Coconut development projects, continuation of minimum support, price stabilization and productivity, enhancing production and productivity, expansion of area under coconut, integrated farming, new technologies for food and beverage industries etc are necessary.

Thus to achieve competitiveness in the liberalized era we have to reorient the production process towards global market rather than domestic market. One has to be proactive with the changing consumer preferences and market conditions in the global market. We have to attain global competitiveness in cost of production and value chain process and create a brand image by supplying only quality products. We have to boost spices production and ensure quality. Import of low-grade spices to India and re-export of mixed (Indian and foreign) under the Indian label should be banned.

3. Non-Gaussian Time Series Models for Crop Prices Data

Now we develop time series models for modeling time series data on agricultural crop prices. We develop non-Gaussian AR(1) time series models in Cauchy and Generalized Laplacian variables. Usual normal ARMA models are also developed. Since observed prices arise in a time sequence, it is possible that the consecutive observations are dependent. Therefore a time series model based approach has been tried to explain the fluctuations other than trend and seasonal variations. A fairly good estimate of the parameters of the series is obtained only if the series is stationary. Plotting of the original data shows that it is not stationary. Therefore, for further analysis, we take a first order difference of the prices given by $Z_n = X_n - X_{n-1.}$

Firstly we try to model the prices using the Box Jenkin's (BJ) method. In this technique a model can be fitted to data by studying the behavior of the characteristics such as ACF and PACF or by using some Information criteria like AIC. After identifying order and nature of the relationships, the model parameters are to be estimated. These models can be used for short term forecasting, because most of the autoregressive models place emphasis on recent past rather than its distant past.

As part of this study we will construct ARMA models and in special Auto Regressive (AR) Processes. An ARMA (p, q) model has the general form

$$X_t = a_0 + a_1 X_{t-1} + \ldots + a_p X_{t-p} + \varepsilon_t + b_1 \varepsilon_{t-1} + \ldots + b_q \varepsilon_{t-q}$$

The simplest AR process is the AR(1) model having the structural equation

$$X_n = a X_{n-1} + \varepsilon_n \ ; \ |a| < 1.$$

where $\{\varepsilon_n\}$ is a sequence of independent identically distributed (i.i.d.) random variables, independent of distributed (i.i.d.) random variables, independent of $X_0, X_1, \ldots, X_{n-1}$. We can obtain the structure of the innovation process $\{\varepsilon_n\}$.More details including the properties of are available in Brockwell & Davis (2002).

As part of this study we have developed different non-Gaussian Auto Regressive processes. The autocorrelation function and partial autocorrelation function along with Akaike Information Criterion (AIC) led to the conclusion that AR(1) models are sufficient to model the data on crop prices to a satisfactory level.

ARCH models

In conventional econometric models the variance of the disturbance term is assumed to be constant. However, most economic time series like price data exhibit periods of unusually large volatility followed by periods of relative tranquility. We assume a time dependence on conditional variances through an autoregressive equation for the squared innovations. This led us to construct Auto-Regressive Conditionally Hetroscedastic models.

An AR(p)–ARCH(q) model has the general form given by the structural equation

$$X_n = a_0 + a_1 X_{n-1} + \ldots + a_p X_{n-p} + \varepsilon_n$$

where $\{\varepsilon_n\}$are distributed as normal with means zero and conditional variances given by

$$h_n = b_0 + b_1 \varepsilon^2_{n-1} + \ldots + b_q \varepsilon^2_{n-q} + \nu_n$$

where $\{\nu_n\}$ is a white noise process.

The details are summarized as follows.

3.1 Some non-Gaussian Time series models

(i) An Auto-regressive Model with Cauchy innovations

Consider the AR(1) model

$$X_n = aX_{n-1} + \varepsilon_n \; ; \;\; |a|<1 \qquad (1)$$

where $\{\varepsilon_n\}$ is i.i.d. and independent of $\{X_{n-1}\}$. In terms of characteristic functions, equation (1) can be rewritten under the stationary case as

$$\varphi_X(t) = \varphi_X(at)\, \varphi_\varepsilon(t)$$

$$\therefore \;\; \varphi_\varepsilon(t) = \varphi_X(t)/\varphi_X(at) \qquad (2)$$

Consider the Cauchy distribution whose characteristic function is

$$\varphi_X(t) = e^{-|t|}$$

Substituting in (2), we get the characteristic function of the innovation process as

$$\varphi_\varepsilon(t) = e^{-(1-|a|)t}$$

Hence the p.d.f. of $\{\varepsilon_n\}$ is another Cauchy density.

(ii) etric Stable Processes

In this case also the innovations are also distributed as symmetric stable.

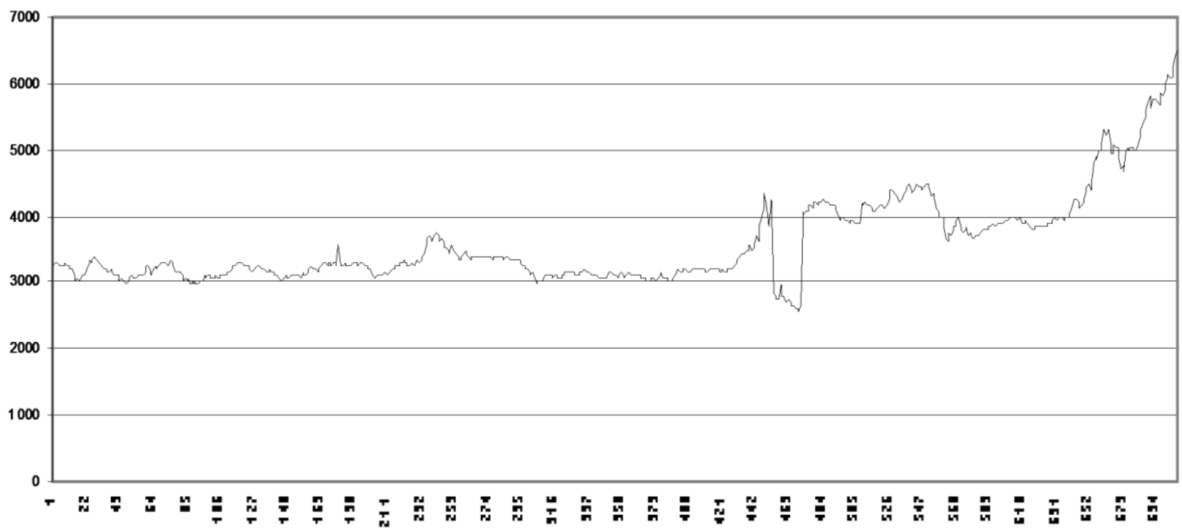
(iii) Generalized Laplacian Processes

The generalized Laplacian random variable being the difference of Gamma random variables is the sum and difference of a number of exponential random variables. It has wide flexibility and can model data from various contexts having a growth-decay structure. Agricultural crop prices can be regarded as the net effect a number of positive and negative factors. Hence a generalized Laplacian autoregressive process may be most appropriate in this context. The innovation distribution can be derived easily as before.

3.2 A Cauchy model for Coconut prices

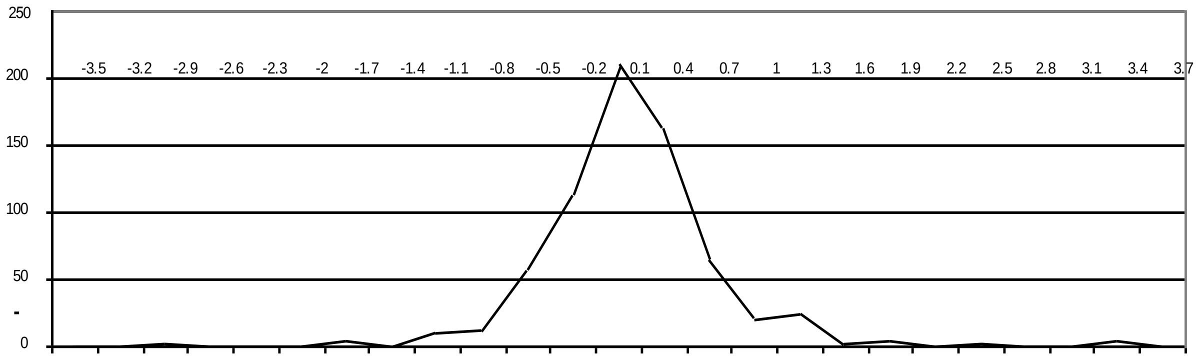
We apply the Cauchy model developed above to model a set of data consisting of daily coconut oil prices (in Indian Rupees per quintal) at Cochin market for a period from January 1994 to December 1996. The analysis is mainly concerned with the price recorded on each trading day.

Time series plot of Coconut Oil Prices (1993-96)



The time series plot of the original data shows an increasing trend while the differenced series is stationary. So it is convenient to analyze the changes in the successive prices. Let X_n be the original price on the day 'n', then we make the transformation $Z_n = (X_n - X_{n-1}) / \sigma (X_n - X_{n-1})$, where $\sigma (X_n - X_{n-1})$ is the standard deviation. For testing normality, we use Geary's (Cooper and Weeks (1988)) test statistic G, which is the ratio of the mean deviation to the standard deviation. The G-statistic for the transformed values of the coconut oil prices is G = 0.4956 and hence we reject the hypothesis that the underlying distribution is normal.

Frequency curve of the transformed coconut oil prices



The figure suggests that the other possible distributions may be Cauchy, generalized Laplace, Linnik etc as we are dealing with the price data. To confirm the applicability of the distribution we have to test the goodness of fit. The transformed data is symmetric about zero. Goodness of fit test concludes that the transformed sequence follows a Cauchy distribution.

Finally we get the model $Z_n = 0.033277\, Z_{n-1} + \varepsilon_n$, where $\{\varepsilon_n\}$ is a sequence of independent and identically distributed random variables which follows Cauchy C(0.966723,0) distribution .

3.3 ARMA and ARCH Models for Coconut Oil Prices

In this section we develop various time series models for coconut prices/indices. In order to achieve stationarity we make the following transformation. If X_t is the price at time t, the first order difference is $Z_t = X_t - X_{t-1}$. The first order differences are labeled as 'dprice'. In the case of coconut and rubber we analyze both prices and wholesale price indices. The data on prices is monthly prices of coconut at Cochin market.

Since the AIC and RSS for all the models are not much different the most parsimonious model is the AR(1) model given by

$$Z_t = 22.921 + 0.3088\, Z_{t-1} + \varepsilon_t$$

where $Z_t = X_t - X_{t-1}$ and $\{\varepsilon_t\}$ is the innovation process. The innovations may be assumed as following distributions like Linnik, stable, Cauchy, Laplacian, generalized Laplacian etc.

In a similar manner AR(2), ARMA (1,1), ARMA (2,1), ARMA (2,2) models can be constructed. The fitted ARMA model is

$$Z_t = 19.509 + 1.736\, Z_{t-1} - 0.9976\, Z_{t-2} + \varepsilon_t + 1.70224\, \varepsilon_{t-1} - 0.9976\, \varepsilon_{t-2}$$

Since the AIC and RSS for all the models are not varying much we conclude that the most parsimonious model is the AR(1) model given by

$$Z_t = 1.19964 + 0.34036\, Z_{t-1} + \varepsilon_t .$$

For the coconut oil prices data, we get the AR(1) – ARCH (1) model given by

$Z_t = 22.921 + 0.3088\ Z_{t-1} + \varepsilon_t$

where $\{\varepsilon_t\}$ are distributed as normal with mean zero an conditional variances given by

$h_t = 19.4308 + 3.2083\ \varepsilon^2_t + 0.2122\ \varepsilon^2_{t-1} + \nu_t$

where $\{ \nu_t \}$ is a white noise process. Using the models developed we can predict the future values of the process. This method can be used for obtaining forecast and confidence limits for the future values of the series. Similarly we can develop AR-ARCH models for pepper, tea, and cashew prices as follows.

The AR(1) – ARCH (3) model for pepper price indices is $Z_t = 7.1813 - 0.3880\ Z_{t-1} + \varepsilon_t$ where $\{\varepsilon_t\}$ are distributed as normal with mean zero an conditional variances given by

$h_t = 3.1435 + 326.0578\varepsilon^2_t + 0.6210\ \varepsilon^2_{t-1} + 0.2143\ \varepsilon^2_{t-3} + \nu_t$ where $\{ \nu_t \}$ is a white noise process.

The AR(1) – ARCH (3) model for tea price indices is $Z_t = 1.15963 + 0.19433\ Z_{t-1} + \varepsilon_t$

where $\{\varepsilon_t\}$ are distributed as normal with mean zero an conditional variances given by

$h_t = 2.7698 + 285.4655\varepsilon^2_t + 0.5540\ \varepsilon^2_{t-1} + 0.2844\ \varepsilon^2_{t-3} + \nu_t$ where $\{ \nu_t \}$ is a white noise process.

The AR(1) – ARCH (3) model for cashew price indices is $Z_t = 1.30989 + 0.19557\ Z_{t-1} + \varepsilon_t$

where $\{\varepsilon_t\}$ are distributed as normal with mean zero and conditional variances given by

$h_t = 1.1594 + 47.6680\ \varepsilon^2_t + 0.3887\ \varepsilon^2_{t-1} + 0.0791\ \varepsilon^2_{t-3} + \nu_t$ where $\{ \nu_t \}$ is a white noise process.

4. Conclusions

The paper makes a detailed analysis of the various problems faced by Indian agriculture in the new liberalized era under W.T.O. regime and points out the challenges ahead. The economics of globalization is based on Ricardo's principle of comparative advantages. Our comparative advantage is mainly in the field of agriculture. It should always be remembered that the only means of success under the W.T.O. regime of liberalization are increased productivity, high quality and value addition.

The new time series models developed can be used for short-term predictions only since agricultural prices depend on government policies and various other factors. Problems like proper data warehousing and management, developing advanced statistical tools, diagnostic checking, statistical inference, developing more efficient algorithms etc are problems for further research

ABSTRACT

Computation of Agriculture is a concept to encourage sustainable growth of agriculture and rural development. The concept is anticipated through an analytically enabled digital platform, "e-Rural Services". The platform helps to capture data through digital means and process through advanced analytical models to provide valuable insights from the data. It helps to reduce uncertainty in farming business and enhance productivity. The agri-business services through analytical tools and engaging multiple corporations make the application economically viable and encouraging. The public and policy making institutes will be interested to monitor periodic developmental metrics and suggest strategies for sustainable growth. Thus the stakeholders of entire eco-system are encouraged to be participated in the developmental process through this analytical platform, modernizing the farming systems and encouraging the youths in agriculture.

Keywords: Analytical Models, Digital applications, Developmental Goals

1. Introduction

Agriculture is the noblest profession in the world. The livelihood feeds the world. The farmers are the key contributors for the food securities of nations and the world. Technological innovations have changed the urban livelihood and business. But the countryside life has been enriched but not at the pace of urban world. The discrepancies in the standards of living have given birth of multiple problems, including shift from agriculture profession. This has direct bearing to the food security. The situation is more miserable in under-developed and developing countries, where farmers have limited resource and small and marginal land size. It is very difficult for them to combat against modern challenges in agriculture; climate change, increase in disease and insect pests incidences, decrease in soil fertility, water scarcity and market dynamics. The rural youth feel very much discouraged to have agriculture as their future profession. This is a matter of concern for all of ours existence.

Agriculture business needs to be modernized.The data science and digital technologies can revolutionize the ways of business in agriculture as it is observed in urban space. With increase in population and decrease in resources it is needed to adopt precision farming tools and optimize farming through scientific means. The modern technologies being cost effective, it is challenging to adopt for the small and marginal farmers. The farmer cooperatives and groups are not even successful due to various socio-economic and political issues. Considering the challenges it is very likely that the data science can group probable friendly farmers through a virtual platform, to facilitate in agri-business activities.

It has been envisioned to modernize the living standards of the rural world through computation of agriculture data and provide analytical insights on farming business strategies through e-Rural Services platform.The metrics measured on farming livelihood development is targeted to address the indicators of United Nations developmental goals. This helps the regional and national institutes to reap the benefit of the farmers' data. The agri-business information can be suitable for the corporations in agriculture to improve their sales with useful insights on demand and supply. The farmers the key beneficiaries will be provided with basic agricultural productivity information; crop selection based on soil, weather and available resources, disease and insect pests alerts through weather modelling, weather forecast alerts and market information. Each of the stakeholders' participation in the platform will make the digital eco-system economically viable and sustainable. The periodic self-initiated updates on the farmers' data will be helpful to monitor, identify and uplift the weaker zones of the society. The data collection is facilitated through mobile phone technologies which is mostly accessible.

2. e-Rural Services Platform

The "e-Rural Services" is a digital platform for agricultural and rural development. It is an integrated platform to collect sanitizes and store data, analyses and disseminates information. The services related to the initiative aredesigned for the major stakeholders of the agri-business. The farmers are the key beneficiaries with basic agriculture information, livelihood developmental support from institutes and farming business support from corporations.The platform is believed to be economically self-sufficient and sustainable with more data and information related services.

The platform is divided in three components; Data Collection, Data mining through Analytical models and Reporting (Figure 1).

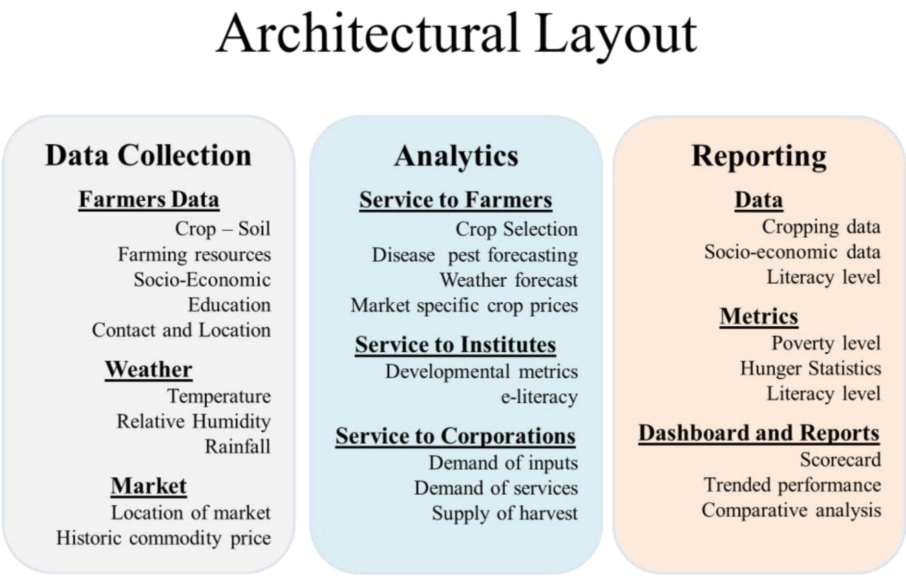

Figure 1: *Architectural Components of e-Rural Services*

The platform is a web-based application. It facilitates the users and operators to function irrespective of location and time.This helps in improvement of the services and penetrates to the remote locations. The internet connectivity and smart phone technologies may not be affordable to all the farmers. It is being bridged through farmer- agents, who can enrol multiple farmers in the application. The information on cropping practises and weather are facilitated through SMS and voice calls. It eliminates the immediate requirement of IT gadgets and subscriptions.

The initial services on agri-business prompt the farmers to enrol and update in the digital platform. Information related to agricultural activities and resources and weather data will abreast to build the models to provide precision services for cropping practises. The market location and trended crop-prices will help to locate best revenue of the harvests. The input requirements (seed, fertilizer, pesticides, farm machineries etc.) for cropping practises will help the corporations to assist the farmers with competitive prices and in right time. It will help the agri-input companies to maintain the customer loyalty and the farmers to be advanced in their farming productivity with new products. The available harvests can trigger the output agriculture services to procure harvests at field with best prices. It will eliminate the intermediate business exchanges, thus providing improved pay-off.

The information related tocropping practises, socio-economic and education will help to derive useful insights related to the livelihood development of the location. It will be an interest of the policy making institutes to improve the metrics, which contribute to the overall development of the Nation.

The digital platform is operated seamlessly with the support of advanced analytical models and modern tools on information technologies which enable to provide useful insights and presentable automated reports. The information for the farmers through SMS, voice call, mobile app messages are very simple to understand and executable. They are encouraged to connect with system for further clarification and information.

3. Description of components of e-Rural Services Platform

The components of the digital platform are represented as Data Collection, Analytical processing of the data and Reporting (Figure 1). The components are enabled to be connected with each other for automated processing, real time output generation and information dissemination. Each of the modules is depicted in details in the following sub-headings.

3.1 Data Collection

The data collection and periodic updates on data from the users are the fuel for analytical engine of the platform to be functional. The good data collection is one of the major challenge for operation of the functionalities. The digital means of data collection will facilitate to reduce costs and with increase data quality. The data assortment is done under following heads –

a) Farmers'Data –The farmers' data are collected through the mobile application. Farmers' friend and agents in fields helps for initial registration process. The registered farmers are being connected with the system through voice calls and SMS. Since most of the data fields are pre-defined and selective there are less chances of data entry errors.

b) Weather Data – The historic and predicted weather information are being pulled from government sources and transmitted through the system. The weather information are required for model building exercises for recommendation on agricultural services. With growth of services and farmers' empowerment automated weather stations can be installed for more precise forecasting services.

c) Market Data – The regional level local market locations and crop prices data are being fetched through farmers' network. The recognized market places and the prices are recorded in government websites. Those data are pulled for analysis and transmission to the respective location specific farmers. Online markets can be linked to the platform to provide best bid to the farmers.

The mobile application has been explored for data collection from the farmers. The application can be operated as Farmer, as Agent and as Administrator (Figure 2), demonstrating different data requirements. The operational hierarchies are needed for effective communication management enabling good data collection and viability (Figure 3).

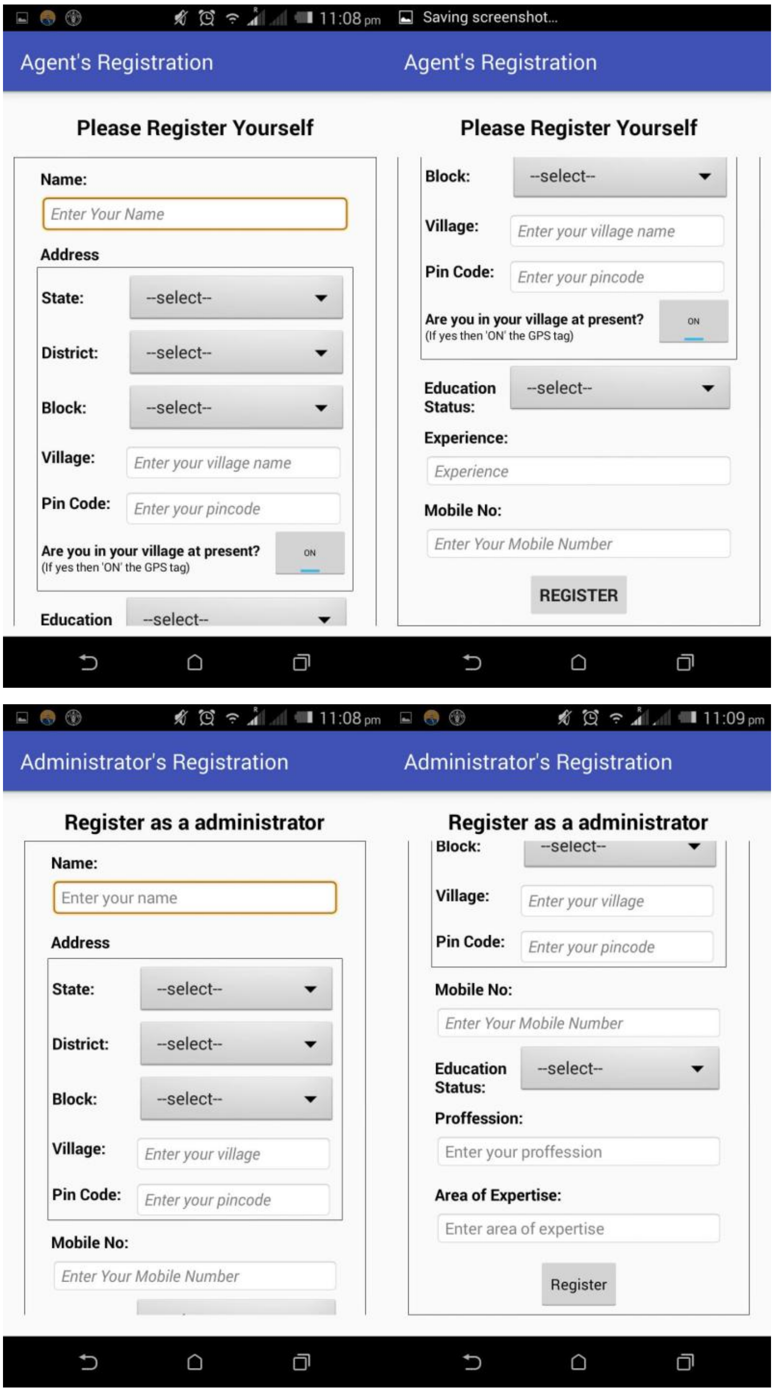

Figure 2: *Mobile Application screen shots for registration of different operators*

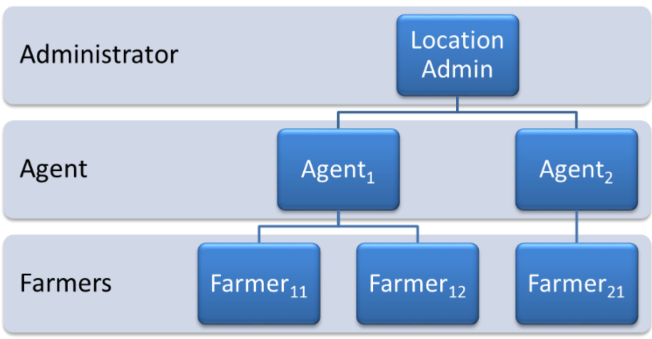

Figure 3: *Operational hierarchy for communication management*

3.2Analytics

The services provided to the different stakeholders are based on data analytics. This enables the farming business eco-system to be viable and transparent. Following are the brief description on the analytical modules based on the stakeholders.

a) Service to Farmers –The analytical infrastructureisdesigned to process varieties of services through data modelling. The data being gathered are subject to undergone through sanity checks (through trend and growth analysis) and cross-validation for exceptional entries. It is then processed for further inferential operations. Following are the current focus points –
   i. Crop Selection:Crop selection is done based on the available resource information and probable weather conditions. Linear programming and regression based models are being explored to determine best profitable crop for the cultivator.
   ii. Disease and insect pests forecasting: The weather based models are developed to forecast incidences of crop specific disease and insect pests and strategies to control them. The machine learning (Logistic regression and Artificial Neural Network) and differential equation based techniques are explored for model building.
   iii. Weather Forecast: Forecast for weather parameters like temperature, relative humidity and rainfall are subscribed through weather portals of government and other agencies.
   iv. Market specific crop prices: The right market search and price forecasting are one of the important services for the farmers. The time series forecasting mechanism (ARIMA and Spline regression) approach is being explored. The best market search is based on distance of the field to farm and profit margins.

b) Service to Institutes – The rural and agriculture development institutes comprising of public and private domains will be interested to know the performance metrics for the group of the farmers. The data being updated periodically will help to gauge the developmental trends.The developmental metrics focussed on first two goals of Millennium Development Gaols; Eradicate Extreme Poverty and Hunger (Goal 1) and Achieve Universal Primary Education (Gaol 2). The goals are followed as No Poverty (Goal 1), Zero Hunger (Goal 2) and Quality Education (Goal 4) under Sustainable Development Goals (SDGs). –
   i. Developmental Metrics:
      a. Proportion of population below \$1.25 (PPP) per day

$$P_0 = \frac{1}{N} \quad {}_{i=1}^{n} I \quad y_i \leq z \quad = \frac{N_p}{N} \qquad (1)$$

where I(.) is an indicator function that takes on a value of 1 if the bracketed expression is true, and 0 otherwise. If individual consumption or income (yi) is less than the poverty line (z), then I(.) is equal to 1 and the individual is counted as poor. Np is the total number of the poor. N is the total population. As followed in MDGs indictor definition.

      b. Poverty gap ratio

$$P_1 = \frac{1}{N} \sum_{i=1}^{N} \left(\frac{G_n}{z} \right), G_n = (z - y_i).I(y_i \leq z) \qquad (2)$$

where the poverty gap (Gn) is the difference between the poverty line (z) and income or consumption for those who are poor (the non-poor have a poverty gap of zero). I(.) is an indicator function that equals 1 if the bracketed expression is true, and 0 otherwise. N is the total population. As followed in MDGs indictor definition.

      c. Proportion of population below minimum level of dietary energy consumption

This indicator has been defined within a probability distribution framework. As followed in MDGs indictor definition.

$$P(U) = P(x < r_L) = \int_{x<r_L} f(x)dx = F_x(r_L) \qquad (3)$$

where,

P(U) is the proportion of undernourished in total population;

(x) efers to the dietary energy consumption or intake;

r_L is a cut-off point reflecting the minimum acceptable dietary energy consumption;

f(x) is the density function of dietary energy intake; and,

Fx is the cumulative distribution function.

d. Literacy rate of 15-24 year-olds, women and men

Literacy rates are computed by dividing the number of people aged 15–24 years who are literate by the total population in the same age group, the result is then multiplied by 100. As followed in MDGs indictor definition.

$$LR_a^t = \frac{L_a^t}{P_a^t} \times 100 \qquad (4)$$

LR_a^t= Literacy rate of age group “a” in year “t”

L_a^t = Literate population of age group “a” in year “t”

P_a^t= Population of age group “a” in year “t”

ii. e-Literacy:The metrics defined to measure the level of e-Literacy for sharing of knowledge for agri-business. It is the ratio the farmers registered did self-registration and maintains smart phone and internet to the total no. of registered farmers. It is also a measure of economic prosperity to avail advance knowledge through modern tools.

c) Service to Corporations

The corporations can explore the experience of direct trading with the end consumers through the digital platform. Following metrics can be useful for managers of the corporations.

i. Demand of Inputs:The farmers’ agricultural input requirements can be based on forecasted models for the crop section and pesticide requirements. Fertilizer module being integrated can be an area of interest. Agricultural machineries can be placed at farmers’ utilities based on the crop stages information.

ii. Demand of Services: Various services can be explored for the farmers to improve the crop productivity and financial improvement. It can be the initiatives of various input companies to place their product and improve farmers’ loyalty. Financial services from banks and insurance institutions can aid the farmers to advance in their agri-business.

iii. Supply of Harvest:Harvest gathering information will be interests for the retail chains and various food industries. Farmers and the food services can mutually be benefitted eliminating intermediate business exchanges.

3.3Reporting

The reporting service from the platform is one of the most important modules of the digital platform. It enables the users to take benefit of the data for their respective businesses improvement encompassing around public, private and personal sectors. The agri-businesses, mostly the personal sector, are the largest sector in terms of employment. But the sector suffers from less revenue due to uncertainties in farming business and improper management. The reporting section is aimed to provide insights and opportunities to improve the sector’s performance. It will help the farmers to increase their efficiencies. The public and private sectors contributions will enhance the improvement.

The reporting of the information has been categorized under following heads –

a) Data:The processed data on cropping activities, socio-economic informationand literacy will be helpful for the responsible authorities to perform personalized studies.
b) Metrics: The automated metrics generated on the data processing will benefit all the sectors, in particular the public sector design policies for countryside development.
c) Dashboards and Reports: The dashboards and reports are the vital to monitor the periodic progress.

4. Conclusion

The "e-Rural Services" is a platform to perform agricultural analytics and provide services to different agri-business stakeholders. The digital platform can serve as an automated monitoring system to gauge periodic agricultural development. The farmers being engaged with the system for agricultural and business services, helps to inflow of data in the platform. With the passage of time it is envisioned as a self-serviced, economically viable and sustainable analytical-digital platform for agriculture. The platform being in service for public, private and personal sectors of the rural ecosystem, the penetration of the services to maximum farmer population is highly expected. It will encourage development in every aspect of country side life. Thus stabilizes uniform sustainable growth of the Nations.

ABSTRACT

Statistics Canada's goal for modelled yield estimates was to produce a midseason estimate of crop yield and production based on information received as of the end of August, similar to what has been traditionally done with the September Farm Survey. The November Farm Survey estimates are considered the most accurate estimates of yield for a given year, due to the fact that the data are collected after the majority of harvesting has been completed and the sample size is the largest of the Field Crop Reporting Series. The modelled yield estimates and September Farm Survey estimates were both compared to the November Farm Survey estimates to verify the accuracy of the yield model results compared to the survey. Nineteen crops were introduced to the modelling process but published results were restricted to 15 when rules based on data availability and quality were implemented.

In 2015, the model-based yield estimates were disseminated for the first time by Statistics Canada as a supplemental publication 3 weeks in advance of the September Farm Survey and 11 weeks in advance of the November Farm Survey results.The modelled yield estimates had less deviation from the November Farm Survey than the September Farm Survey for canola, corn for grain,mixed grains, oats, rye, soybeans, and canary seed. Conversely, the September Farm Survey had less deviation from the November Farm Survey than the model for barley, flaxseed, dry peas, spring wheat, winter wheat, lentils, and mustard seed. Equal deviation was noted for durum wheat yield.

Feedback through government and industry consultation has been very positive and commencing in 2016, Statistics Canada replaced the September Farm Survey with the Model-based Principal Field Crop Estimates.

Key words: Remote Sensing, Normalized Difference Vegetation Index, Yield Model, Agriculture, Crop Statistics

1. Introduction

Innovative approaches in estimating crop yields are continuously being sought with the objective of reducing respondent burden while producing accurate, timely and reliable estimates. Statistics Canada, in cooperation with Agriculture and Agri-Food Canada, has developed a crop yield modelling approach as a non-intrusive method of producing yield forecasts that incorporates the 1 km resolution Normalized Difference Vegetation Index (NDVI) data used as part of Statistics Canada's Crop Condition Assessment Program, statistical survey data from Statistics Canada's Field Crop Reporting Series, and agroclimatic data for the agricultural regions of Canada. Although both the agroclimate and crop yield data had a longer time series, the study period was chosen according to the availability of the satellite data; a 29-year time series from 1987 to 2015.

Each year, Statistics Canada has traditionally conducted six farm surveys, in part, for estimating seeded area, harvested area,expected yield and production as part of the Field Crop Reporting Series. Like many other national statistical agencies, it is under increasing pressure to reduce response burden and cost of the traditional surveys while maintaining relevance, accuracy, timeliness, accessibility, interpretability and coherence.

Statistics Canada has therefore been researching and evaluating alternate methods of incorporatingadministrative data into its program to produce non-intrusive estimates of field crop yields and production.Agriculture and Agri-Food Canada (AAFC), has also been investigating the use of yield modelsfor the same purpose.To ensure no duplication of effort, a yield model that was being developed by AAFC using R statistical language software was transferred to Statistics Canada. The two organizations workedtogether on developing a robust yield model. Within Statistics Canada, the yield model was ported to a SAS platform.

The two departments modified the model with the goal of producing principal field crop yield estimates as of August 31.The 2015 modelled results were deemed of acceptable quality and were published by Statistics Canada3 weeks in advance of the September Farm Surveyresults and 11 weeks in advance of the November Farm Survey results.

This paper provides an overview of the background and general methods used to model reliable crop yield estimates as a preliminary estimate ofthe November Farm Survey estimates.

2. Methodology

A methodology for modelling crop yield was developed and tested in fiveCanadian provinces(Alberta, Saskatchewan, Manitoba, Ontario, and Quebec)forcrops that are typically published at the provincial and national levels by the September Farm Survey. These five provinces account for about 98% of the agricultural land in Canada and for the purpose of this paperare referred to as the national level when the yield model resultsare discussed.

2.1 Data sources used in the model

The modelling methodology used three data sources: 1) NDVI derived from coarse resolution satellite data (Latifovic et al., 2005)an integral component of Statistics Canada’s Crop Condition Assessment Program (Bédard, 2010); 2) area and yield data collected through Statistics Canada’s Field Crop Reporting Series, and 3) agroclimatic data for the agricultural regions of Canada.

2.1.1 Normalized Difference Vegetation Index (NDVI)

Since 1987, Statistics Canada has monitored crop conditions across Canada using the 1-km resolution, Advanced Very High Resolution Radiometer (AVHRR) sensor aboard the National Oceanic and Atmospheric Administration (NOAA) series of satellites. The NDVI was processed on a weekly basis throughout the growing season and used within Statistics Canada’syield model as a standardized index of vegetation health. These weekly NDVI values are available for download fromStatistics Canada’s Canadian Socio-Economic Information Management System (CANSIM), Table 001-0100.

2.1.2 Survey area and yield data

Survey estimatesfrom Statistics Canada’s Field Crop Reporting Series provided accurate and timely estimates of the seeded area, harvested area, yield and production of the principal field crops in Canada at the provincial level (Statistics Canada, Table 001-0010; Table 001-0017).

Results from the surveyswere only utilized in modelling activities when the crop wasrelatively abundant. If the crop wasabundant in a province, the yield estimates wereavailable at sub-provincial geographicunits.This finer level of geography usually correspondedto the Census Agriculture Regions (CAR) of which there are 82 across the agriculture region of the country (Statistics Canada, 2011). If the crop wasnot abundant, then yield estimateswereavailable at the provinciallevel only.

For abundant crops, CAR level crop yield estimates from the July and November Farm Surveys from 1987 to present were used as input variables for developing the model while yield estimates from the September Farm Survey and the November Farm Survey were used to validate the yield model results. For less abundant crops, the survey data and model results wereanalyzedat the provincelevel.

Area data from the June Farm Survey were used to aggregate yield estimates to larger geographic regions as described in Section 3.2. This area data along with yield data from the July and November Farm Surveys were used as part of the publication rules to determine which of the modelled yields were of acceptable quality for publication. The publication rules are described in Section 4.1.

2.1.3 Agroclimatic data

Climate data from 416 climate stations throughout the agriculture region of the five provinces was the third data source used as part of the crop yield modelling process. The station-based daily temperature and precipitation data provided by Environment and Climate Change Canada and other partner institutions were re-analyzedby AAFC to generate the climate-based predictors which amongst others included crop moisture stress, cumulative precipitation and growing degree days(Newlands et al. 2014, Chipanshi et. al. 2015). These data were provided to Statistics Canada by AAFC.

3. Modelling survey yields

3.1 Development of Statistics Canada'syield model

AAFC has an extensive history in developing field crop yield models. The most recent were documented in Newlands et al. (2014), and Chipanshi et al. (2015). These models incorporated non-Bayesian and Bayesian methods at different steps. The variable selection step used a non-Bayesian approach by the least-angle robust regression algorithm. Yields were then estimated using a Bayesian approach.

Statistics Canada had different modelling needs than AAFC. The AAFC model used Bayesian methods in order to estimate yields throughout the growing season at monthly intervals. Early season estimates were produced when data for the current year were not available. Unavailable data for the rest of the growing season were generated using a random forest method (Liaw and Wiener, 2002) which allowed crop yield results to be displayed as a probability.The Statistics Canada model was to be used in the middle of the growing season when the majority of thedata forthe current season werealready available, thereforethe Bayesian approach was not required. Statistics Canada also required that the model run on a SAS platform which is the standard programming tool used at the Agency. The AAFC models were programmed using Rstatistical language software.

Statistics Canada'smodelling goalwas to predict the final crop yield, therefore, the dependent variable of the model was the crop yield estimate from the November Farm Survey. There were 80 potential explanatory variables derived from the three data sources described in Section 2. Thus it was necessary to implement an appropriate method of selecting the model's explanatory variables. Bédard and Reichert (2013), established that the optimal number of explanatory variables to be selected for modelling was five. Khan et al., (2007), emphasized the importance of using robust modelling methods for selecting the explanatory variables for the model and estimating the yields. As there was no robust variable selection procedure in the SAS software it was necessary to use non-robust algorithms as an alternative at the selection step and then to estimate the model in a robust way. The Least Absolute Shrinkage and Selection Operator (LASSO) method was selected from the five variable selection algorithms available in SAS. The MM method (Yohai, 1987) was chosen from the robust regression methods available in SAS due to its ability to effectively treat outliers (Copt et al. 2006).

Preliminary evaluations were conducted using the data from 1987 to 2014. The median absolute differences in yield at the national level between the AAFC and Statistics Canada models for the seven largest crops in Canada were all between 0.9% and 2.4% (barley, 0.9%; canola, 1.0%;

corn for grain, 1.4%; durum wheat, 1.3%; oats, 0.9%; soybeans, 2.4%; and spring wheat, 0.9%)(Statistics Canada 2015). Since the two methods produced similar results, Statistics Canada made the decision to adopt a model using LASSO variable selection and the MM robust regression estimation in SAS.Throughout the remainder of the paper, results will only be discussed for this model used by Statistics Canada and will be referred to as the “yield model”.

3.2 Aggregating modelled yield estimates

For the majority of the crops, modelling was done at the CAR level, the smallest geographic unitfor which historical survey data were available, or, for less abundant crops, the provincial level. The CAR level yield estimates are weighted based on seeded area estimates from the June Farm Survey and aggregated to produce a provincial estimate. For crops that are less common in a province, the model estimates werebuiltat only the provincial level. A similar weighting approach was used to aggregate provincial and the national yield estimates.

3.3 Model evaluation method

The November Farm Survey estimatesare considered the most accurate estimate of yield for a given year, due to the fact that the data are collected after the majority of harvesting is completed and the sample size is the largest of all six of the survey occasions. The results of the September Farm Survey can be considered a preliminary estimate of the November results. Therefore, Statistics Canada’sgoal for the yield model wasnot to replicate the results of the September Farm Survey but rather to obtain a sufficiently accurate yield estimate in advance of the November Farm Survey results.

The relative difference (presented as a percentage) between the yield estimate of a given method (i.e., September Farm Survey or the yieldmodel) and the November Farm Survey yield estimate was the measure of accuracy.A negative relative difference indicated that the given yield estimate was smaller than the November Farm Survey estimate, while a positive relative difference indicated that the given yield estimate was larger than the November Farm Survey estimate.

$$Relative\ difference = 100 * \frac{Given\ yield\ estimate - November\ Farm\ Survey\ yield\ estimate}{November\ Farm\ Survey\ yield\ estimate}$$

4. Publishing the yield estimates

Modelled crop yield estimates wereproduced at the CARlevel whenever possible and then rolled-upto the provincial and national levels.Statistics Canada has established three criteria based on data availability and quality that must be met to ensure the statistical integrity of the estimates and to determine which of the modelled crop yields were of acceptable quality for publication. Each year, the yield model estimates for individualcropsmust be evaluated to determine whether there is sufficient quality to warrant publication.

4.1 Publication rules for modelled yields

A minimum of 12 years of historical survey yield data for both theJuly and November Farm Surveys must be available as well as area and yield estimates for the current year from the June and July Farm Surveys, respectively. If these conditions are not met, then a modelled yield estimate will not be produced for that CAR or province.

The provincial yield estimate for a crop will not be published if the total cultivated area estimated by the June Farm Survey from suppressed regions (based on the previous set of conditions) exceeds 10% of the provincial area for the crop. Similarly, if provincial yield estimates for a crop were not published, the national level estimate will not be published if the total cultivated area for the suppressed provinces exceeds 10% of the national area.

Finally, if the coefficient of variation (CV) of the provincial or national estimate from the model was greater than 10%, the estimate was not published at that level. Model based CVs are calculated differently than those for survey estimates. Different CV thresholds are used to determine which estimates are suitable for publication than those used in the Field Crop Reporting Series. The 10% CV threshold for the model is the approximate equivalent to allowing a maximum absolute relative difference of 25% between the modelled yield and the November Farm Survey yield estimate.

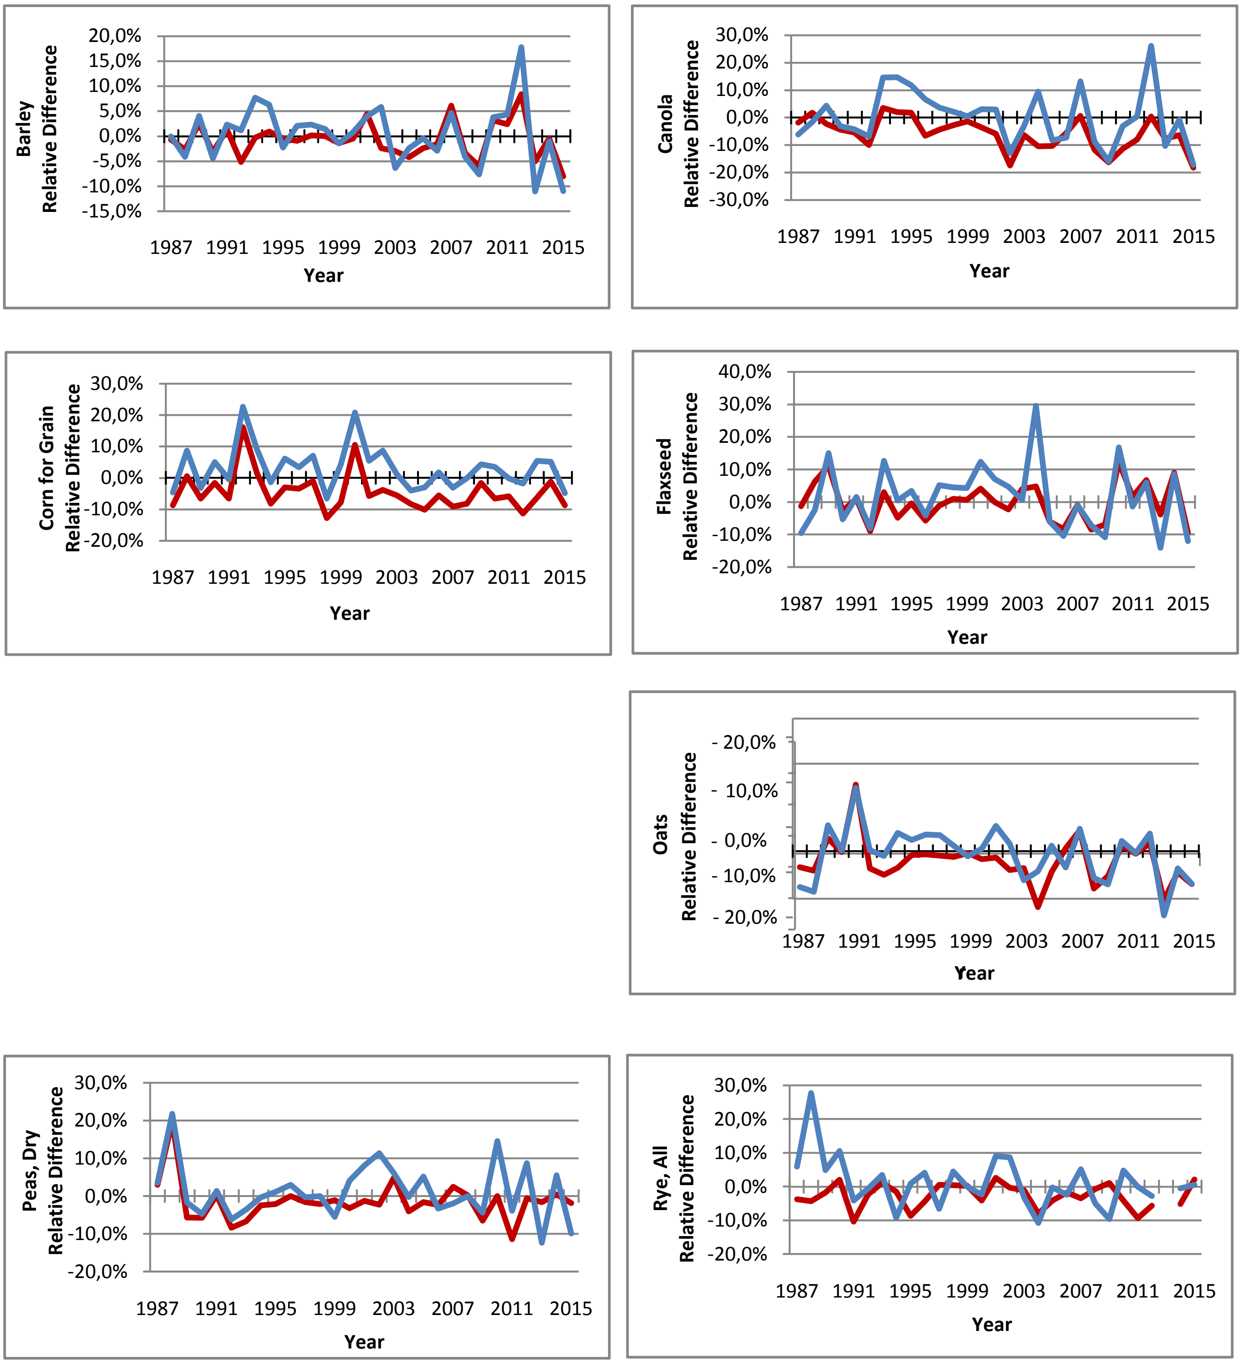
In cases where the estimates for some provinces were suppressed due to quality, but an estimate for the national level was still produced, only provincial estimates that were of an acceptable level of quality were used.

5. Results

5.1 Comparisons of the modelled and survey yields

Nineteen crops were introduced to the modelling process at Statistics Canada but published results in 2015 were restricted to 15 when rules on data availability and quality were implemented. The four crops suppressed were chick peas, coloured beans, sunflower seed, and white beans.

To verify the accuracy of the yield model,the relative difference of its yield estimates relative to those from the November Farm Survey were computed from 1987-2015. The September Farm Survey yield estimates were also compared to November Farm Survey yield results to provide a comparison of the accuracy of both methods.Figure 1 presents the comparison graphs for the 1987-2015 time series for the 15 crops for which modelled yield results were released in 2015.



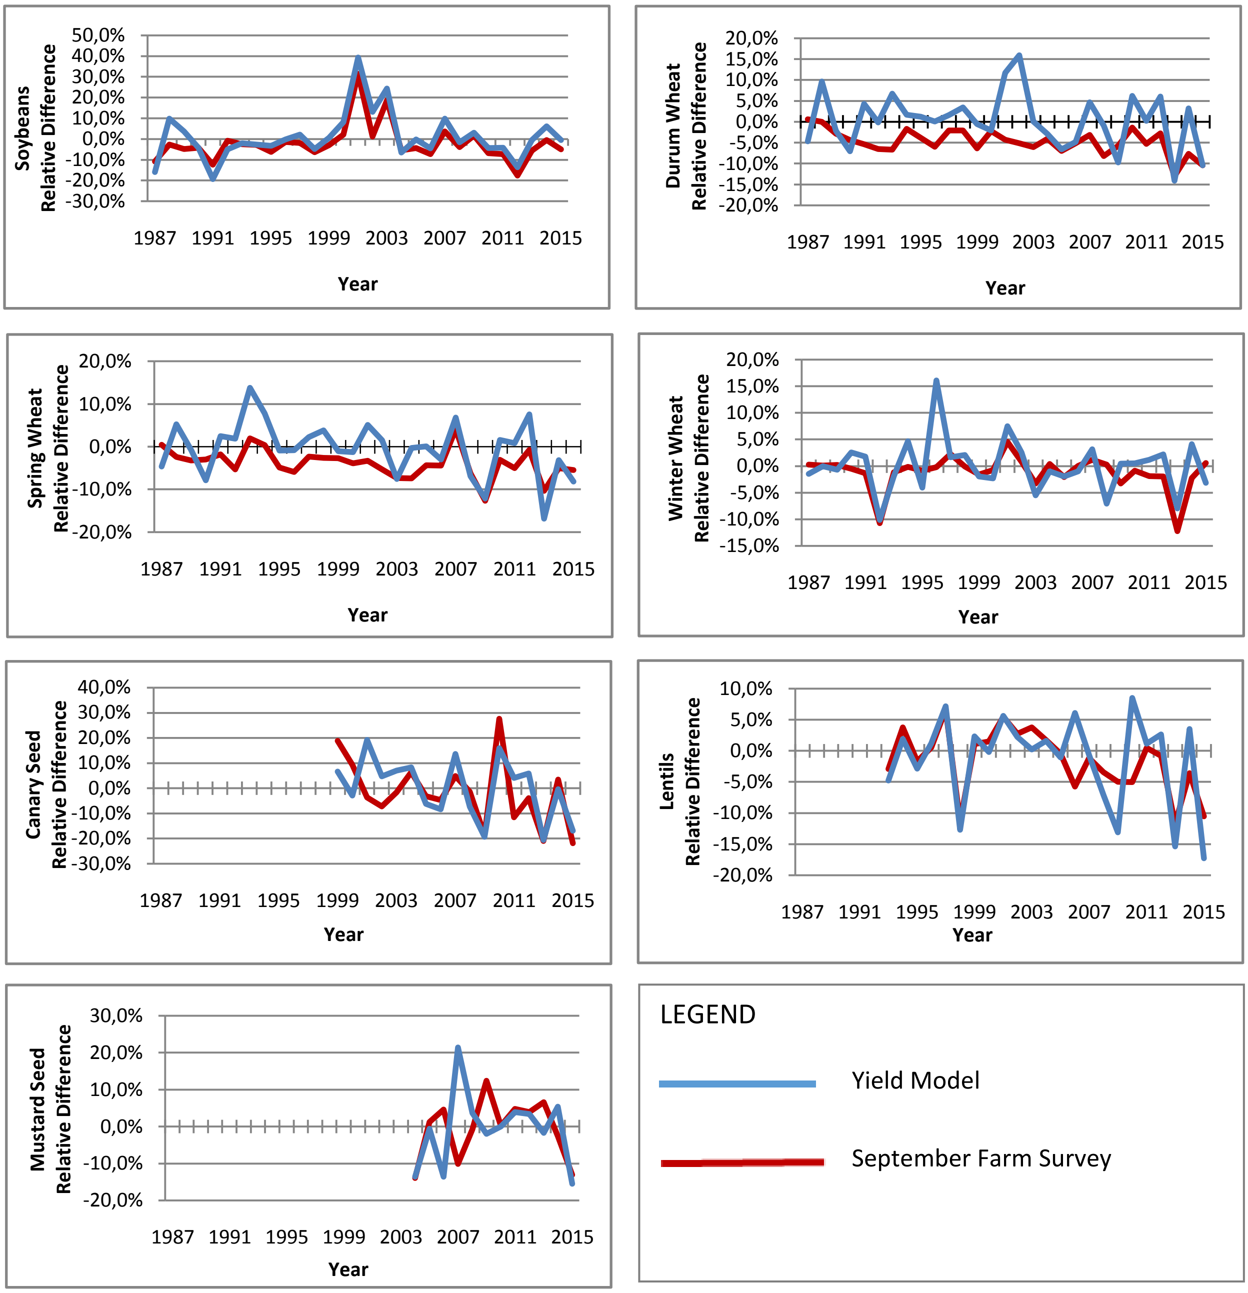


Figure 1. Relative difference of the yield model and the September Farm Survey from the November Farm Survey yields at the national level, 1987 to 2015.

The analysis shows that there is no consistent pattern when the yield model estimates and the September Farm Survey yield estimates are compared to the November Farm Survey for the 1987-2015 time series (Figure 1). Neither method is consistently closer to the November Farm Survey estimates for any crop. For soybeans and corn for grain, the two methods follow a similar pattern of estimates for the 29 years with regard to how the estimates change from year to year. However, this pattern is not present for the other crops. Additionally, for any given year, one method does not consistently perform better for all crops. In general, the yield model and the September Farm Survey yield estimates have comparable relative differences from the November Farm Survey estimates. However, the modelled estimates tend to have larger relative differences in cases where an extreme relative difference is observed (e.g., the maximum and minimum relative differences are larger).

One pattern that can be seen is that the September Farm Survey results tend to be low when compared with the November Farm Survey results (below the x-axis) more often than the model results. This is particularly evident with canola, corn for grain, durum wheat, spring wheat, and rye. For more details on the comparative analysis refer to Statistics Canada, 2015.

On September 17, 2015, Statistics Canada disseminated the Model-based Principal Field Crop Estimates for the first time as a supplement publication 3 weeks in advance of the September Farm Survey estimates and 11 weeks in advance of the November Farm Survey estimates (Statistics Canada, Table 001-0075). Feedback to the modelled estimates through government and industry consultation has been very positive because of reduced response burden and reduced survey cost all while maintaining relevance, accuracy, timeliness, accessibility, interpretability and coherence.

Table 1 contains the 2015 summary comparison for yield and relative difference between the yield model and the November Farm Survey and between the September Farm Survey and the November Farm Survey.

Table 1. Summary comparison at the national level of Statistics Canada's yield model, the September and November Farm Survey, 2015.

Crop	Yield Model August 31, 2015	September Farm Survey	November Farm Survey	Yield Model compared to November Farm Survey	September Farm Survey compared to November Farm Survey
	Yield (bushels per acre)			Difference (%)	
Barley	**57.8**	**59.8**	**65.0**	**-11.0**	**-8.0**
Canola	**32.6**	**32.2**	**39.4**	**-17.3**	**-18.3**
Corn for grain	**158.9**	**150.8**	**165.5**	**-4.0**	**-8.9**
Flaxseed	**20.5**	**21.1**	**23.3**	**-11.9**	**-9.3**
Mixed Grain	**65.6**	**67.5**	**65.4**	**0.3**	**3.2**
Oats	**79.6**	**79.4**	**85.7**	**-7.1**	**-7.4**
Peas, dry	**29.1**	**31.7**	**32.3**	**-10.0**	**-2.1**
Rye, all	**38.2**	**38.8**	**38.0**	**0.5**	**2.2**
Soybeans	**43.3**	**41.3**	**43.5**	**-0.5**	**-5.1**

Wheat, durum	**30.9**	**30.9**	**34.5**	**-10.3**	**-10.3**
Wheat, spring	**40.5**	**41.6**	**44.0**	**-8.0**	**-5.5**
Wheat, winter	**62.8**	**65.2**	**64.8**	**-3.1**	**0.6**
	Yield (pounds per acre)			**Difference (%)**	
Canary seed	**865**	**813**	**1,040**	**-16.8**	**-21.8**
Lentils	**1,151**	**1,246**	**1,392**	**-17.3**	**-10.5**
Mustard seed	**711**	**731**	**841**	**-15.4**	**-13.1**

The September and November yield estimates listed in Table 1 have been adjusted to take into account any suppression that was applied during the yield modelling process as described earlier thereby providing a normalized comparison of the results between the three occasions.

The yield model had less deviation for canola, corn for grain, mixed grain, oats, rye, soybeans, and canary seed. Conversely, the September Farm Survey had less deviation than the model from the November Farm Survey for yield for barley, flaxseed, dry peas, spring wheat, winter wheat, lentils, and mustard seed. The two methods had equal deviation for durum wheat yield.

In general, the results from 2015 yield model and the September Farm Survey estimates had deviations from the November Farm Survey estimates of varying degrees. For certain crops the yield model estimates had less deviation while for others the September Farm Survey estimates had less deviation. Both methods produce estimates that can be both very similar to the November estimates for some crops while having more significant deviation for other crops.

8. Summary

The estimates produced by the yield model were comparable to those produced by the September Farm Survey in terms of relative difference from the November Farm Survey estimates for the 15 crops modelled.

In 2015, modelled yield estimates for field crops deemed to have a sufficient level of quality were published as a preliminary estimate 3 weeks in advance of the September Farm Survey estimates and 11 weeks in advance of the November Farm Survey results. Statistics Canada consulted with provincial and federal government counterparts, members of the grain industry, and academia regarding the yield model. Based on a proven, non-intrusive, scientific method and the strong outreach support coupled with the federal government's desire to reduce respondent burden and survey cost, it was decided that, commencing in 2016, Statistics Canada would replace the September Farm Survey with the Model-based Principal Field Crop Estimates. The replacement of a statistical field crop survey with a remote sensing model-based administrative data approach is a first for any statistical agency worldwide. Moving forward, Statistics Canada and Agriculture and Agri-Food Canada are evaluating methods of using other administrative data sources (such as crop insurance and additional satellite crop classification data) to derive crop area estimates which can be used in conjunction with the modelled yield estimates to create reliable estimates of crop production.

ABSTRACT

To our knowledge, attempts to directly model longitudinal change in macronutrients and energy intake of a population, with taking into account that individual change may not occur in the same fashion (i.e., develops at same growth rate), have never been practiced. In this respect, ambition of this paper is to propose the latent approach, by means of Latent Growth Curve Modeling (LGCM; Bollen & Curran, 2006) to the analysis of change in the nutritional status, namely fats, proteins and carbohydrates, and energy intake) of a target population in order to understand the time trend of the nutritional patterns at individual level. To this end, LGCM is able to outline the functional form of the individual growth trajectories and estimates the degree of individual variation and covariation around these just specified functions along with individualizing points of convergence and curvature. The subsequent application of multivariate LGCM allowed to check for gender invariance within people belonging to the same family and for multiple developmental trajectories while passing from urban to rural zone. The longitudinal data used as real example were taken from China Health and Nutrition Survey (CHNS) Household Food Inventory. From this survey a sample of 1229 households from urban and rural area, comprising of two adult family members of different gender, with having complete records of 3-day macronutrients and energy intake in 2000, 2004, 2006, 2009, 2011 was randomly selected. Interestingly, linear trajectories were found for fats and proteins at family level with convergence in 2009, and in 2006 and in 2012 respectively at rural and urban family level, whereas non-linearity was found for carbohydrates and energy intake. These nonlinearities were accommodated with polynomial functions and piecewise linear components with curvatures and knots for energy intake focalized respectively in 2006 and 2007. On the whole, the trajectories highlighted an equilibrium in the growth process with decreasing in the rate of change while passing from an initial heterogeneous amount of macronutrients and energy intake in 2000 to a more homogeneous status over the subsequent time period up to 2011. These results seemed in line with Chinese agricultural

reforms started in 2004-05, and 2008-09, from which Chinese families took benefit from by following a more balanced diet as well.

Keywords: Macronutrients, Latent Growth Curve Models, Structural Equation Models.

1. The nature of dynamics patterns

We define dynamics patterns as connected routes of repeated measures of variables at individual level. Repeated measures can be associated to time, as they usually do with typical longitudinal studies, or to different situations of repeated measurement such as the strength of an external stimulus (e.g., drug dosage). The main rationale of dynamics patterns is to have repeated measures "assessed or administered in a within-subject fashion and ordered in some logical way" (Preacher, 2010; p. 187). By simultaneously observing how these repeated measures vary across waves of measurement means studying how each individual behavior changes in terms of those measures. Hence, the study of dynamics patterns concerns the study of change in individual behaviors and how they deviate from a group-level change in common behaviors. This study is known as growth curve modeling (Muthén, 2001; p. 291). Despite of the fact that individuals may differ or not, in such repeated behaviors their connected routes outline trajectories. All these trajectories can follow a common average path or depart from it (Bollen & Curran, 2006). Further, they may have a theory of change behind, or take form of unspecified curves, but what is pretty sure is that they are ruled by a lawful, often unknown, developmental path that encompasses continuous and/or discontinuous phases. This effort to find out types of laws that rule over individuals, and group of individuals, change has already been faced over a century of research (see Bollen & Curran, 2006; p. 9-14), but it is still an ongoing challenge across scientific disciplines. Notwithstanding, what is of actual experiment is to understand this individual growth changing behavior as much as it does in the real world where individuals do not develop at the same rate and everything covaries. In this manner, a concrete starting point has been placed by the latent approach to the analysis of change. In this respect, the spirit of this paper is pioneering as it wants to propose such approach to an unusual area of research like nutrition and therefore making known potentialities and cutting edges.

2. Latent growth curve modeling rationale and outcomes

Unfortunately, when a researcher is dealing with a large number of repeated observations and wants to understand their patterns it is impossible to capture an immediate functional form, or known rule, that summarizes all these individual dynamics at first glance. A researcher can hypothesize that the patterns may follow some growth theory in advance and therefore confirming, or disconfirming, this theory with imposing, more or less realistic, constraints on these paths. But, what happens when no theory is available at the outset? An opening simple answer rises up: *to leave the repeated measures free to covary and thus observing how they interplay each other over the waves of measurement*. By doing so, a researcher is indirectly postulating that a possible unobserved common pattern may rule over this longitudinal covariation among the repeated measures. This latter is the main rationale of the latent approach to the analysis of individual growth change: the unobserved common pattern is a latent trajectory outlined by latent common factors that gives rise to the way how the repeated measures covary across the waves of measurement. By *gambling* on this hypothesis, a researcher combines the study of growth curve modeling with structural equation modeling (SEM) that typically estimates relations between latent factors and observed variables. This fusion takes the name of latent growth curve modeling (LGCM; Bollen & Curran, 2006) whereas the aforementioned latent common factors take the name of latent growth factors.

The so-called unconditional LGCM is condensed in the following simple equation:

$$y_{it} = \alpha_i + \lambda_t \beta_i + \varepsilon_{it} \tag{2.1}$$

where y_{it} are the repeated measures of a variable y for each individual i across points in time t (t=0, n), α_i represents the i individual value of y at the initial time point (i.e., t=0) from which the change in y starts and needs to be compared with the following values $y_{it+1.}$ Hence, α_i is the well-known regression intercept for each individual value of y_i and thus it has a mean and a deviation from mean (i.e., variance): μ_α and $\sigma^2{}_\alpha$. Now, in the most common case that a change is occurring from the initial value α_i , and therefore $y_{it} \neq y_{it+n}$, a dynamic trajectory starts to take form with a slope β_i that defines the inclination (i.e., difference from the initial values) of the trajectory for each individual i and thus it also has a mean and a variance: μ_β and $\sigma^2{}_\beta$.

Granted that, α_i, and β_i are now a sort of covariates that want to commonly explain the dynamics patterns in the repeated measures y_{it} with controlling for the errors ε_{it} (with the usual assumptions of mean equal to zero for all i and t, uncorrelated with the covariates, non-autocorrelated and homoscedastic) from which these covariates depart to outline the dynamic change. This is the point at which SEM structure with latent factors takes action and the equation (2.1) gains, in turn, all the benefits of the SEM analytic technique. The covariates α_i, and β_i become common latent growth factors that vary and covary by means of the estimated growth parameters μ_α, $\sigma^2{}_\alpha$, μ_β, $\sigma^2{}_\beta$ and $\sigma_{\alpha\beta}$, respectively; λ_t are the factor loadings that represent the degree to which the latent growth factors are able to explain the dynamic change in the repeated measures or, in other words, the way how the progress of time (situation) influenced the change in the repeated measures. As a consequence, the simultaneity estimation of these SEM-based latent growth parameters permits to release the assessment of the compound symmetry and thus taking into account that individuals develop at different growth rate alike in the real world. Hence, LGCMs are more flexible than traditional ANOVA-like methods for longitudinal studies.

It is intuitive from the equation (2.1) that a researcher can outline many different functional forms starting from the basic linear function to high-order of polynomials until more complex known functions and their re-parametrizations (please refer to Preacher and Hancock, 2015) as well as hypothesizing high-order growth factors for modelling multiple measures and groups of respondents (e.g., multivariate and multilevel designs; Duncan, Duncan & Stryker, 2006). For example, should the function (2.1) not be linear, but depicting a known curvature it is still possible to select a new metric λ_t into the equation (2.1) that, in turn, advances via depending on the selected non-linear function. For example, for quadratic (2.2) and cubic (2.3) polynomials the function (2.1) respectively becomes:

$$y_{it} = \alpha_i + \lambda_t \beta_{1i} + \lambda^2{}_t \beta_{2i} + \varepsilon_{it} \tag{2.2}$$

$$y_{it} = \alpha_i + \lambda_t \beta_{1i} + \lambda^2{}_t \beta_{2i} + \lambda^3{}_t \beta_{3i} + \varepsilon_{it} \tag{2.3}$$

Where β_{2i} and β_{3i} are further new growth parameters that take into account the new curvatures. Running these models by means of SEM and checking for the well-known diagnostics it is possible to confirm or disconfirm the hypothesized functions until reaching the one that fits better. In addition, SEM framework allows to explore for non-linearity of the repeated measures by leaving λ_t to be freely estimated for t = 2, .., n, with just setting $\lambda_o = 0$ and $\lambda_1 = 1$ or $\lambda_o = 0$ and the last $\lambda_n = 1$ for the latent factor metric. So that, the other un-standardized factor loadings are able to empirically estimate the type of non-linearity over the underling repeated measures. Furthermore, another very useful strategy for accommodating non-linearity in the trajectories is the so-called piecewise linear LGCM (Bollen & Curran, 2006). It simply consists in breaking the non-linear trajectories in the so-called breaking points, or transition (Bollen & Curran, 2006) or even discontinuity points (Hancock, Harring & Lawrence, 2013) and therefore connecting these points with linear functions till reaching a spline trajectory and thus looking into how it fits. Essentially, once λ_t are formalized, the functional form of the repeated measures is nearly outlined and the latent growth parameters μ_α, σ^2_α, $\mu_{\beta j}$, $\sigma^2_{\beta j}$ and $\sigma_{\alpha\beta j}$ (with j=1, n) can be estimated. The metric for α_i is always 1 because the intercept is the factor that simply blocks the initial amount of the repeated variable when there is no growth over time, $\beta_{it} = 0$.

The literature stipulates further useful statistics that can be inferred from the latent growth parameters. The first one is the so-called relative gradient for each slope $(RG_\beta)=\mu_\beta/\sigma_\beta$ (Hancock & Choi, 2006). The information it provides is about how many trajectories have a positive or negative inclinations. Furthermore, if a researcher assumes that the growth rates are distributed as $N(\mu_\beta, \sigma^2_\beta)$ the subsequent non-central standard normal distribution for RG can be re-written as N(RG,1) and it is possible to compute the proportion of positive and negative slopes with using the well-known non-central normal density curve table. A second statistical index is the so-called *aperture* (Hancock & Choi, 2006). Basically, the aperture is the point in time where the individual trajectories converge. It is noteworthy noticing that with a linear trajectory only just one aperture point is possible, with a piecewise linear-linear trajectory as many aperture points as the spline lines, but with nonlinear functions there might be multiple apertures. To our knowledge the math to locate multiple apertures in nonlinear scenarios and the related software commands have to be still worked out by academics. So then, we just report the three simple equations to determine the *aperture shift coefficient* a^{ap}, and its related moments, for a general linear time/situation interval metric of {a, b} (Hancock & Choi, 2006):

$$a^{ap}=a + (\sigma_{\alpha\beta}/ \sigma^2_\beta) \tag{2.4}$$

$$\mu_a^{ap} = \mu_\alpha + (a - a^{ap})\, \mu_\beta \tag{2.5}$$

$$\sigma^2_a{}^{ap} = \sigma^2_\alpha - [(\sigma_{\alpha\beta})^2 / \sigma^2_\beta] \tag{2.6}$$

The aperture point and the moments permit, in turn, the estimation of the relative aperture location (RAL) and relative aperture variance (RAV) (Hancock & Choi, 2006):

$$RAL = - a^{ap} / (\lambda_p - \lambda_1) \tag{2.7}$$

$$RAV = \sigma^2_a{}^{ap} / (\sigma^2_\alpha + b^2\sigma^2_\beta) \tag{2.8}$$

RAL with values between 0 and 1 supplies information on the proportion of time span in which the aperture occurs (e.g., with RAL=0.30 the aperture occurs after 30% of the total time interval has passed) whereas with values of 0, below 0, 1 and over 1 it reveals that the aperture respectively occurs at the initial time point, below the investigated time span, on the final time point, over the investigated time span. RAV with values close to 0 indicates that the trajectories have a strong degree of convergence around the point a^{ap}, with exactly 0 there is perfect convergence. On the other hand, with RAV values close to 1 the aperture is wide and the convergence is weak since the trajectories tend to be parallel and distant each other; with exactly 1there is no convergence at all.

3. Real data example

In order to illustrate the strength of LGCM we used longitudinal real data from China Health and Nutrition Survey (CHNS) Household Food Inventory. From this survey a sample of 1229 households from urban and rural area, comprising of two adult family members of different gender, with having complete records of 3-day average macronutrients (fats, proteins and carbohydrates in grams) and 3-day average energy intake (in kcal) in 2000, 2004, 2006, 2009, 2011 was randomly selected. To simulate the growth change of the macronutrients and energy intake trajectories and to reflect the effective passage in time from 2000 (the reference point in time from which the change starts) to 2011the change in score per unit of time metric λ_t was fixed to the following unequal spaced units λ_{00}=0, λ_{04}=4, λ_{06}=6, λ_{09}=9, λ_{11}=11 so as to respect the yearly intervals {0,1}. The increasing sequence of numbers for λ_t hypothesizes how much an initial linear growth increases. For instance, the number 4 indicates that, on average, the change from 2000 to 2004 is 4 times as great as the change from 2000 to 2001 and so forth.

The analyses were initially conducted at member level in order to explore if there were similar functional forms for gender, separately. Successively, the final LGCMs were developed at family level both for the whole sample and territorial sites (i.e., urban vs rural) by applying multivariate representations of the growth process. These high-order levels of latent growth factors models accommodates for intra-class correlation occurring at members belonging to the same family (i.e., unique errors covariances free to covary) and for invariance of members trajectories (i.e., factor loadings between the first and the second order fixed to be equal over time of each family member; see Duncan, Duncan & Stryker, 2006; p. 69-74). In order to preserve space, we report results at family levels only since they are also the most relevant. Robust maximum likelihood (RML) estimation within LISREL 8.8 (Jöreskog & Sörbom, 2007) for fats and proteins individual trajectories provided good data-model fit (according to the main and well-known SEM fit indices and cut-off criteria: Chi-square not significant, Root Mean Squared Error of Approximation (RMSEA) under 0.05, Comparative Fit Index (CFI) over 0.95, Standardized Root Mean Squared Residual (SRMR) under 0.09) for common routes of linear growths in both gender and thus at family level (whole sample): Chi-square (df)=661.69(178), p<0.001, RMSEA=0.047 with 90 % Confidence Interval (CI) for RMSEA = (0.043 ; 0.051), CFI=0.94, SRMR=0.056. Latent growth factors parameter estimates and statistics are reported in table 1. Intercept and slope variances were statistically significantly different from zero with yielding to a significant individual difference of fats and proteins trajectories both at initial level and in the rate of change, although slope variances were smaller than intercept variances. These results would mean that fats and proteins patterns became even more similar in their rate of change. Interestingly, the covariance between the growth factors is significant and negative, and then the correlation is of -0.55. It means that the families with low fats and proteins score started to grow more, while the ones with high score to grow less. These latter were the most part since the RG provided 58% of family trajectories with negative slopes. Besides, the mean value over the time span was significant and negative as well. The statistics RAL and RAV showed a weak tight of convergence after 85.8% of the total time has passed, so then roughly 9.4 years after the initial 2000, in the first months of 2009.

A very interesting result was found when the sample was split in urban (i.e., n=362) and rural site (n=867). Although the dynamics patterns for fats and proteins were linear for both urban and rural families (i.e., for urban: Chi-square (df)=309.64(178), p>0.001(p=0.162), RMSEA=0.045, with 90 % CI for RMSEA = (0.037 ; 0.054), CFI=0.96, SRMR=0.066; for rural: Chi-square (df)=615.42(178), p<0.001, RMSEA=0.053, with 90 % CI for RMSEA = (0.049 ; 0.058), CFI=0.93, SRMR=0.064). For the former the trajectories were most negatively inclined (see table 1) with showing a decreasing across years with a convergence, although not very strong, above the time period and exactly slightly more than one year beyond 2011, in 2012. On the contrary, fats and proteins trajectories for rural families were pretty flat with a convergence, although pretty weak as well, after 55.6% of the time span has passed and therefore after 6.11 years, in 2006.

Completely different situation was found for carbohydrates and energy intake dynamics patterns. In order to preserving space and due to similar results we present here just the results from energy intake (in kcalories). Since the observed variances for kcalories were extreme, the measures have been rescaled (i.e., multiplied by 0.1) in order to facilitate the model convergence (Hancock & Mueller, 2010) without affecting differences among the scores (Kline, 2011). The fit indices for linear trajectories of energy intake by gender suggested to explore potential forms of new curvatures that depart from linearity (i.e., for males: Chi-square (df)=94.86(10), p<0.001, RMSEA=0.083, with 90% CI for RMSEA=(0.068; 0.099), CFI=0.86, SRMR=0.051; for females: Chi-square (df)=68.12(10), p<0.001, RMSEA=0.069, with 90% CI for RMSEA=(0.068; 0.099), CFI=0.91, SRMR=0.038). By doing so, LGCMs for energy intake individual trajectories at family level were run with fixing the first λ_{00} and the last λ_{11} loadings respectively to 0 and 1 while leaving the others to be freely estimated (Bollen & Curran, 2006). This strategy permits to discover the proportion of cumulative change occurred from the initial time point to the specific time period in reference to the total change of the entire period. The trend was quite similar for both family members. By explaining it for males (M) the values of λ_{04}=0.19, λ_{06}=0.09, and λ_{09}=0.28 respectively reflected that 19%, 9%, 28% of the total change in energy intake occurred between 2000 and 2004, 2000 and 2006, 2000 and 2009. By computing the following differences (0.19-0.09=0.10) and (0.28-0.09=0.14) it yielded to 10% of the total change between 2004 and 2006 whereas 14% between 2006 and 2009. Similar results were found for females (i.e., λ_{04}=0.19, λ_{06}=0.09, and λ_{09}=0.26). As a consequence, it is straightforward noticing that most of change in the energy intake occurred after 2006 and these two trends seem to reflect an up and down growth process that departs from linearity to outline a cubic polynomial function with a potential curvature after 2006.

Table 1: *Estimates and statistics for fats and proteins common trajectories at family levels*

Whole sample

Parameter	σ^2_α	σ^2_β	$\sigma_{\alpha\beta}$	$\rho_{\alpha\beta}$	μ_α	μ_β

	-0.010	50%	50%	-3.89	0.556	0.990

Note: t-values <|2| are not significant.

As a matter of fact, by applying equation (2.3) to the energy intake repeated measures we obtained excellent fit indices: Chi-square (df)=37.38(29), p>0.001(p=0.137), RMSEA=0.015, with 90% CI for RMSEA=(0.00; 0.028), CFI=1.00, SRMR=0.018. So then, the energy intake dynamics are definitely cubic. Nevertheless, in order to better detangle these nonlinear patterns, a piecewise LGCM strategy was applied here with splitting the curve into two linear trajectories and fixing the breaking point at year 2006 from which a second line departs. By doing so, the loadings λ_{06}, λ_{09}, and λ_{11} of the second linear slope β_{2i} were respectively fixed to 0, 3 and 5 according to the initial metric and thus simulating a new linear form departing from 2006. The piecewise linear model fitted well: Chi-square (df)=100.76(35), p<0.001, RMSEA=0.039, with 90% CI for RMSEA=(0.030; 0.048), CFI=0.97, SRMR=0.029. In the tables 2 and 3 are depicted the cubic and the piecewise linear LGCMs growth parameters for energy intake directly at family level (results about urban and rural area were not shown for preserving space. They can be requested, but they showed similar negative trends although more marked in the urban site families). Three slope factors (table 2) described the curvilinear function with showing significant variances in decreasing sequence indicating that the growth change in energy intake became more and more similar across individuals while passing time. This was a decreasing change since two factor means out of three were negative along with higher percentages of negative slopes as well. The covariances (correlations) indicated this decreasing growth process that already started from the linear part of the polynomial function (i.e., parameters of slope β), with a little increasing when passing to the quadratic part until decreasing again with a steeper acceleration down in the cubic part. These results were confirmed more clearly by piecewise linear model (table 3) with a decreasing of energy intake especially after 2006. Furthermore, a strong convergence point (i.e., $RAV_{\beta\beta2}$=0.04) occurred when roughly 21.5% of time passed after 2006. It means after 1.07 years after 2006, in 2007.

4. Wrap-up and conclusion

At present, we do believe that by attempting to detangle the complexity of nutritional growth processes in the human over a time span, or different situations of intervention, requires of inspecting variations at individual level. In this respect, what is needed is of a statistical technique that is able to estimate variations and shared-variations among individual trajectories, simultaneously. Advances in this direction have been made by latent growth curve models. Latent growth parameters of such curves permit to catch a lot of detailed information that deserve to be further investigated. The real data example concerning fats, proteins, carbohydrates and energy intake individual trajectories of Chinese people collected in unequal blocks of years from 2000 to 2011 showed different growth functions. Nevertheless, all the individual trajectories tended to be negatively inclined with also reducing the high discrepancies occurred before Chinese agricultural reforms took place in 2004-05 and 2008-09. The former introduced direct subsidies to farmers, agricultural tax reduction, support to seed and machinery purchases whereas the latter introduced investments to housing, to rural constructions and infrastructure so as to enhance domestic demand and people's livelihood . These reforms presumably encouraged people to follow a more balanced diet since the general reducing of macronutrients and energy intake discrepancies yielded to many convergence points (in 2006, 2007, 2009, 2012) and interesting curvatures in 2006 occurred both after and throughout the corresponding aforementioned time intervals of such reforms.

Small Area Estimation for Crop Acreage in Remote Sensing Assisted Crop Survey

— A Case of Major Crop Acreage Estimation in Liaozhong County

ABSTRACT

Applying remote sensing to estimate the planted acreage is typically by using regression estimator or calibration estimator which is taking advantages of combining the sample data from ground survey with satellite image classification. For most cases of regression estimator, the crop acreage estimation for a target population such as a province or county only satisfies the precision for itself but could not be disaggregated to small areas, such as county and town level statistics.

Taking the Liaozhong county affiliated to Shenyang city, Liaoning province as a study area, the satellite images from the moderate resolution Landsat 8 OLI is classified for rice and corn as auxiliary information for population, and high resolution Chinese GF-1 and ZY-3 are visually interpreted for rice and corn which is regarded as ground truth. The whole county is segmented into grids of 100m*100m as sampling units, a simple random sampling is adopted to select samples with replicates 1000 times to do simulation of building small area models. From our simulation study, it reveals that a basic level small area model in the form of one-response multiple regression with random effects and fixed effects are both feasible to produce the estimates at town and township level. Meanwhile, the aggregate of estimates of every town could (approximately) be the estimates for the county under the assumption of linear regression. It is concluded that the small area estimation method is applicable to solve crop acreage estimation from province to county level simultaneously when targeting an entire province.

Keywords: Crop Acreage, Small Area Estimation, Remote Sensing

1. Introduction

China is a major agricultural production country as well as a large consumption and trade country in terms of farm products. Depending on the various agricultural information especially on the planted acreage statistics of major grain crops, it has been an important gist for decision making with respect to grain and food policy as well as economic development plans at national level. To acquire the planted acreage of major grain crops and their spatial distribution in a timely, accurate, quantitative way is of significance for making decision on agricultural production at various levels of governments, in order to ensure food security, steer and adjust the crop planting structure through macro-economic control, as well as improve the operational management for relevant enterprises and farms (Blaes and Vanhalle et al.; Tao and Yokozawa et al.; Chauhan and Arora et al.). The traditional approach to obtain crop acreages are usually conducted by a sample survey usually by a national statistics agency. However, this process is time-consuming, labor-intensive and lacking in spatial information (Ma et al.). Remote sensing has been used for crop acreage estimation over the last few decades and is considered to be an effective tool for detecting the crop area extents and changes at regional or global scales (Hall and Badwar; Yang et al.; Xiao et al.). Some countries has already conducted a series of operational programs which aims at the estimation for land cover/land use and crops acreage, such as the USA (LACIE,1974-1977; AGRISTARS,1980-1986; CDL,1997-2010), European Union (MARS,1998; LUCAS, 2001-2009; Geoland2, 2008(2011)) and ROK (Implement RS Application System, IRSAS, 2008-2012).

Similarly to the American and European remote sensing programs for crop acreage estimation, since year 2010 the National Bureau of Statistics (NBS) of China has collaborated with external research institute to preliminary establish an operational business mode—Remote Sensing Assisted Crop Survey (RSACS) for major provinces in terms of grain outputs in China. The RSACS basically involves (1) selecting sample segments for each individual province based on area frame, (2) conducting field survey and collecting crop data, (3) crop spatial classification based on moderate satellite images, (4) crop acreage estimation.

Many studies have been carried out on crop acreage estimation for remote sensing assisted crop survey. To produce the estimates of crops acreage for a target population, there are usually three approaches could be adopted (F.J. Gallego). The first is direct expansion estimator which is a typical sampling approach to produce the estimates by only using survey samples. The second is called calibration estimator which is based on the crop classification result from remote sensing through adjusting the classification by confusion matrix. The third is regression estimator which refers to build a linear regression model by combining the ground survey data with the classification results from remote sensing. Theoretically, the regression estimator could gain precision of estimation due to combing the ground survey data with crop classification from remote sensing, which is taken as an auxiliary information for population. The regression estimator is essential derived from linear regression method which could be widely adapted to a particular problem solving, for example, Yaozhong Pan proposed an approach to estimate winter wheat area through building regression on Crop Proportion Phenology Index (CPPI) which disaggregated from the MODIS vegetation index (VI) (Pan et al.). The Chinese RSACS has also developed a feasible solution on acreage estimation for major crops such as wheat, corn, rice at provincial level by using linear regression method. However, the current methods of crop acreage estimation mostly concentrate on producing the estimates for the target population (province) but could not be disaggregated to sub-regional (county) levels.

In the Chinese context of remote sensing assisted crop survey, the sample segments and crop classification are directly linked to meet the requirements for the target province, while the estimates for crop acreages are expected to meet the precision for both province and county level. From literature study, small area estimation is the most dominant approach to solve the multi-level estimation such as estimates for both county and province level simultaneously. In 1988 a nested-error small area model is specified for the relationship between the reported hectares of corn and soybeans within sample segments from ground survey and the corresponding satellite determination for areas under corn and soybeans, and predictions of mean hectares of corn and soybeans per segment for the 12 Iowa counties are presented (Battese G.E. et al). In 2003 small area estimation is applied in a survey conducted in the Rathbun lake Watershed in Iowa, erosions are estimated for 61 small areas within the study region (Opsomer J.D. et al). In 2006 Small area model which included sampling and model weights was proposed and applied in agriculture for predicting minor crops (Militino A.F.).

In this study, we attempt to produce the crop acreage estimation at multi-levels by using method of small area estimation. The study area is chosen in Liaozhong county which is affiliated to Shenyang city, Liaoning province of China. Two kinds of spatial resolution satellite images has been acquired and processed for year 2014. The visual interpretation results from high resolution GF-1 and ZY3 for rice and corn was regarded as ground truth, while extracted crop classification for rice and corn from the moderate resolution Landsat 8 OLI was taken as the auxiliary information for population. We explored the small area model of basic unit level with random effects and fixed effects respectively by combining the ground truth data with auxiliary information of population. Given different sampling fraction under simple random sampling by using Monte Carlo simulation, the result of coefficient of variation (C.V) derived both from the model based mean square error (MSE) and simulation based MSE are computed and make comparison.

2. Experimental Area and Procedures

2.1 Experimental area

We choose the Liaozhong county, which is affiliated to Shenyang city of Liaoning province, as experimental area or target population in sampling terminology. There are altogether 20 towns and townships within the Liaozhong county, regarded as small areas or domains in our study. Liaozhong located in 122°28~123°6′ longitude east and 41°12′~41°47′ latitude north, having the total territory area around 1460 square kilometers. Liaozhong is situated in lower tier of Liaohe river watershed, belong to a washed plain impacted by Laiohe river and Hunhe river. On annual average, the cumulative sunshine hours are 2575 hours and cumulative precipitation is 640 millimetre, it is suitable for agricultural production. The major species for grain crops are rice, corn and soybean.

2.2 Moderate spatial resolution images

For large scale crop monitor program by using remote sensing, usually the moderate resolution satellite images are adopted to extract optical spectrum to distinguish the crops. In this study, Landsat 8 OLI satellite imagery on June 4, August 7 and September 8 are acquired respectively, and geometry correction as well as radiation correction are processed. Based on post-processed standard orthophoto images, a maximum likelihood classifier (MLC) is adopted to extract the rice and corn on pixel-base.

The three temporal images are classified for rice and corn individually by using MLC, and then the final distinguished crops of rice and corn are obtained by detecting the dynamic change of three temporal results. In the process of MLC applied to distinguish different crops, the real crop survey data in 2014 from Liaoning Survey Organization of National Bureau of Statistics(NBS) had been used as training set of samples when applying MLC. From the ongoing crop sample surveys conducted in Liaozhong county by the survey organization of NBS, we had 15 sample villages and each village allocated 5 sample segments in the size of 2 hectares. Altogether there are 75 sample segments of survey data could be used as ground truth in the process of satellite image classification. Finally the classified results and spatial distribution for rice and corn are obtained in format of vector data, which covers the whole county and serves as auxiliary information of population.

2.3 High spatial resolution images

We acquired the Chinese GF-1 and ZY-3 satellite images (high spatial resolution imagery) to be visually interpreted to distinguish corn and rice corresponding to each arable field or plot respectively. Subject to the limitation of acquisition of qualified satellite images, we have acquired one temporal GF-1 images dated on October 7, 2014 and one temporal ZY-3 images dated on June 4 and June 14, 2014 before the autumn harvest. The acquired high resolution images are pre-processed by geometry and radiometric correction as well as a fusion of 2m panchromatic and 8m multi-spectral images. Taking the advantages of the coverage of delineated cropland for this county being obtained from a previous land survey, it facilitated the visual interpretation to distinguish of rice and corn within the cropland effectively. The result of visual interpretation is used as an approximate ground truth for corn and rice, and is also applied to assess the accuracy of crop classification from moderate resolution images.

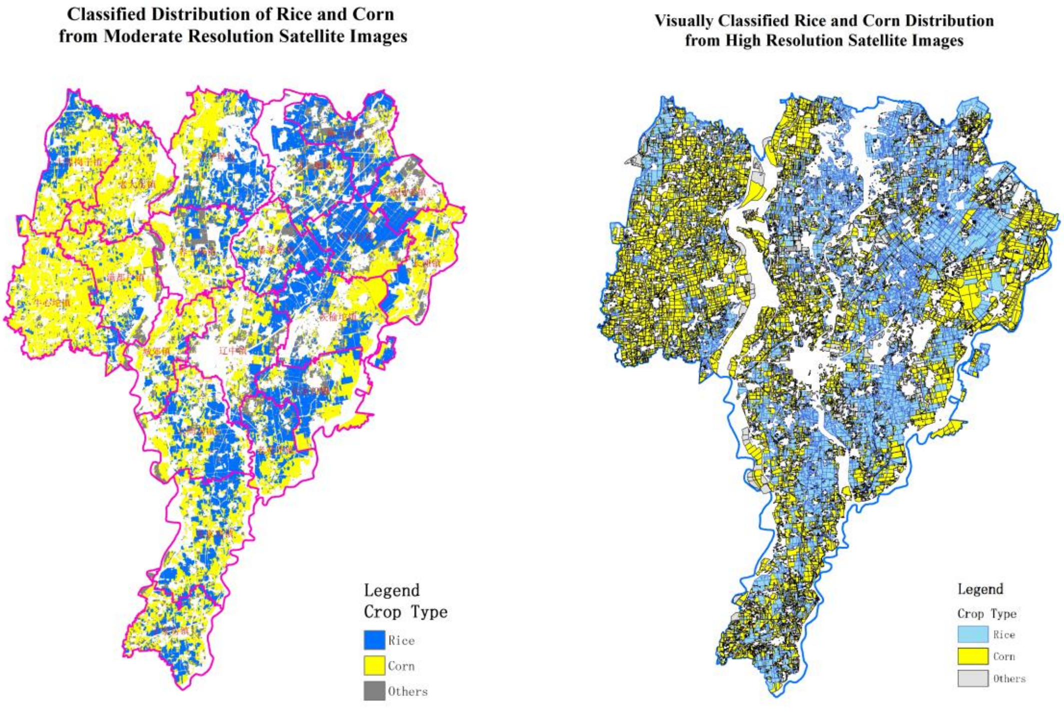

Figure 1: *Planted distribution of rice and corn from moderate and high resolution satellite images respectively.*

2.4 Sampling design

With the facility of GIS system, we delineated the whole territory of Liaozhong county into squared grids in size of 100 meters×100 meters. There are altogether 138279 grids, which are regarded as sampling units. A simple random sampling is adopted to select samples, and sampling fraction are chosen as 0.07%, 0.14%, 0.25%, 0.5%, 1%, 2%, 5% respectively to make comparison. In our study, the crop classification from the satellite images of Landsat 8 is taken as the auxiliary information for population, while the crop interpretation from the GF-1 and ZY-3 is regarded as data of ground truth.

2.5 Analysis for multi-level estimation

We probe the multi-level estimation for major crop acreage in the context of remote sensing assisted survey in Liaozhong county, which aims to produce the crop acreage estimates at town level and simultaneously generate the estimates for the county. The method of small area estimation is adopted, and a basic unit level model for small area is specified. The small area model is set in two scenarios for the effects of small area, one is the random effects and the other is fixed effects. Given the sampling scheme of simple random, a replicate of 1000 samples are selected for crop acreage estimation and consequent precision assessment. For each town and township, the estimate precision derived from the small area model is compared with the precision from direct domain estimation. In our study, we present simulation results as the following: (1) Computing the MSE of the model according to parameter estimation such as Empirical Best Linear Unbiased Prediction (EBLUP) and its CVs, (2) Based on the estimates from each individual model from replicates, computing the MSE and its CVs by simulation, (3) Based on the direct domain expansion, computing the mean squared error (MSE) and its coefficient of variation (CVs).

3. Multi-level Estimation by Small Area Model

3.1 Small area model with random effects

3.1.1 Model setting

For the crop of interest y_{ij}, assuming the random effects for small area, the adopted unit level small area model is as follows:

$$y_{ij} = \mu + X_{ij}^{T}\beta + v_i + e_{ij}, \quad j = 1,2,...,n_i \;, \quad i = 1,2,...,m \tag{1}$$

Where, y_{ij} is a specified crop (rice or corn) acreage for the jth sample grid in the ith town and township, m is the total number of towns and townships, in our case m=20, while n_i is the sample size in the ith town and township, μ is the intercept in the model, $X_{ij} = (x_{ij1},...,x_{ijp})'$ refers to the crop classification results from the moderate satellite which is composed of the variables $x_{ij1},...,x_{ijp}$. Random effects v_i and error term e_i are independent and identically distribution, subject to normal distribution with mean 0 and identical variance σ_v^2 and σ_e^2 respectively.

From the generalized ordinary least square method, we have

$$\hat{\beta} = \left(\sum_{i=1}^{m} X_i' V_i^{-1} X_i\right)\left(\sum_{i=1}^{m} X_i' V_i^{-1} Y_i\right) \tag{2}$$

$$\hat{v}_i = \frac{\sigma_v^2}{\sigma_v^2 + \sigma_e^2 / n_i}(\bar{y}_i - \bar{x}_i\hat{\beta}) \tag{3}$$

Where, $V_i = \sigma_v^2 1_{n_i}^{'} 1_{n_i} + \sigma_e^2 I_{n_i}$, $X_i = (X_{i1},...,X_{in_i})'$, $Y_i = (y_{i1},...,y_{in_i})'$, $\bar{x}_i$ is the sample mean for the auxiliary information of the ith town and township.

Hence, the estimate for the sub-population total of the ith town and township is as follows:

$$\hat{Y}_i = N_i[\bar{X}_{ui}\hat{\beta} + \frac{\sigma_v^2}{\sigma_v^2 + \sigma_e^2 / n_i}(\bar{y}_i - \bar{x}_i\hat{\beta})] \qquad (4)$$

Where, $\bar{X}_{ui}$ is the sub-population mean of classified result of rice or corn from moderate satellite images of the ith town, N_i is the total number of grids in the ith town and township.

For the variance estimation of random effects v_i and error item e_i, we adopt the moment method introduced by Fuller and Battese（1973）:

$$\hat{\sigma}_e^2 = SSE(1)/(n - m - p_1), \quad \hat{\sigma}_v^2 = \max\{[SSE(2) - (n-p)\hat{\sigma}_e^2]/\eta, 0\}$$

Where, $SSE(1)$ is the sum of squared residuals from the regression $y_{ij} - \bar{y}_i$ on $X_{ij} - \bar{x}_i$, $SSE(2)$ is the sum of squared residuals from the regression y_{ij} on X_{ij}, p_1 is the number of non-zero in $X_{ij} - \bar{x}_i$, $\eta = \sum_{i=1}^{m} n_i - n_i^2 \bar{x}_i (\sum_{i=1}^{m} X_i^{'} X_i)^{-1} \bar{x}_i^{'}$. If the estimates of variance plugging into formula (3) and (4), then we have the total estimate $\hat{Y}_i^E$ for the ith town and township by EBLUP estimation:

$$\hat{Y}_i^E = N_i[\bar{X}_{ui}\hat{\beta}^E + \frac{\hat{\sigma}_v^2}{\hat{\sigma}_v^2 + \hat{\sigma}_e^2 / n_i}(\bar{y}_i - \bar{x}_i\hat{\beta}^E)] \qquad (5)$$

Where, $\hat{\beta}^E$ is the estimate of β when plugging into the estimates of variance in formula (2). Alternatively the parameter estimates could be estimated by the ML or REML method, there are no significant difference among the estimates.

3.1.2 MSE of EBLUP at town level

For each small area (town) of the model, the MSE of Empirical Best Linear Unbiased Prediction depends on the model, Rao(2003) gave the formula as follows.

$$MSE(\hat{Y}_i) = g_{1i}(\hat{\sigma}_v^2, \hat{\sigma}_e^2) + g_{2i}(\hat{\sigma}_v^2, \hat{\sigma}_e^2) + 2g_{3i}(\hat{\sigma}_v^2, \hat{\sigma}_e^2) \qquad (6)$$

Where the definition of $g_{1i}(.)$, $g_{2i}(.)$ and $g_{3i}(.)$ are referred to Rao's literature Small Area Estimation.

3.1.3 Population total at county level

In the random effects model, the sum of acreage estimate Y_i for the total number of small area $i = 1$ to m is approximately equal to the total acreage at county level in the assumption of general linear regression. In fact, sum of the expectation of each Y_i is equal to expectation of total $\hat{Y}$. Due to the $E(v_i)=0$, we have the follows.

$$E(\hat{Y})=E(\hat{Y}_1)+E(\hat{Y}_2)+...+E(\hat{Y}_m) \quad (7)$$

3.2 Small Area model with fixed effects

3.2.1 Model setting

The formation of prediction model with fixed effects of small area is the same as the model in equation (1). The only difference is that v_i is assuming as fixed effects instead of random effects, that is to say for each small area (town) there is a fixed value of v_i in the model.

By differential method for the parameter estimation, we have:

$$\hat{\beta}=\left(\sum_{i=1}^{m}X_i^TQ_iX_i\right)\left(\sum_{i=1}^{m}X_i^TQ_iY_i\right) \quad (8)$$

$$\hat{v}_i=\bar{y}_i-\bar{x}_\mathbf{i}^\mathbf{T}\hat{\beta}-\bar{y} \quad (9)$$

Where $Q_i=I_{\mathbf{n}_i}-\frac{1}{n_i}1_{\mathbf{n}_i}1_{\mathbf{n}_i}^T$, $X_i=(x_{i1}^T,...,x_{in_i}^T)^T$, $Y_i=(y_{i1},...,y_{in_i})^T$, $\bar{x}_i$ is the sample mean of auxiliary information from the ith town and township.

The estimate for the population mean of small area is as follows:

$$\hat{\bar{Y}}_i=\bar{X}_{ui}^T\hat{\beta}+(\bar{y}_i-\bar{x}_i^T\hat{\beta}) \quad (10)$$

Where $\bar{X}_{ui}$ is the sub-population mean of classified rice or corn from moderate satellite images of the ith town. $\bar{y}_i$ is the sample mean of the ground truth for rice or corn of the ith town. $\bar{x}_i$ is the sample mean of the classified rice or corn of the ith town.

Then the estimate for the population total of small area is $N_i\hat{\bar{Y}}_i$.

The estimate for the error term e_i is as follows:

$$\hat{\sigma}_e^2=SSE(1)/(n-m) \quad (11)$$

Where, $SSE(1)$ is the sum of squared residuals from the regression $y_{ij}-\bar{y}_i$ on $X_{ij}-\bar{x}_i$.

3.2.2 MSE of model prediction at town level

For each small area (town), the MSE which depends on the model is as follows:

$$MSE(\hat{Y}_i)=E(\hat{Y}_i-Y_i)^2=n_i^2(\bar{X}_i-\bar{x}_i)^T(\sum_{i=1}^{m}X_i{}^TQ_iX_i)^{-1}(\bar{X}_i-\bar{x}_i)+n_i\hat{\sigma}_e^2 \quad (12)$$

Where, $\hat{Y}_i$ is the estimate of crop acreage from the ith town, Y_i is the approximately real planted acreage which is visually interpreted from the high resolution satellite imagery. $\bar{X}_i$ and $\bar{x}_i$ are sub-population mean and sample mean of the crop acreage which are classified from moderate satellite imagery. The definition of X_i is the same as in formula (8) , and the definition of $\hat{\sigma}_e^2$ is the same as in formula (11).

3.2.3 Population total at county level

In the fixed effects model, for total estimates of each town and township level, we have:

$$\hat{Y}_i = N_i \bar{X}_{\mathbf{ui}}^{\mathbf{T}} \hat{\beta} + N_i(\bar{y}_i - \bar{x}_{\mathbf{i}}^{\mathbf{T}} \hat{\beta}) \quad (13)$$

To sum up Y_i over the number of m towns and townships, we have the total estimates for entire county as follows:

$$\begin{aligned} \hat{Y} &= \sum_{i=1}^{m} [N_i \bar{X}_{\mathbf{ui}}^{\mathbf{T}} \hat{\beta} + N_i(\bar{y}_i - \bar{x}_{\mathbf{i}}^{\mathbf{T}} \hat{\beta})] \\ &= \sum_{i=1}^{m} N_i \bar{y}_i + \sum_{i=1}^{m} N_i (\bar{X}_{\mathbf{ui}}^{\mathbf{T}} - \bar{x}_{\mathbf{i}}^{\mathbf{T}}) \hat{\beta} \end{aligned} \quad (14)$$

Therefore, the sum of acreage estimates Y_i for the total number of small area $i = 1$ to m is exactly equal to the total acreage at county level in the assumption of general linear regression. Similarly, under the context of sampling weight to be applied, the sum of acreage estimates over all of small areas is also exactly equal to the total acreage at county level in the assumption of general linear regression.

4. Simulation Results

4.1 Experimental Data

For the experimental area Liaozhong county, we have delineated the whole territory into grids in size of 100 meters ×100 meters. There are altogether 138279 grids which is used as the sampling units (PSU). The information used in small area model building are as follows (Table 1), among them column (5) and (6) are used as dependent variables, column (7) and (8) are used as independent variables. In our study, the Liaozhong county is the target population, and its affiliated 20 towns and townships are regarded as small areas (domains). Two major crops of rice and corn are our variables of interest.

Total			138279	42498.532	50534.077	35964.847	45810.884

We adopted simple random sampling to select samples, and designated seven different sampling fraction respectively as follows: (1) 0.07%, (2)0.14%, (3)0.25%, (4)0.5%, (5)1%, (6) 2%, (7) 5%.

With respect to each sampling fraction, we do the simulation by selecting the samples k=1000 times. In our case, we adopted small area model to estimate the rice and corn acreage for each town and township. We attempted two scenarios for the small area with random effects and fixed effects respectively. Meanwhile, In order to assess the estimate precision from the method of small area model, we compared the results with that from the direct expansion estimation for small area.

For the 1000 replicate samples, in order to compare the estimate precision of crop acreage, we computed the MSE and C.Vs with respect to rice and corn acreage for each town and township by the following three approaches: (a) direct expansion for domain estimates; (b) model prediction (EBLUP) from the small area model; (c) the estimates (prediction) for each town and township based on each individual small area model from replicates.

For the above approaches (a) and (c), the mean square error (MSE) for each small area i could be computed by replicates.

$$MSE_s(\hat{Y}_i) = E(\hat{Y}_{ir} - Y_{ir})^2 = \sum(\hat{Y}_{ir} - Y_{ir})^2 \Big/ k \qquad (15)$$

Where, $\hat{Y}_{ir}$ is the rice or corn planted acreage estimated from the rth replicate of the ith town and township. While Y_{ir} is the rice or corn truly planted acreage from the rth replicate of the ith town and township. Converting to coefficient of variation (CV), we have:

$$C.V(\hat{Y}_i) = \frac{\sqrt{MSE_s(\hat{Y}_i)}}{Y_i} * 100\% \qquad (16)$$

For the above approach (b), for each replicate we got $MSE_r(\hat{Y}_i)$ and $C.V_r(\hat{Y}_i)$ from model itself, then taking the average of all these $C.V_r(\hat{Y}_i)$ as a result of $C.V(\hat{Y}_i)$.

4.2 Simulation results for rice and corn

Referring to the formation of equation (1), y_{ij} refers to rice or corn real planted acreage from approximate ground truth, X_{ij} refers to rice and corn acreage which is classified from image. There are m=20 towns and townships in Liaozhong county. We illustrate the simulation results from the small area model with random effects and fixed effects.

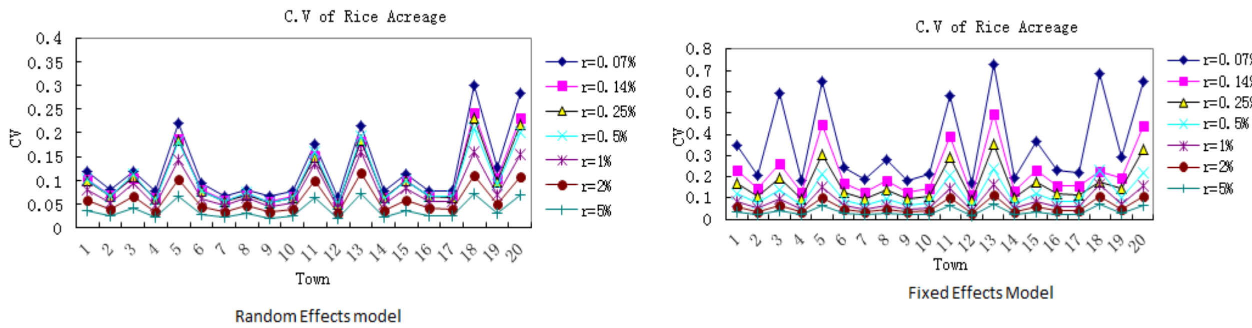

Figure 2: *C.Vs of rice acreage from MSE of Prediction for small area model*

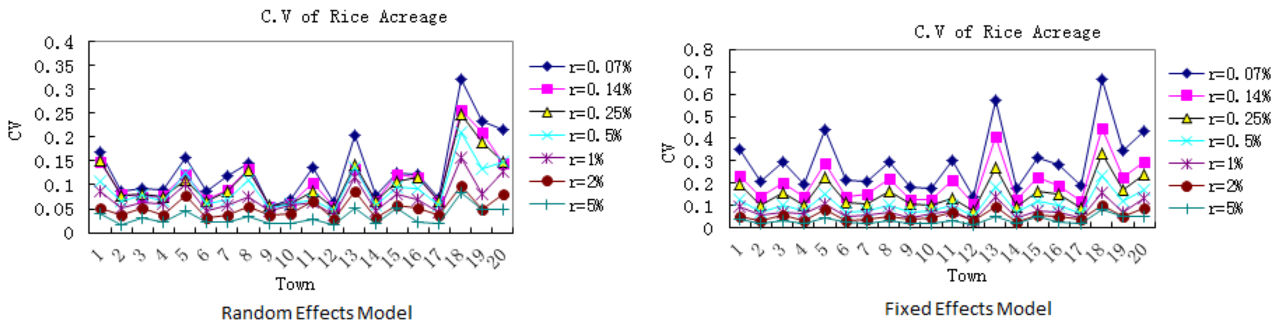

Figure 3: *C.Vs of rice acreage from MSE based on individual estimates derived from models*

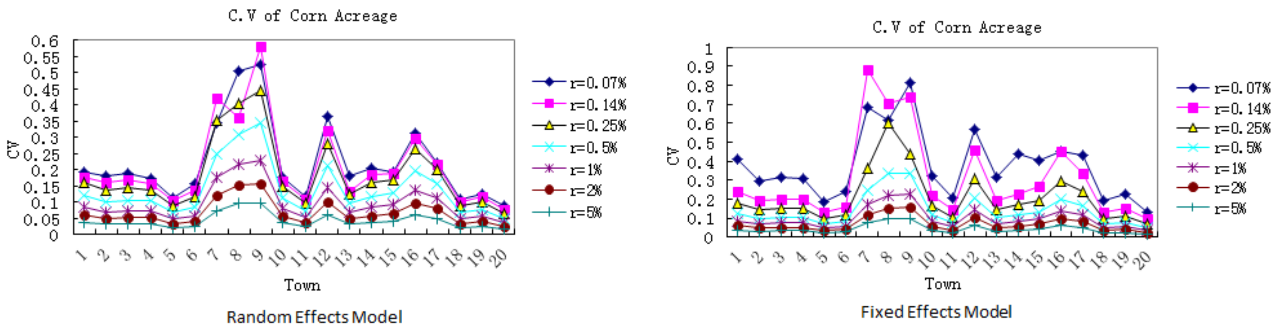

Figure 4: *C.Vs of corn acreage from MSE of Prediction for small area model*

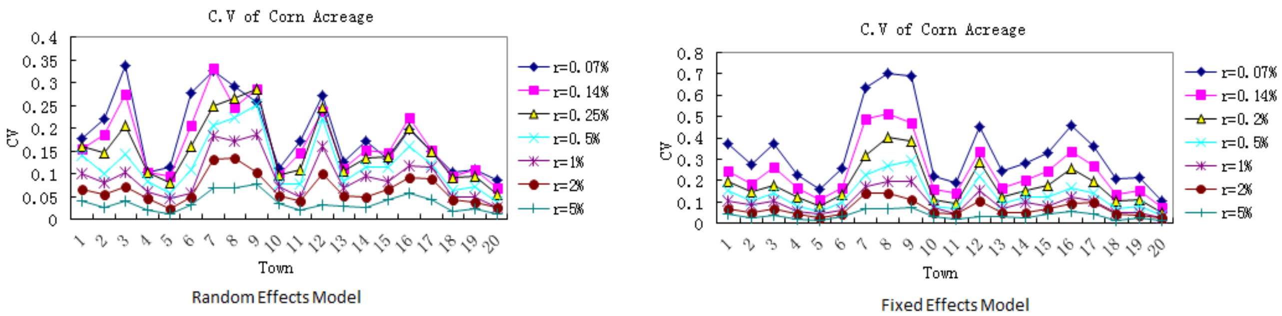

Figure 5: *C.Vs of corn acreage from MSE based on individual estimates derived from models*

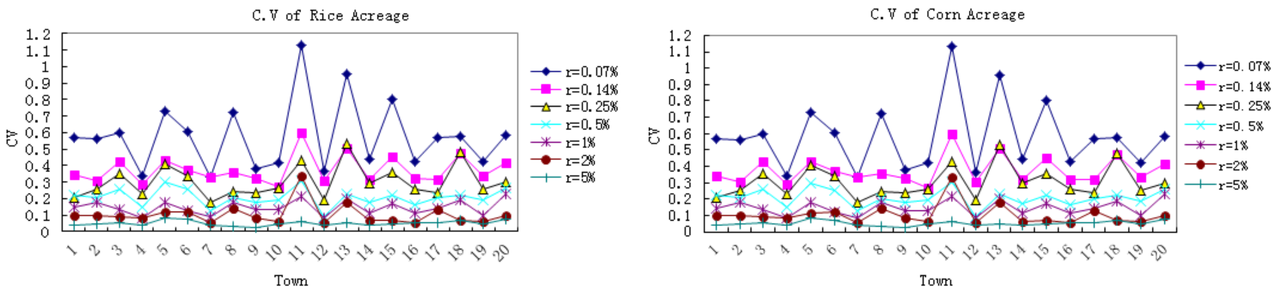

Figure 6: *C.Vs from the direct expansion for domain estimates*

The above Figure 2 and Figure 3 are C.Vs of rice acreage computed from model based MSE (approach b) and simulation based MSE (approach c) respectively. Similarly, Figure 4 and Figure 5 are C.Vs of corn acreage computed from model based MSE (approach b) and simulation based MSE (approach c) respectively. For small area model, if model fitness is good enough, then the MSE derived from the model should be very close to the MSE calculated from the simulation. To simplify the assessment of estimate precision for small areas, we could focus on the C.Vs results of Figure 3, Figure 5 and Figure 6 to make comparison.

Obviously, the precision of estimates gain significant improvement for small areas either in random effects model or fixed effects model especially for a smaller sampling fraction, compared with the direct domain estimation approach. For small area model with fixed effects, it holds on an additive property under the assumption of linear model that the aggregate of all estimates of each town and township is strictly equal to the population total for the whole county. While for the small area model with random effects, the above equilibrium is approximately hold on.

In our simulation, we also examined the C.Vs of aggregate at county level from summation of individual estimates of towns and townships in either random effects or fixed effects model. The C.Vs are even outperformed than that of a direct expansion at county level (Table 2).

Table 2: *C.V of rice and corn acreage at county level*

Sampling Fraction	Direct Expansion: Ground truth		Model Simulation Random Effects		Model Simulation Fixed Effects	
	C.V of Rive	C.V of Corn	C.V of Rice	C.V of Corn	C.V of Rice	C.V of Corn
r=0.07%	14.60%	12.28%	8.22%	10.74%	6.06%	5.77%
r=0.14%	8.62%	6.65%	7.21%	8.69%	4.20%	4.12%
r=0.25%	7.20%	5.26%	6.76%	6.75%	3.04%	3.32%
r=0.5%	4.82%	3.62%	4.78%	3.83%	2.14%	2.53%
r=1%	4.21%	3.12%	2.55%	2.20%	1.35%	1.78%
r=2%	2.25%	1.81%	1.53%	1.25%	1.15%	1.02%
r=5%	1.18%	1.08%	0.79%	0.71%	0.71%	0.63%

5. Discussion and Conclusion

5.1 Precision Efficiency

Especially in the scenario of small sampling fraction, our study illustrates that model fitness of small area model with random effects is better than that of model with fixed effects, which is reflected in the results of statistical test for parameters as well as the efficiency gain of precision. To examine the precision of estimates for each individual town and township, it is obviously that the C.Vs (defines as in section 4.1) is relatively lower when applying random effects model compared to fixed effects model especially for a smaller sampling fraction. When sampling fraction is 0.07%, taking the average C.Vs of rice acreage and corn acreage for all the 20 towns as indicators, the ratio of the C.Vs from random effects over the C.Vs from fixed effects is around 44% and 60% respectively, this implies that model fitness of random effects in this scenario is better. When sampling fraction is increased to 5%, the ratio of the C.Vs from random effects over the C.Vs from fixed effects is around 98% and 99%, this implies there is no significant difference between random or fixed effects model. On average, the ratios corresponding to all the other scenarios of sampling fraction lies in between of lower level 44% and upper level 99%.

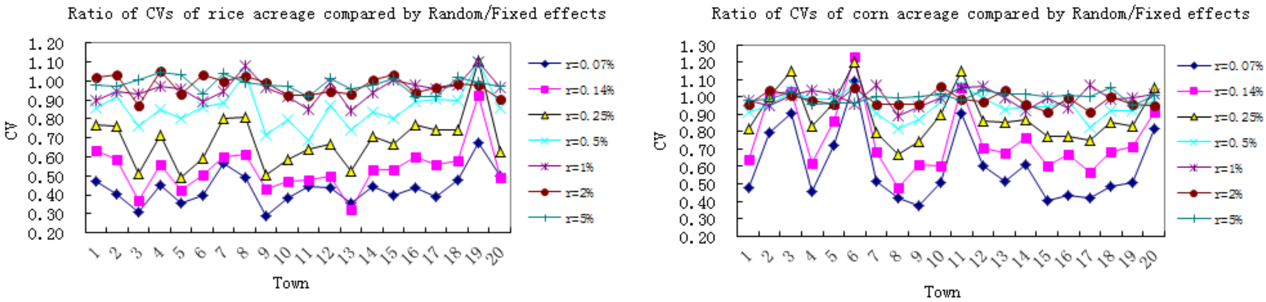

Figure 7: *The ratio of CVs from MSE under model with random effects versus fixed effects*

5.2 Model Fitness

In real situation, the setting of small area model either with random effects or fixed effects mostly depends on the user's assumption and understanding to the problem solving. In econometrics, usually the Hausman test is used to check whether there is a fixed or random effects preferred to the underlined component. But the validity of the Hausman test not always guaranteed, that means sometimes it is difficult to determine whether to choose fixed effects or random effects. In this study, even if the small area model with fixed effects does not have a sufficient model fitness compared with that of model with random effects especially when a smaller sampling fraction, it is also robust to predict a reasonable results for each town and township when we scrutinize the estimates and its C.Vs. Therefore, it implies that small area model with either random effects or fixed effects are mostly feasible to produce estimates for domains like town and township in this case.

With regard to the multi-level estimation both for the town and county level simultaneously, for the model with fixed effects the summation of each estimate of towns exactly equals the estimate for the whole county under the assumption of general linear regression. While for the model with random effects the summation of each estimate of towns approximately equals the estimate for the whole county under the assumption of general linear regression.

5.3 Model Sensitivity of Classification Accuracy

As we have seen, small area model of basic unit level with random effects or fixed effects is constructed by combining the ground truth data with classified image data regarded as auxiliary information of population. Since the satellite image classification affected by many factors such as the image quality and classification methods, the accuracy of classification may varied from good to medium. Given the certain sampling fraction, the model precision for estimates at town level could be impacted by the classification accuracy.

Based on the originally classified vector data from Landsat 8 OLI, which overall accuracy for rice and corn are around 85% and 90% respectively. In order to simulate different accuracies for classification, we added a disturbing term which is a certain constant multiply a random number subject to the standardized normal distribution for each grids. Then we calculated the accuracy of classification again by comparing the pseudo classified data with ground truth from visually image interpretation.

For the random effects model, the average C.Vs of rice acreage and corn acreage at town level corresponding to various accuracies are shown in Figure 8. Taken rice as an example, when sampling fraction is 0.07% and classification accuracy is 80%, the average C.Vs at town level is around 10.7%. Given the classification accuracy at 65%, in order to obtain the same average C.Vs at around 10.7%, we need to have the sampling fraction at 0.14% which means a doubled sample size. It reveals that both classification accuracy and sample size determines an expected CVs at town and township level. In practice, we need to consider the trade-off of more accurate classification or field work of samples.

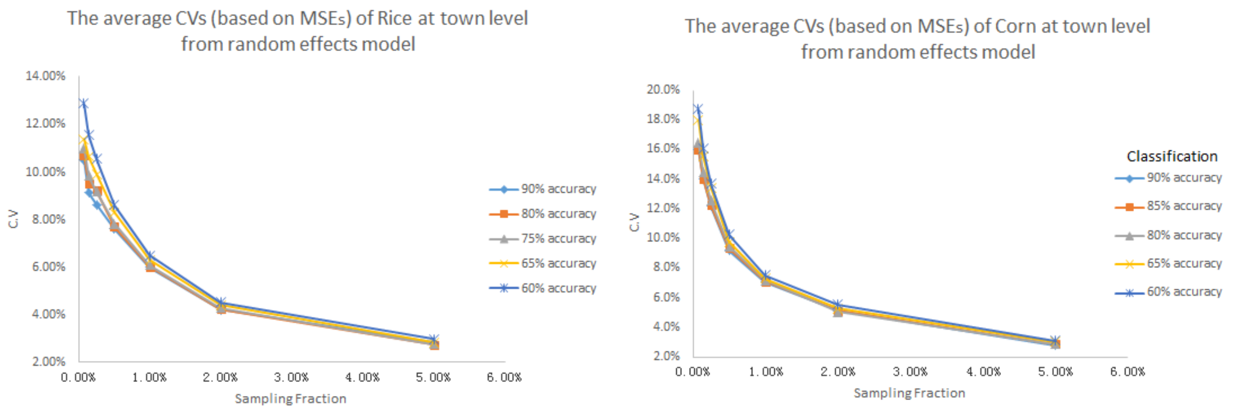

Figure 8: *The average CVs at town level under random effects model with various accuracy*

5.4 Conclusion

In this study, it is illustrated that a basic level small area model in the form of one-response multiple regression with random effects and fixed effects are both feasible to produce the estimates at town and township level. Compared with the fixed effects model, the random effects model gains more efficiency in terms of its C.Vs for town and townships level. Taking the advantages of small area model which combines the sample data with auxiliary information of population, this method could produce the estimates for each small area even if there is rare or none sample within the domain. Given a certain sampling fraction, a more accurate classification for crops which is taking as auxiliary information for population will benefit the estimate precision for each town and township from small area model.

Small area model provide a solution to produce estimates not only for the towns and townships but also for the entire county simultaneously. For fixed effects model, the aggregate of estimates of every town and township is exactly equal to the estimates for the county under the assumption of linear regression. While for random effects model, this additive property is approximately hold on. Therefore, it is provide a solution for multi-level estimation by applying small area model.

In practice, for the crop surveys which samples are selected from province as target population like the business mode of China's agricultural statistics, there would be a significant precision gains of applying small area model which could produce the estimates for every county as well as province itself in a coherent way.

ABSTRACT

Despite major technological advancements, Earth Observations (EO) are nowadays seldom used in national agricultural statistical systems at an operational level. This is with the exception of a few countries and is especially true in Africa (but for Morocco, South Africa and a few other cases). Moving from small tests confined to research to operational contexts, poses a number of challenges. There are many aspects that still restrict the use of this technology: the high cost of some of the images, the level of expertise, overall organisation and institutional arrangements needed to operationally run the different components of the system.The FP7 AGRICAB project provided an important opportunity to evaluate the role of EO specifically for crop area estimates using spatial frames in Africa. This is with reference to: 1) the construction and stratification of a (point) sampling frame, 2) the support to the ground surveys, and 3) the use of the image classifications to further improve the accuracyof the estimates from the surveys alone. The approach was tested in selected areas in Mozambique, Senegal and Kenya. The contribution of EO for the last aspect cited was evaluated only for the latter two areas, where high geometric resolution images (RapidEye) were used. Sampling frames were built based on high geometric resolution images accessible through Google Earth. This contributed significatively to the frame construction and to increased sampling efficiency through land cover stratification. As to the use of EO for survey preparation/execution, the images also provided invaluable support to the geolocation of sampling units especially if combined with GPS. Finally, EO data were used for reducing the variance of ground estimates. If a high correlation between the classification of the image and the ground truth exists, it is possible to produce estimates with a lower sampling error. From a theoretical point of view a perfect correlation between spectral signatures of a generic crop and the corresponding parcel, would promote pure remote sensing approaches such as pixel counting and sampling frames combined withground surveys unnecessary. Unfortunately this high correlation rarely exists and in most cases satellite images cannot be used directly. Confusion matrixes generated from the supervised classifications of the test areas showed a very low overall accuracy and hence, a very low contribution to the reduction of the variance of the estimates which was evaluated further in terms of net efficiency and cost efficiency. This was to be expected, considering the characteristics of most Sub-Saharan agricultural landscapes, i.e.: small fields vs. pixel size, continuous and mixed cropping, low planting densities. The use of multi-temporal images and the combination of optical and radar EO data can probably increase such correlation although a rigorous cost/benefits analysis would be needed to evaluate its added value also in view of new satellite products (e.g. those provided by the Sentinel missions).

Keywords: spatial frames, satellites, relative efficiency

1. Introduction

There are two main methods to derive crop area statistics from Earth Observations (EO) data: pure remote sensing approaches such as pixel counting, and methods combining field survey data and image classification results (FAO 2015). Pixel counting is the more direct way, although it is often criticized for the bias which can be introduced (Gallego at al., 2008 and Gallego et al., 2010). This seems to be especially true with reference to smallholders farming systems in Sub-Saharan Africa.

Despite major technological advancements, EO are nowadays seldom used in national agricultural statistical systems in an operational way. There are a limited number of countries where this occurs worldwide and, apart from Morocco, South Africa and a few other cases, this is especially true for Africa.

Moving from small tests confined to research to operational contexts, poses a number of challenges. There are many aspects that still restrict the use of this technology: depending on their use, the high cost of some of the images, the level of expertise required, overall organisation and institutional arrangements needed to run operationally the different components of the system.

The FP7 AGRICAB project provided an important opportunity to evaluatethe contribution of EO specifically for crop acreage estimates using spatial frames in Africa. This is with reference to three levels in the methodology: 1) construction and stratification of a point sampling frame, 2) support to the ground survey, and 3) its use to further improve the accuracy of the estimates from the survey alone.

The project initially targeted selected areas in Senegal, Kenya and Mozambique and together with national partners mandated with agricultural statistics in the countries. EO products were effectively used in all areas. However only in the case of Senegal and Kenya, where images with high geometric resolution were available, it was possible to cover all cited levels of application.Due to the cloud cover, for MozambiqueEO products were used only atthe first two levels.

2. Materials and Methods

2.1 Materials

The areas selected were the District (Département) of Nioro Du Rip in Senegal, and the County of Kakamega-Butere in Kenya. As mentioned, only for these areas it was possible to acquire images with high geometric resolution.In Mozambique the area selected was the District (Distrito) of Inharrime. The three areas are indicated in Figure 1.

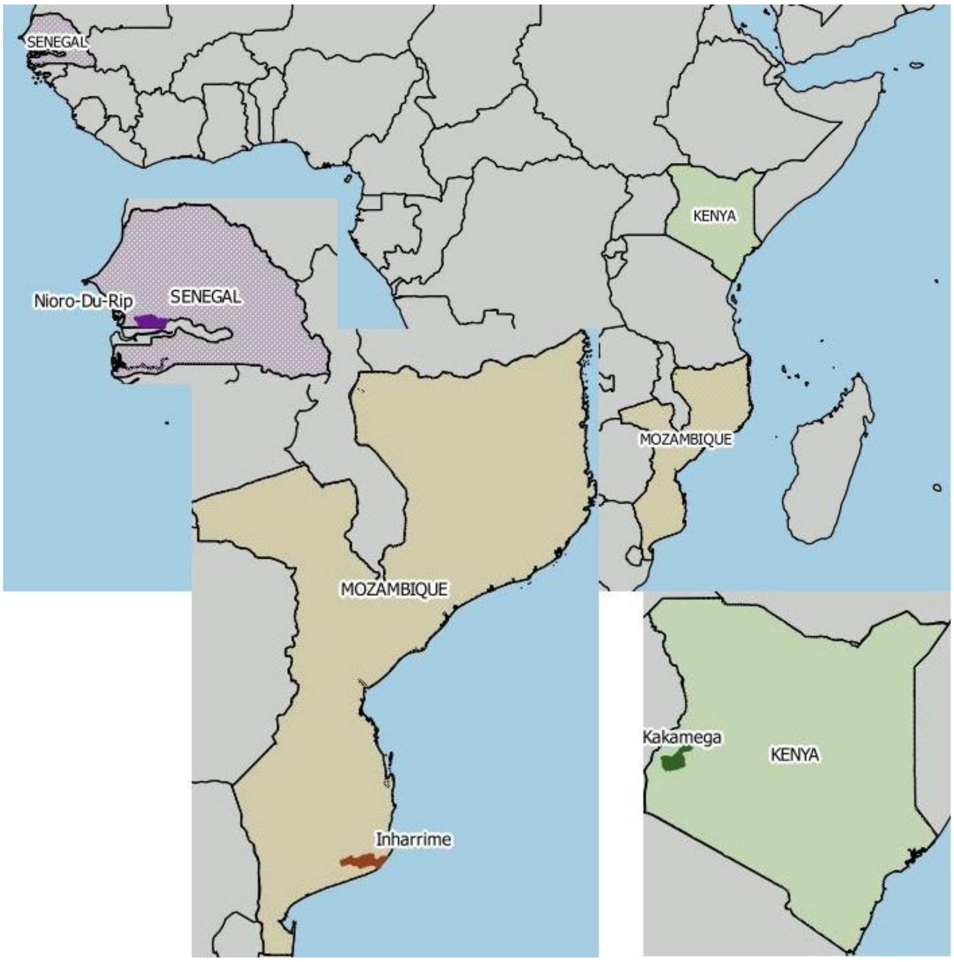

Figure 1: *The three areas of interest*

The EO images used belong to the RapidEye satellite constellation. For the cited study areas the provider programmed the image acquisition at a convenient time with reference to the presence of the targeted crops. Harvesting periods relating to the two area tests were indicated by experts from the respective Ministries of Agriculture who have knowledge of the climate and the characteristics of the selected test areas. In Kakamega-Butere the period was 15 May - 30 June while in Nioro Du Rip, 15 August - 30 September.

Table 1: *Main features of RapidEye images.*

MISSION CHARACTERISTIC	INFORMATION	
Number of Satellites	5	
Spacecraft Lifetime Over	7 years	
Orbit Altitude	630 km in Sun-synchronous orbit	
Equator Crossing Time	11:00 am local time (approximately)	
Sensor Type	Multi-spectral push broom imager	
Spectral Bands	Capable of capturing all of the following spectral bands:	
	Band Name	**Spectral Range (nm)**
	Blue	440 510
	Green	520 590
	Red	630 685
	Red Edge	690 730
	NIR	760 850
Ground sampling distance (nadir)	6.5 m	
Pixel size (orthorectified)	5 m	
Swath Width	77 km	
On board data storage	Up to 1500 km of image data per orbit	
Revisit time	Daily (off-nadir) / 5.5 days (at nadir)	
Image capture capacity	4 million sq km/day	
Camera Dynamic Range	12 bit	

As it discussed in the next sections, satellite images are complementing survey data. A description of the content of such information as well as the way in wich ground data are collected is also given in the next setions.

2.2 Sampling Frame Construction

The sampling frame is the most important element in methodology developed. Its functions are:

- to enumerate all the units of the population;
- to label and stratify the same units based on a limited number of land cover classes;
- to allow the extraction of sampling units for a specific statistical survey;
- to subsequently extrapolate to the universe the values derived from the sample.

The construction of the frame requires the following steps:

Defining the units of the population. These units are represented by geographic points located at the vertices of a grid of 500 x 500m. All points within an administrative boundary represent the population whose parameters (crop area in this case) we intend to estimate.

Building the frame. This implies assigning (labelling) the land cover type to each unit based on very few and simple classes. This is done through on screen visual interpretation of satellite imagery. The images do not necessarily need to be of the same year of the survey, nor need to be taken during the growing season; the higher the resolution, the better, since it allows a more accurate identification of the named classes. In this respect very high resolution (VHR), i.e. sub-metric satellite images freely available on Google Earth or similar sources were found to be the most suitable basis to derive the land cover types related to the points making the population.Only in a few cases high resolution images were not available.

Stratification. The land cover classes assigned to the points in the frame provide a basis for its further stratification.

Satellite images are importantfor the construction of the frame. Without their contribution the said frame would rely on ortho-photographs in digital format (which are simply not available in most African contexts) or be built using only topographic maps. These maps in most cases do not contain information useful for the stratification hence reducing the efficiency of the statistical system as a whole.

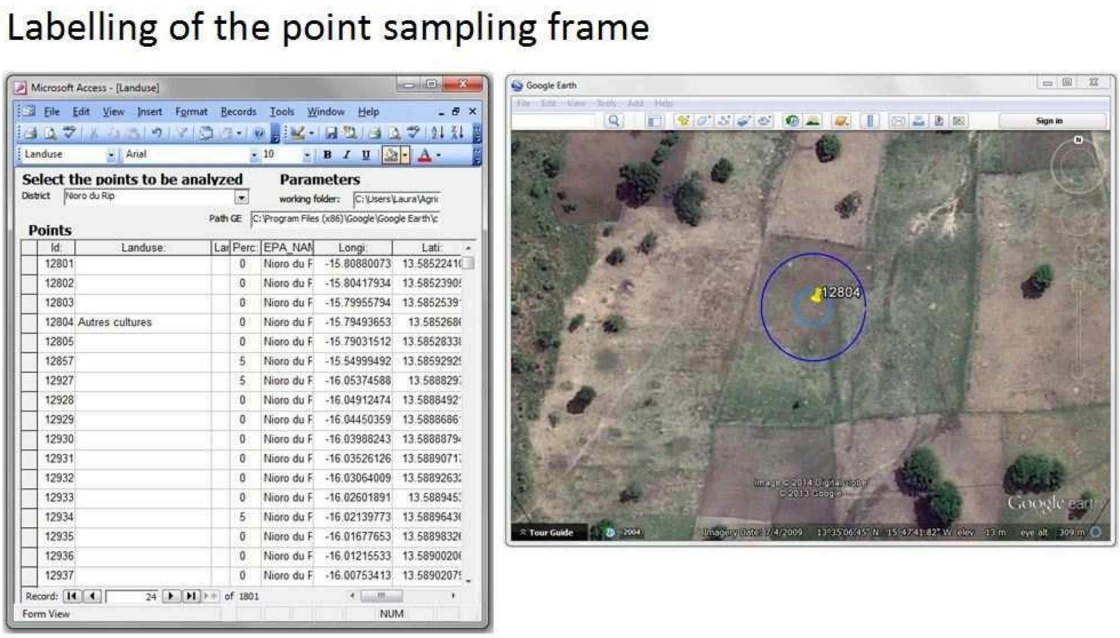

Figure 2: *Labelling of the point*

2.3 Support to ground-survey

The ground survey consists of the identification of crop types and other additional information in each sampling point. In this way objective, verifiable and repeatable data on crop occurrence can be collected based on rigorous sampling schemes. The ground observations are carried out by the surveyor whit reference to an area (usually a circle of fixed radius) around each point.

When carrying out the ground survey, the surveyor is faced with a number of challenges such as poor road network and lack of topographic information. Areas are also often largelyuninhabited,with long distances between points, and may present poor accessibility as well as specific dangers. Therefore the survey must be carefully planned beforehand and constantly revised on the ground.

Recent, very high resolution EO products are required for the purpose.There are usually three types of maps available to the surveyors, all having satellite information as a backdrop image. Examples are given in Figure 3. An “indexmap” is used as a topographic base map to locate the tiles. A “tile map” is a portion of the base map, generally at a 1:50.000 scale, and contains the points which should be visited by a surveyor. A “(sample frame) point map”,generally at a 1:2.000 scale, which is used together with a hand held GPS to identify and access the sampling point. Such map with the sampling units superimposed on satellite images can greatly facilitate the proper recognition of their position. For the geolocation of the points one should not rely exclusively on most GPS used in these types of surveys, which have known limitations in their geometric accuracy.

It is important to underline that the type of land cover and crop type information which needs to be associated to each point, cannot be derived directly from the satellite images used in the construction of the frame and in its stratification. This is due to the fact that such images are usually taken before the ground survey (i.e. when the cloud cover is minimal). Therefore they usually do not allow for a proper identification of the crop type or, if this is the case, may represent crops which have changed over the different cropping seasons.

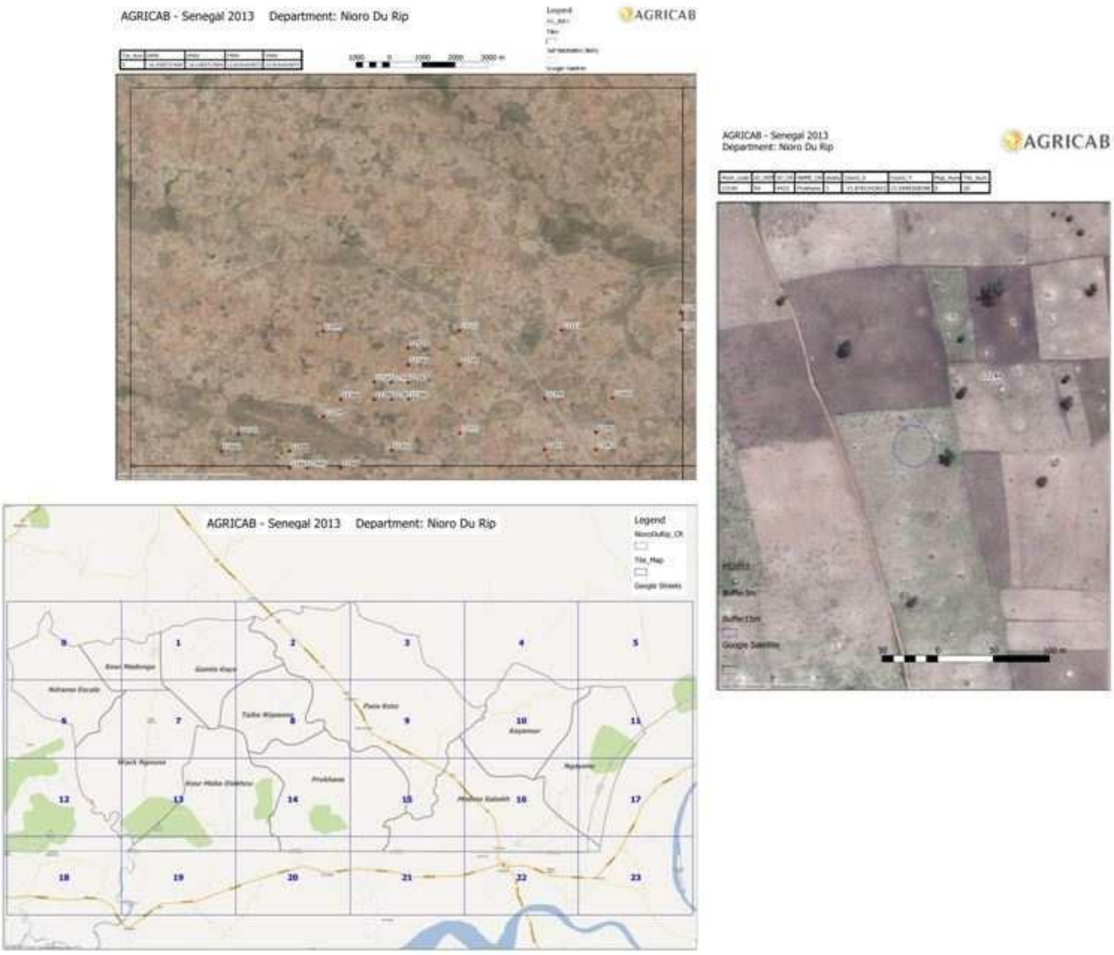

Figure 3: *Field Maps (from bottom left: Index, Tile and Point Map)*

Using the point maps, the surveyor can also plan the best itinerary to reach the different sampling units. Each surveyor has access to a series of field tools (the same field maps, field forms and a GPS). These would allow him a) to reach, as quickly as possible, each sampling unit and to identify with high accuracy (from a geographical point of view)the point of observation of the same unit, b) to identifythe type of crop according to a pre-defined legend and classification rules. An illustration of the field tools is given in figure 4.

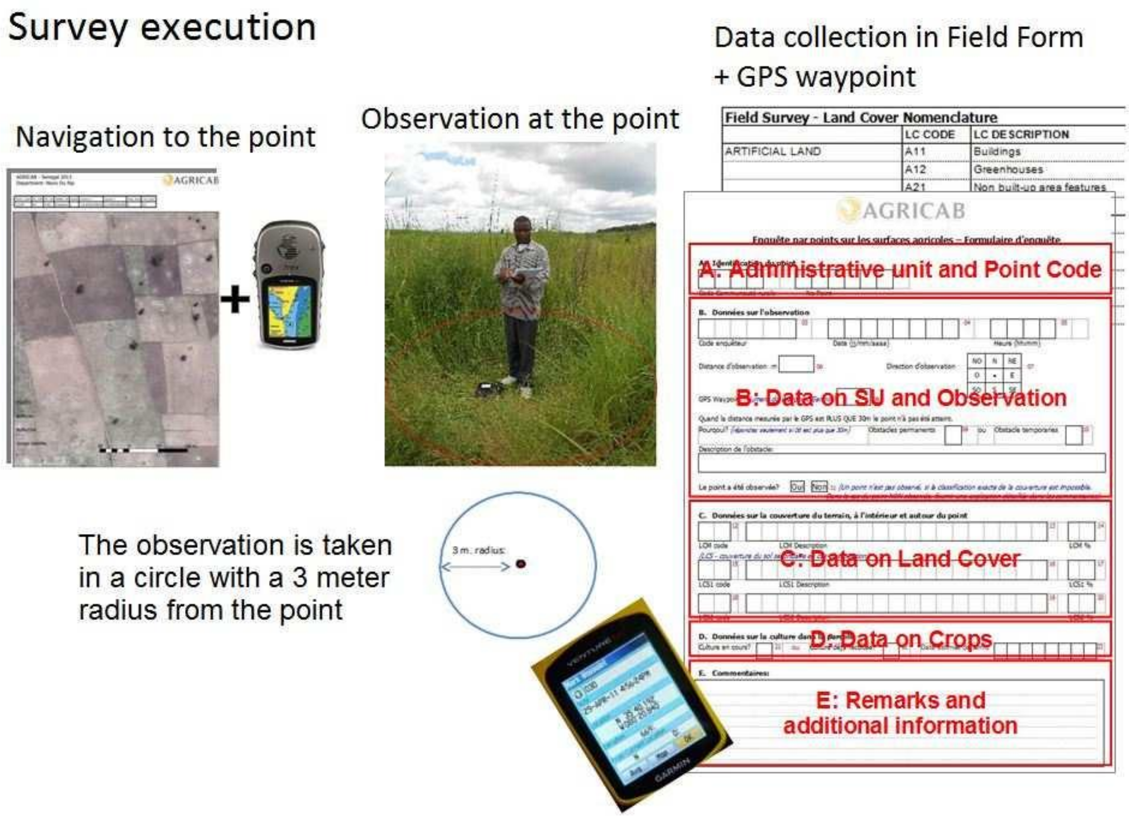

Figure 4: *Survey field tools*

Based on the experience in the different surveys conducted we can conclude that VHR images, combined with other baseline information and the location of the same sampling units provide an invaluable support for survey planning and execution. They make it possible to carry out the survey quickly and rigorously without the need of contacting the farmers.

2.4 Use of the image classifications to further improve the accuracy of the estimates from the ground surveys

This is, at least in principle, one of the most important aspects related to the application of EO data for crop area estimates. If a high correlation between the classified images and the ground truth exists, it is possible to generate crop area estimates characterized by a lower sampling error (expressed in terms of coefficient of variation, or CV). The RapidEye images acquired for the two study areas have been processed with the aim to verify the degree of the correlation between the spectral signatures of the main crop types and the corresponding ground truth observed during the survey. The following procedures have been utilized for processing the satellite images:

Image pre-processing.includes geo-referencing through registration of images, mosaicing of the RapidEye tiles with the same dates and same atmospheric conditions, production of masks to remove non-agricultural areas from the classification (otherwise introducing a bias).

Spectral signature extraction. The final outcomes of this step area number of Regions Of Interest (ROI) which are then used to guide the classification and to provide the ground truth locations needed for generating the confusion matrix.

The extraction was carried out using the observations collected during the surveys. Data varyaccording to the study areas and the respective methodologies. For Kenya the ground truth was based on the "Field Sample Points" grid(around 1.000 points) and on an additional sample of "Photo-clusters"(each cluster is a meshof 100 points with 50 meters spacing). This sample was classifiedby visual interpretation of aerial ortho-photos collected by the Department of Resource Surveys and Remote Sensing (DRSRS) during the survey period. In Senegal the available ground truth came from the "Field Sample Points" grid data (again around 1.000 points collected in the field) and the "Parcel Segments"data collected by the “Direction de l'Analyse, de la Prevision et des StatistiquesAgricoles” (DAPSA) of the Ministry of Agriculture, with the support of the “Centre de SuiviEcologique” (CSE). Crop sample areaswere collectedby GPS during the “Enquêteagricole 2013” in conjunction with the AGRICAB point frame survey. The procedure needs to be adjusted to each area due to differences in the type of the ground truth data i.e. to differences in the classification rules applied and tothe geometry of the data (points or areas). Such information is often collected in difficult environmental conditions and this goes sometimes to the detriment of its quality and accuracy. Moreover important factors related to the spectral signature (phenological state, health conditions, farmingpractices, water stress, etc.) could not always be captured during the surveys.

Supervised classification of the images. The final mask, the mosaics and the ROI dataset were imported in a GIS environment. In Kenya the classification was carried out based on the QGIS and GRASS open source solutions, while in Senegal the software ERDAS was used.The ROI dataset was used to generate the signature files, one for each mosaic. The classification was performed applying the maximum likelihood classifier (pixel based).

Considering the available information it was decided to classify the images focusing on the most representative crops: Sugarcane and Maize for Kenya and Millet, Maize, Sorghum and Groundnuts for Senegal. All the other land use classes were grouped as "other land cover/land use” (LC/LU).

The following tasks were performed for the classification:

- **use ofsub-classes** in order to cover as much as possible the various spectral signatures that characterize each LC/LU class;
- **adding the most important natural/non-agriculture sub-classes** to reduce the variance in the classification of the agricultural classes;
- **aggregating the sub-classes** corresponding to the various spectral classes obtained from the images in LC/LU classes and all the non-agricultural sub-classes as "Other LC/LU";
- **filtering the classified pixels** with a confidence level of at least 66% to70%;
- **calculating the confusion matrix** and the accuracies;

An example of the original image and of the classification is given in Figure 5.

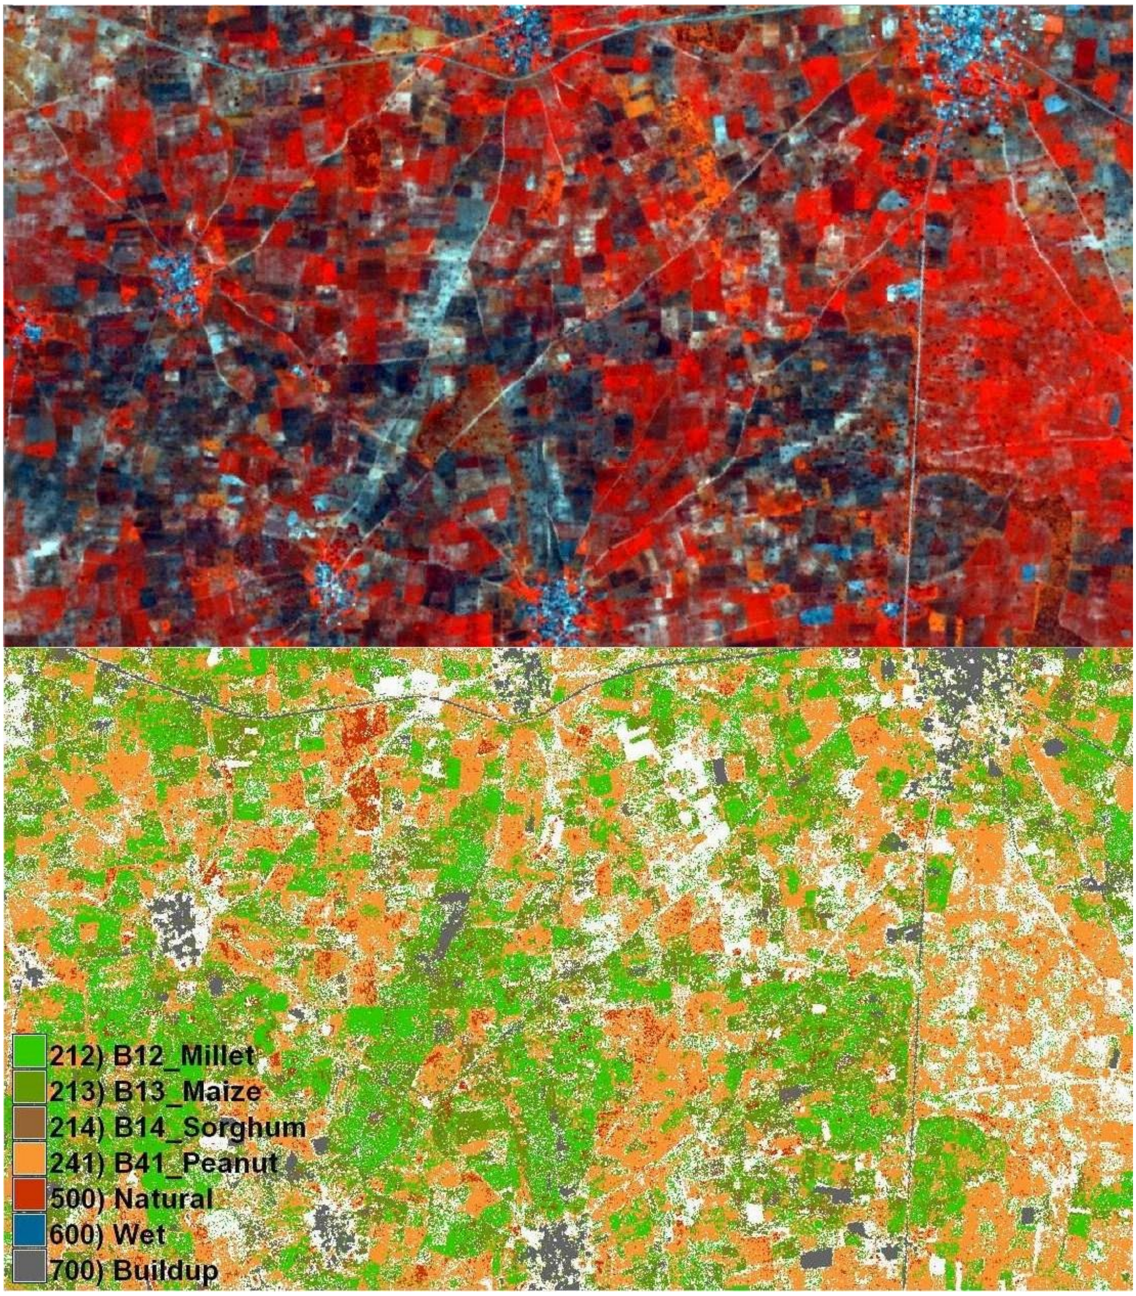

Figure 5: *Example of the original image and the classification in Senegal, Nioro Du Rip. From top: composite RGB 543 and classified raster image*

The accuracies derived from the confusion matrix should not be regarded as a post classification assessment, but rather as an indicator of the validity of the classificationin further reducing the estimates based on ground survey data alone.

Second stratification. The classification provides information on land cover and crop types that could be used to achieve better estimates of crop areas. The principle is that this information, known for the whole of the population and not only for the sampling units, can be used to build a stratification of the population in homogeneous strata where the variance of the estimates is expected to be significantly lower than in the population as a whole.

A new stratification is performed on top of the initial one (see 2.2), using a binary classification for each point in the sample frame.For instance in the case of maize four new strata are derived as a combination of the original strata, and the points classified as maize (or "not-maize") in the image.

3. Results

As shown in the tables 2 and 3 below, the confusion matrices generated in the two different study areas show a very low overall accuracy in the classification: around 45% for Senegal and around 40% for Kenya. For the main crops occurring in each area omission and commission errors are relatively better.

Table 2: *Confusion matrix Nioro Du Rip, Senegal*

		GROUND TRUTH							
	CLASS	B12	B13	B14	B41	NAT	Row Sum	COMMISSION ERROR	User's Accuracy inclusion
CLASSIFICATION	B12 millet	**56**	18	2	44	7	**127**	55.91%

	OMISSION ERROR	52.94%	66.00%	100.00%	48.60%	88.00%	ACCURACY OVERALL	**44.80%**	
		Producer's Accuracy exclusion							

Table 3: *Confusion matrix Kagamega-Butere (Kenya)*

		GROUND TRUTH						
	CLASS	B13	B35	Z99	Row Sum			
CLASSIFICATION	B13 maize	**10**	11	22	**43**	76.74%	COMMISSION ERROR	User's Accuracy inclusion
	B35 sugar cane	10	**22**	14	**46**	52.17%		
	Z99 Other LC/LU	6	5	**14**	**25**	44.00%		
	Column Sum	**26**	**38**	**50**	**114**			
		61.54%	42.11%	72.00%	OVERALL ACCURACY	**40.35%**		
		OMISSION ERROR **Producer's Accuracy exclusion**						

Possible reasons behind these low accuracies can be ascribed to several factors. Some factors are of general applicability while others are especially important in the agricultural landscapes targeted in this study (i.e. characterized by small-holder farmers, with low levels of management and crop densities). Altogether they all contribute to the fact that the relationship between crops on the ground and their spectral signature is less evident:

Geometric resolution: related to the pixels size. In this case parts of the cropped areas can be characterised by fields which are too small to be shaped by the pixels. This aspect could, at least in principle, be reduced by the introduction of EO data with higher geometric resolution.

Atmospheric conditions: different atmospheric conditions can occur, even at local level, when the dates of the images are distant in time.

Crop phenology: each crop speciesand even variety develops according to different phenological phasesto which representative spectral signatures can be associated.It is thus very difficult that crops reach the most representative spectral signature at same time.

Seeding date: even within a species and variety having a specific phenology, the starting (i.e. seeding) date of the crop cycle can change according to several factors including climate and, locally, topography and soil conditions. Management choices of farmers are also very important.

Continuous cropping: the agro-ecologic conditions allow some overlap in the growing cycles of crops especially in sub-tropical environments.

Intercropping: in the same parcel different crops are sown at the same time or with a little time lag (relay cropping) resulting in a non-distinctive spectral signature, being a mix between two existing classes. A similar problem is given in case of weeds.

Crop density: it relates to farmers management practises, soil fertility, pathologies, water stress. Soil in the background alters the natural spectral signature.

Difficulty in determining the best date to collect the satellite images: it is due to the unpredictability of the weather conditions and the lack of synchronization of cultural practices/crops phenology.

The area estimations can be now calculated based on the binary stratification described in section 2. The crops where the classification performs better are selected for this purpose, i.e. Groundnuts in Senegaland Maize in Kenya (Butere-Mumias only). Results are given in Table 4 and 5:

Table 4: *Estimations with and without the image classification: Groundnuts, Senegal*

Approach	Crop area (ha)	StdDeviation	CV
only survey	72.229.70	2.713.10	3.76
survey + classification	72.597.02	2.688.12	3.7

Table 5: *Estimations with and without the image classification: Maize, Kenya*

Approach	Crop area (ha)	StdDeviation	CV
only survey	29.537.73	2.633.56	8.92
survey + classification	29.421.20	2.615.51	8.89

Comparing the results above the gain in precision (expressed in terms of reduction of the CV) achieved introducing the classification in the area estimates can be observed. Since there is only a minor decrease in the CV for both areas and crops, one can conclude that the contribution of the image classifications to further improve the accuracy of the estimates from the surveyis altogether very modest.

A more formal way to assess the contribution of EO data can be expressed in terms of Relative Efficiency (RE), which is the ratio between the variance of the ground survey area estimate and the variance after this estimate has been corrected withthe aid of classified satellite images. RE values close to 1 indicate that the EO contribution towards reducing the sampling variance estimations is very low:

$$RE = (Var.withouteo \,/\, Var.with\ eo)$$

Where:

Var.without eo = Variance estimation obtained without the contribution of EO data
Var.with eo= Variance estimation with the contribution of the EO data.

In both areas the RE is in the order of 1.01 (1.009 for Senegal and 1.007 for Kenya).If the cost components are known, also the cost efficiency can be computed. This is expressed in terms of Net Relative Efficiency (NRE) and calculated as follows:

$$NRE = RE \times (Costs\ without\ eo / Costs\ with\ eo)$$

Where:

Costs without eo = Costs without the contribution of EO data (i.e. ground survey costs).
Costs with eo = Costs considering the contribution of EO data (i.e. ground survey costs, cost of the images, of the radiometric and geometric corrections and of the classification).

In the two selected areas the NRE is in the order of 0.21, which indicates a rather low performance in terms of cost-efficiency.

4. Conclusions

As far as the generation of crop area estimates the contribution of EO was evaluated for two of the areas (and the main crops cultivated within) selected as use cases in the project AGRICAB. As to the contribution to the third level of application (image classifications to improve accuracy of estimates from the ground surveys) the results were evaluated in terms of RE and cost efficiency. The result indicates a low contribution in improving the estimates and, as a consequence and due to the type of images used, an even lower cost-efficiency.

Nevertheless, the other two levels of application, i.e. the construction and stratification of the sampling frame, and the support to ground surveys, were deemed very important, although it was not possible to further quantify their contribution.

In the future, in order to increase the efficiency in the use of EO data, a multi spectral/temporal approach can be further explored. A minimum of at least two images must be foreseen. A critical issue related to the areas of interest and similar environments is the presence of cloud cover during the main growing seasons. This poses a constraint on the proposed multi temporal approach using optical satellites only. In perspective, a combination of SAR (Sentinel 1) and optical satellites (Sentinel 2) may provide a useful opportunity for this type of applications.

ABSTRACT

Small Unmanned Aerial vehicles (UAV), better known as drones, have invaded very quickly the public debate. Besides the headlines on their military use, the potential civil applications are widely discussed. Agriculture is one of the fields in which drones appear to be very useful. In particular many agricultural statisticians would like to understand how much information can be extracted from UAV images and how cost-efficient such images may be.

This paper has several purposes:

- Discussing the cases in which UAV images can substitute field surveys.
- Analysing suitable sampling schemes for such image acquisition.
- Presenting practical implications and limitations in a test by the ITA consortium in Malawi.

Sampling long thin stripes to be surveyed with UAV has a good efficiency in terms of variance, but the feasibility is linked to two conditions that appear to be very difficult to meet: possibility to identify all major target crops on images with 2-3 cm resolution and flight regulations in the country that allow flying long distances far away from the operator. Small traditional airplanes with pilot might be a more realistic approach than UAV for surveys based on a sample of aerial photographs.

Keywords: Crop area estimation, Drones, Area frame sampling, Transects.

1. Introduction

The scientific community is paying attention to Unmanned Aerial Vehicles (UAV) and the possible civil applications of the images they can provide (Floreano and Wood, 2015). The debate on the use of UAV, better known as drones, includes the agricultural applications (Malveaux et al., 2014, Anderson, 2014), and the health aspects of agricultural practices (Capolupo et al., 2014). The limitations imposed by flight regulations are also analysed by the scientific literature (Freeman and Freeland, 2014). The image processing technology is well advanced and should not be a major limitation for practical applications (Zarco-Tejada et al., 2012, Hruska et al., 2014, Liu et al., 2014). Most applications of drone images to agriculture refer to local crop monitoring (García-Ruiz et al., 2013, Duan et al., 2014, Uto et al., 2013), in particular for precision agriculture (Zhang and Kovacs, 2012, Stehr, 2015). The possible application to agricultural statistics is often discussed, but at the time of drafting this paper, we have not been able to find any published paper that specifically addresses the topic.

If we consider the standard approaches to use imagery for agricultural statistics (Carfagna and Gallego, 2005), the requirements for yield estimation or forecasting seem far from the characteristics of low altitude flights because a large number of images along the cropping season is a critical condition and this would be too expensive. The use of images as a covariate in regression or calibration estimators appears also unfeasible at the current stage of the technology because it requires covering a very large area, in principle the whole targeted geographical domain

The most realistic use of drone images is substituting field visits in an area frame survey. At the current status of technology it is reasonable to cover for example an area of 1 km x 1 km with a single flight by mosaicking stripes of about 100 m width with a resolution that can range between 2 and 5 cm. Such resolution may be enough to identify single crops in some cases. The usability of such images to identify single crops depends very much on the type of agricultural landscape. One of the purposes of this paper is presenting the conclusions of a test run by the ITA consortium in Malawi. The conclusions of this test are likely to be useful for many countries in sub-Saharan Africa.

If we assume that most crops of interest, or at least some key crops, in a given region or country can be identified, several points still need to be discussed:

- Is a drone-based survey cost-efficient compared with a standard field survey?
- How can we optimize a sampling plan of spatial units to be observed with drones?

Analysing survey costs on the basis of pilot studies is not easy. The cost per sampling unit tends to be lower when a survey becomes operational (Taylor et al., 1997), but with a very heterogeneous pace. Pilot surveys in developing countries may be more expensive than in developed countries due to difficulties linked to transportation infrastructures and logistics, but the cost can be also very different when a pilot study is paid by an external donor.

The idea of using samples of aerial photographs have been used for agricultural and environmental estimates is not new. It has been applied already in the 70's (Jolly and Watson, 1979), but needs to be revisited taking into account the technological advances.

2. Pilot Test in Malawi.

A test has been carried out by the ITA consortium in Malawi. A subsample of 20 clusters of 4 x 4 points 250 m apart was covered with UAV flights. The leaf shape of maize, by far the most important crop in the country, can be reliably recognised with the 2-3 cm resolution images, but associated crops (less visible than maize) were very difficult to identify and distinguish from weeds. Other crops such as ground nuts, soya and cassava are difficult to discriminate for different reasons including the relevant presence of the intercropping practices and the different phenological stages for the same crop types during the drone overpass. Figure 1 provides an example of image acquired by a drone in the Malawi test. The fields in the right side of the image can be clearly identified as maize, but it is very difficult to identify if the associated vegetation are simultaneous crops or weeds.

Figure 1: *Example of image with 2-3 cm resolution acquired by a drone in Malawi.*

3. Data and Sampling Schemes.

We have made simulations using as pseudo-truth the farmers declarations in the Netherlands in 2012 . The data we have contains approximately 770,000 plots declared by farmers in 2012 in the Netherlands, out of which 345,000 correspond to cropland. The rest corresponds mainly to grassland and a minor part of natural vegetation plots owned or managed by farmers. For the examples based on this data layer we will focus exclusively on cropland. The interest of using this data set is that it behaves very much like the real spatial layout of cropland. The consistency of the data set has been checked by crossing it with the Eurostat point survey LUCAS (Gallego and Delincé, 2010) that has resulted in a nearly perfect match, with the exception of a significant undercover on potatoes. Similar data sets exist in all European Union (EU) member states, but most of them consider these data confidential. The Dutch authorities have considered that these data may be made public if they only contain data that anyone can observe on the field. The layer can be found in http://geodata.nationaalgeoregister.nl/brpgewaspercelen/atom/brpgewaspercelen.xml in a GIS format. It would have been better to use a similar data set for a developing country with a more complex agricultural landscape, but it has not been possible to find such data.

There is a wide variety of spatial sampling schemes for agricultural statistics (Benedetti et al. 2015). In this paper we will limit ourselves to comparing:

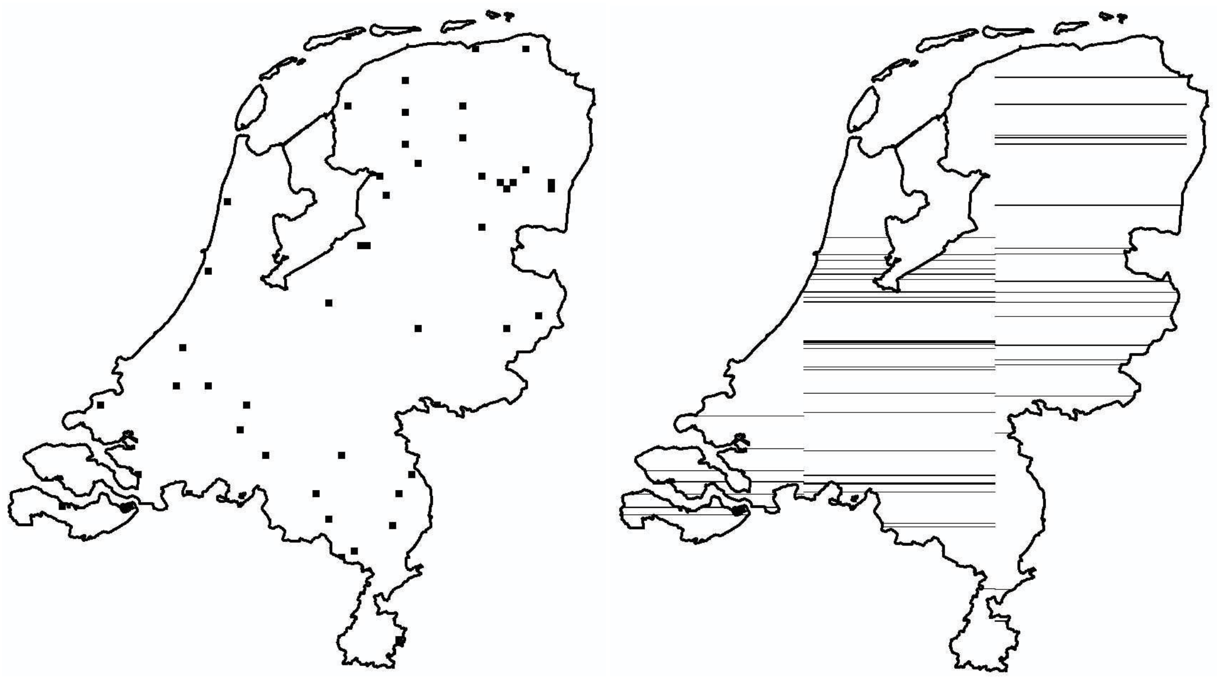
- simple random sampling of points. This is generally not a good choice for the problem we are considering, but we use it as a benchmark.
- Square segments. We have tested segments of 1 km × 1 km and 3 km × 3 km

- Long and thin segments (stripes). We have tested stripes of 10 km × 100 m and 90 km × 100 m that correspond to the same area of the square segments above. Therefore the variance ratio between square segments and stripes may be attributed to the shape and not to the size of the segments.

Long and thin stripes are theoretically better adapted than square segments to low altitude flights. A good quality UAV can fly a straight line of 100 km if the topography is not too complicated. However local or national regulations often forbid such long stripes.

Figure 2 represents the spatial layout of a sample of square segments of 3 km × 3 km and a sample of stripes of 90 km × 100 m. The sample of stripes has been defined with the help of a fixed grid. A large proportion of stripes is incomplete because they are clipped by the country boundary. This is likely to have an impact on the efficiency of the sampling scheme and may need to be reworked with a sampling frame better adapted to the shape of the country. In both cases we have considered simple random samples. Improvements such as stratification or systematic sampling have not been considered in order to focus on the effect of the segment shape.

Figure 2: *Layout of a sample of square segments and a sample of 90 km stripes.*



4. Simulation Results.

For the comparison of variances we use the "equivalent number of points". If a sample of n segments with a given shape and size gives the same variance as a simple random sample of $n \times Q$ points, we say that a segment is equivalent to Q points in terms of variance.

Table 1 reports the equivalent number of points Q of square segments and long stripes for major crops and some less important crops. We can see that Q is generally larger for minor crops. This happens because the spatial auto-correlation is generally higher at short distances for major crops, making clusters less efficient. We can also see that the relative efficiency of stripes compared with square segments is higher when the stripes are very long. This empirical result is fully consistent with the formal link between efficiency of clusters and spatial autocorrelation (Carfagna and Gallego, 1994, Gallego 2012).

Table 1: *Equivalent number of points of square segments and stripes*

		1 km2			9 km2		
	Area (% territory)	*Q* square segment	*Q* stripes	Efficiency stripes	*Q* square segment	*Q* stripes	Efficiency stripes
Maize	7.17	7.2	12.8	1.8	13.8	26.0	1.9
Temporary grass	5.41	6.2	14.1	2.3	14.6	41.8	2.9
Wheat	4.32	4.1	6.1	1.5	6.2	15.2	2.5
Potatoes	4.27	5.7	8.5	1.5	9.0	24.4	2.7
Sugar beet	2.07	8.9	15.1	1.7	18.3	58.5	3.2
Barley	0.84	9.9	18.9	1.9	24.3	69.0	2.8
Flowers	0.65	4.4	6.7	1.5	6.7	20.1	3.0
Orchards	0.51	6.1	12.1	2.0	13.6	43.6	3.2
Pulses	0.19	11.4	25.7	2.2	43.2	115.8	2.7
Flax	0.06	12.6	24.6	1.9	39.3	131.2	3.3

5. Conclusions and Discussion.

Very high resolution images acquired by UAV are a very appealing tool for agricultural statistics. The idea of substituting field surveys with photo-interpretation of geo-referenced images with a resolution of 2-3 cm is attractive, but several limitations appear very strongly:

- The applicability is limited to crops that can be identified on images with a reliability compared to field observations. This is unlikely for associated crops, as in the example of Figure 1.
- National regulations often limit the flights of UAV to the area within the sight of the operator. Square segments of 1 km × 1 km would be feasible, but the statistical efficiency of such segments is not very high.
- A UAV-based survey requires field trips of highly specialized staff and material. The ratio between the cost of field observations in a traditional area frame survey and an UAV-based survey is not easy to estimate with the available information coming from small pilot tests.

For specific food need assessments based on inter-annual changes of maize (assuming maize is the staple food) a sample of UAV-covered stripes can provide a sufficient information if long stripes are compatible with national regulations.

We need to make a reasonable assumption to apply to developing countries with very small plot size the relative efficiency values obtained from data in the Netherlands, where the average field size is around 3-4 ha. We can assume that the spatial correlation structure may be similar if we apply a 1:3 or 1:4 zoom-out. The average field size would become 0.2-0.5 ha, a field size that is much more common in semi-subsistence agriculture. However this “plot reduction” may be not enough to have a landscape similar to a developing country. In particular simultaneous crops are not considered in the results.

The efficiency for long and thin sampling units (e.g. 10 km × 100 m) may be around 2-3 times better than for compact-shaped units (squares). Taking into account the standard operational conditions of UAV (landing near the take-off point), a suitable sampling unit could be a pair of parallel transects of 10 km with a distance of 500 m or 1 km from each other.

When flight regulations are do not allow long distance flights of UAV, small aircrafts with pilot would be an alternative that should be considered. It is less fashionable than UAV and has other requirements (sufficient network of landing fields), but it might be efficient in many cases.

A sampling plan should take into account the orographic characteristics of the surveyed area. A stratification bight be performed to exclude areas with too steep slopes for a smooth operation of UAV. However case by case analysis is needed for an approximate assessment of the potential bias generated by excluding hilly areas.

ABSTRACT

The horticulture subsector is among the fastest growing agricultural sub-sectors in most Sub-Saharan African countries. Compared to traditional field crops, horticultural crops (or vegetable crops) exhibit several advantages that make them attractive to farmers, both commercial and subsistence. Vegetable crops contribute significantly to food security and income generation for a large segment of the population, particularly women. The growth of this sector can also contribute to the reduction of rising unemployment levels in both urban and rural sectors. In recent years, the horticulture industry has become a noticeable earner of foreign exchange; in fact, some of the horticultural crops provide a viable option for diversification hence widening a country's export base.

However, despite this importance, vegetable crop cultivation has been one of the least statistically explored sectors in many African countries. The quantity of vegetable crops produced each year is largely unknown in most countries. There are a number of country experiences or

isolated studies and surveys on the estimation of vegetables and fruits, but since vegetable crops are often outside of the traditional scope of agricultural surveys and censuses, there is no consolidated and internationally validated estimation methodology.

The survey approach for the estimation of area and production is a challenge due to the large variety of vegetable crops. Issues to be taken into account in horticulture crop production estimate methodologies include (iii) Plant phenology, cultivation and harvesting techniques, (iv) implying crop area and yield measurement issues (i) no normalised concepts and definitions for horticulture crops; (ii) Sampling frame and sampling design.

Therefore, there is a need to develop adequate methodologies to estimate vegetables crops areas, yields and production. The purpose of this paper is to propose a consolidated methodology for estimating vegetable crops area, yield and production addressing the main methodological issues and taking into account lessons learnt from past experiences, from country practices and analysis of data from case studies in pilot countries in the context of African countries. The paper will build on a technical paper prepared in the framework of the Research Programme of the Global Strategy to Improve Agricultural and Rural Statistics.

Keywords: Vegetables, Production, Estimates.

1. Background

Accurate statistics on vegetable crop area and yield and production regularly released and communicated to the public must play an important role in planning and allocating resources for the development of the agriculture sector and food security in Africa. Reliable and timely information on vegetable cultivation is of vital importance to planners and policy makers including governments for planning the development of the sector, private companies for important decision-making related to products purchase, storage, distribution, import, export and other related issues.

The challenges for getting accurate estimates on vegetable crop production are not the same for different regions and countries around the world. In developed countries where vegetable holdings are keeping management records and area planted, production, yield, input are registered, the survey or census for estimating vegetable production remain sampling issues, the variable to be recorded are easy to get from the holders. In countries where value chain is well organized and the bulk of vegetable crop production are commercialised through a well-known limited number of markets, the estimates can be obtained through administrative sources related to market data. Expert assessment is also used for vegetable crop production estimates in some countries. The experiences of some countries below illustrate the different methods:

Some countries like Malta and Mexico are collecting vegetable crop data using administrative records and sources of vegetable crop estimates.

The Mexican agricultural statistics program uses administrative registers to obtain vegetable crop data. In particular, the agriculture information includes the sown area, harvested area, damaged area, observed and estimated harvests, etc. The Ministry of Agriculture (SAGARPA) state offices combine advanced reports on sown and harvested areas during the first ten days of each month and continue to capture this information in order to include the cumulated data in the next month's report. The central office of Ministry of Agriculture provides the rules and the information system for processing the data.

In Malta, to do away with expert advice the Agriculture and Fisheries Unit decided to embark, with the support of European Union, on a survey project using scientific methods in order to provide solid foundations for present and future vegetable crop production estimates (TAPAS project).

Interviewing was carried out during a twelve-week period extending from March to May 2005 and the information collected referred to harvested crop production for the calendar year 2004. The households in the sample were informed individually by mail explaining the scope of the survey and the information it was about to collect. Each farmer was asked to prepare area and production figures for the year 2004.

The final results from the TAPAS Project gave a total crop production of 106,922 tonnes in 2004, with a percentage error of 4.3 given a 68 per cent level of confidence. This production was significantly higher than the volume which passed through organized markets which stood at 44,513 tonnes during the same period. The primary aim of the survey was to establish the level of production which by-passes the market. Table 4.1 shows the percentage comparison between the total production from the survey, and the volume of produce that can be collected directly from administrative sources. It can safely be concluded that there are no direct sales for tomatoes, carrots and vegetable marrows and also administrative sources are very reliable. As for beans and onions this is absolutely the opposite as only a small percentage pass through the official markets. On the other hand, the production of beans and onions are mainly grown by part time farmers and are either consumed on the holding or sold directly. A substantial volume of certain crops, namely sugar melons, water melons, cabbages and cauliflowers are sold directly by the holding and by-pass the official market (TAPAS, 2005).

Table 4.1 Comparison between estimated total crop production (t) and crop production (t) from

administrative sources

	Production (t) TAPAS survey	**Total production (t) from administrative sources**	**%**
Tomatoes	15,047	15,051	100
Onions	5,276	2,254	42,7
Beans	1,990	467	23,5
Vegetables Marrow	3,083	3,046	98,8
Water melons	5,148	4,400	85,5
Sugar melons	4,172	2,871	68,8
Cauliflowers	5,065	3,186	62,9
Cabbages	3,482	2,634	75,6
Lettuce	2,720	2,237	82,2
Carrots	1,612	1,648	102,2

Sources: Fruit and vegetable production/Final report (TAPAS, 2005).

Some countries do not implement a specific sample survey or census for vegetable crops. Accordingly, vegetable crop data are collected together within the framework of an existing agricultural survey or census. Therefore, data on vegetable crops are collected together with other crops like cereals, fruits, etc. In many Europeans countries, the Survey on Agricultural Production

Methods, abbreviated as SAPM, was a survey carried out in 2010 to collect data at farm level on agri-environmental measures in the EU. European Union (EU) Member States could choose whether to carry out the SAPM as a sample survey or as a census survey. The SAPM covered all agricultural holdings (including vegetable crops holdings).

In the case of Africa and Asia, due to the diversity situations of vegetable crops cultivation, it is difficult to collect vegetable data production together with traditional crops.

Some vegetable holdings are usually located in specific areas. In developing countries, they are located in the neighbouring of cities, where it is easy to access markets to sell produce due to perishability of these types of crops. In many countries, most of the vegetable crop plots are located in specific sites, generally near water points in rural areas where water is available for irrigation (AFRISTAT & DNSI, 2004). Therefore, a sample used to estimate the production of a set of crops (including traditional and vegetable crops) is not able to capture in an efficient manner the production of the latter. Sampling bias error could be large considering vegetable crops holdings are not spread enough and could be considered as rare crops. Specific surveys with specific sample designs are necessary for the vegetable crop estimate survey.

The specific case of Africa

The practice of growing vegetable crops is prevalent in almost all African counties. Horticultural crops, especially vegetable crops, serve a dual function as both cash and food crops. The methods and techniques employed by producers for growing and harvesting these crops vary from region to region, according to peculiarities of vegetable crops. Furthermore, the specificity of vegetable crops such as continuous harvesting, successive harvesting, staggered harvesting, the different methods of cultivation and marketing strategies adopted by holders including timing and frequency of harvest for staggered crops pose certain statistical challenges (area and yield measurement) that are not present in traditional crops (cereal and root crops).

One particular challenge is that the growing cycle is often short for vegetable crops compared to traditional ones and vary considerably from one vegetable crop to another. This allows several planning and harvesting occurrences for the same vegetable during a single growing season and different crops rotation during the same growing season. As a result, different crops are often sown and harvested on the same piece of land during the agricultural year. This practice is the main characteristic of vegetable growing. In developing countries, another characteristic is that the farmers are typically small holders and are located near wet zones and big cities due to the perishability of these crops and the lack of storage facilities, and close proximity to major markets.

Another challenge is the application of technology such as fertilizers and irrigation to vegetable crops that affects yield and the number of harvests.

Due to heterogeneity among cultivation techniques, and frequency of harvest, choosing the appropriate observational method for a particular crop can be difficult. The observational method should be chosen based on the crop and cultivation technique including necessity for periodical monitoring. For the purposes of this study, vegetable crops are divided into 5 types with regard to the nature of crop (leaf, root, fruit) and the methods of harvest (single, staggered) requiring a specific method for yield estimation:

1) Leafy vegetables with staggered crop harvest;

2) Leafy vegetables with single harvest;

3) Root vegetables with single harvest;

4) Fruit vegetables with single harvest;

5) Fruit vegetables with staggered harvest.

In these cases, staggered harvest crops refer to crops for which fruits or products do not mature at the same time and for which multiple harvests are required and spread over a period of time. Examples include tomatoes, okra etc. On the other hand, single crop harvest refers to crops that are completely harvested upon maturity and destroyed thereafter. These include pumpkins, cabbage, lettuce, carrot, etc.

2. Objectives

Considering the issues of having a sound methodology for vegetable crops production estimate, the Global strategy to improve agricultural and rural statistics added this domain to the list of research topics to be explored in the research plan. A literature review has been prepared to review the methods used in different countries and regions to produce vegetable crop production estimates and to prepare and implement Field Test Protocol (FTP) and a guideline to support countries. The FTP targeted development countries where technical issues are more acute. Among all existing sources (administrative, expert assessment, census, survey) the FTP targeted to conceive and implement survey methodology in order to assess the technical choices and the results and gather elements to prepare a methodological guideline. The FTP has tried to explore all aspects to have a good survey providing accurate estimating of interested parameters including:

- Necessary adaptation of concepts and definitions for vegetable crop survey
- Appropriate sample frame for vegetable crop holdings:
- Appropriate sample design for effective sample selection for the survey aiming at having accurate harvested area and yield estimates for all significant crops including rare and cash crops
- Appropriate methods for harvested area and yield data collection considering the challenges identified for this kind of crop (continuous planting/harvesting, staggered harvest crop)

The FTP has been applied in Ghana and this paper will try to summarize the methodology adopted for measuring vegetable crop area, yield and production based on a sample survey. The paper will address the primary challenges associated with measuring vegetable crop production. More specifically the pilot has addressed the issue of sample frame and sample design and the issues of having easy and accurate measurement methods for production parameters estimates (area harvested, yield). The FTP puts emphasis on:

- The method for choosing or developing an appropriate frame of vegetable crop holdings, and specific variables to be collected during PSUs constitution and listing of vegetable crop holding as a final sampling unit;
- Considering different measurement methods including farmer inquiry and objective measurement for harvested area and yield estimation for various vegetables;
- Considering yield variability over time for staggered harvested crops and the feasibility for using monitoring method and farmer recall to collect data for yield estimate;
- The use of beds for vegetable cultivation allows to pilot other methods for harvested area and yield data collection in addition to the crop-cutting method;

3. Methodological Approach

3.1. The Scope of the Pilot Survey

The administrative sub-division of Ghana is at first level 10 Regions and at second level 216 districts. The scope of the field test is limited to two districs in two close regions. The scope a the pilot survey is two districts. The district target should be the ones where vegetables growing constitutes an important activity and convenient for testing various aspects of the methodology. The Ada West District in the Greater Accra Region and Keta Municipal District in the Volta Region were chosen. by Statistics Research and Information Directorate (SRID) of the Ministry of Food and Agriculture (MOFA) and are known to be sheltering a large number of diverse types of vegetable holders growing a large number of vegetable crops.

3.2. Methodology of Data Collection

Data could be collected through a sample survey. The absence of a sampling frame for vegetable crops (list of vegetable crop holdings) requires a prior listing operation to constitute an exhaustive list of gardeners. Once this has happened, a sample of vegetable holders will be drawn.
The survey will be implemented in several steps:

- Step 1: Listing of vegetable crop growing areas.

The first step is to list all the horticultural sites. Each site will be enumerated with important variables like geographic position, number of vegetable holders, types of vegetable crops grown. This listing will allow establishing a sampling frame for vegetable sites as PSU. The sample of PSU will be drawn from this frame.

- Step 2: Listing of vegetable holdings and the identification of holders.

A full listing of vegetable holdings will be obtained for each sample of vegetable crop areas. This list will be the Secondary Sampling Unit (SSU) frame. During the listing, information will be collected on farmer name, crops on each parcel and specific date of harvest. The latter is very important: the enumerator will record the exact date of the harvest. A return visit will be done on that date in order to collect information on yield.

- Step 3: First visit

In the second step, the main part of the questionnaire is filled. Data are collected on socio-demographic characteristics of farmers, economic characteristics of the farm including labour, land (size and number of plots, number of beds under cultivation, average size of beds by crop, equipment, production costs, etc.). During this visit, we will identify the beds by crop type and a few beds by crops will be measured to get an idea of their average size.

- Step 4: The Yield Survey

The production of a selected sample of plot will be collected and weighed. In some cases, the enumerator will collect and weigh the total production of a bed or count the number of its plants, calculate the average weight of a plant from a few harvested plants and compute the weight of the production of a bed. In other cases, (for staggered harvest crops), he/she will estimate the production of a bed in a number of measurement units and weigh the contents in order to compute the weight of the bed.

In the large majority of countries (developed and developing countries), a proper system to collect area data on vegetable crops does not exist. Some countries, mostly developing countries, rely on Census of Agriculture to collect these data. Some developed countries use administrative data or expert assessment. Very few countries conduct surveys or censuses for collecting vegetable crops area. It is important to examine which method applies to which country and under which conditions. For instance, in Africa, the vegetable plot has often the form of the bed and since some vegetables are staggered harvest crops, one option is to rely on the statement of the holder to have area and production estimates and that requires a significant effort of memory recall from holders.

If the collection of data on vegetable crops is done within a more comprehensive survey/census, it is possible that the questionnaire design and the general techniques of measurement of area and production for "traditional" could not fit the peculiarities of vegetable crops.

The use of administrative data from different sources, that is to say data which were not collect primarily for statistical purposes, can be difficult when reconciling them to obtain statistical data. This can be more difficult for countries where administrative data are outdated. Global Strategy is elaborating a guideline on how to improve and integrate administrative data in the agricultural statistical system (Global Strategy, 2015).

Due to the large species of vegetable crops, the measurement of yield depends on the type of vegetables. Onetime enumeration is not meaningful for some vegetable crops, since they have several growing seasons within a year. It is important to evaluate the best option between: 1) Providing necessary tools and capacity building to the holder and relying on his statement or 2) Follow-up by several visits, with the physical presence of enumerators. In this last case, it is important to determine with the holder, the exact date for crop harvesting. Some crops are left in the field by the holders and harvested when needed.

The yield depends also to the seed varieties. Only information collected from the field could give clear indication on the yield. Administrative data should be extremely detailed to give all these information, for each crop. Therefore, the use of administrative data to identify yield rate could be a daunting task. However, administrative files could be used to assess the production.

The use of a specific seed can be different within a year; the yield rate also can vary considerably during this period of time. For crops which are grown several times during a year period, if the yield estimates for one growing season is used for another one, the results could be inaccurate.

The main challenge for this kind of survey on horticulture crop is to find the best observation methods giving right and accurate measurements of the key parameter for production estimate (area harvested, yield). It is how to find the easiest, the simplest and most user-friendly method for respondents and enumerators, which are fast to implement and are cost-effective that is a challenge.

The vegetables grown in the region (lettuce, carrot, spinach, mint, celery, etc.) are characterised by short growing cycles (1-3 months) and generally non rain-fed crops allowing the practice of continuous planting/harvesting over the year. Certain vegetables like mint, parsley's main characteristic is that they are successive harvest crops and others like okra and tomatoes for which harvest is staggered can last 1 month or more. Hence measuring the harvest area and yield using objective measurement methods needs to monitor each planting/harvesting occurrence and also each harvest occurrence by the sampled holder for okra and tomatoes.

For the exercise, there was not enough budget and probably no national institution would accept to participate in a pilot survey covering one year in the field. The strategy used in this field test is to reduce the number of visits by the enumerators to the farmers at a minimum possible considering the short time allocated to data collection phase in the field (one month). For the recording of area harvested, the combination of objective measurement during the field visits and the farmer recalls allow to calculate estimates covering the reference period (one year). Considering the general cultivation practice of the vegetable growers using the bed as the principal technique for soil preparation and plant sowing, the bed is an area unit that can be used for harvest area measurement.

The questionnaire is designed to allow recording of a suite of variables needed in order to estimate the area and yield of each type of vegetable crops. The variables to be measured and the appropriate methods of measurement vary according to the type of crop, the mode of harvest (i.e. single harvest, staggered harvests, successive harvests), and cultivation techniques (on bed, full field). For yield measurement, two methods are tested, the random selection of a sample of beds to be harvested and the production weighted in the case the plot is sown using the beds and the use of traditional crop cutting method in case the plot is sown using full field. Table 1 below illustrates the proposed variables to be collected during this pilot by type of crop according to the mode of harvest, and cultivation technique.

Note that for root vegetables and fruit vegetables, the determination of the measurement unit is central to estimating production.

3.3. Sampling Frame

A sampling frame can be built using agricultural or population census frame. Some variables collected during these statistical operations allow to identify the vegetable growers. The use of administrative files of producers registered in official government agricultural support programs. It is an important storage of administrative records that allows, through in-office activities, to obtain enormous quantity of information about the vegetable growers.

The experience and knowledge of the field enumerators or technicians about the producers and plots land located in their work areas could make it easier to identify producers and their agricultural holdings.

Sometimes it is necessary to build a proper sampling frame. For instance, during the pilot test in Ghana, this option was used. In the absence of appropriate registers of vegetable holdings in Ghana, the better sample design is the two staged sample. The use of Enumeration Area (EA) of the Population and Housing Census 2010 was an option but due to the time-lag between the two operations (5-6 years), the risk of having obsolete and inappropriate information about vegetable growers of the EAs for drawing a sample of PSU was very high. In addition to that the need for having more information on the PSU for an effective sample selection required to have a step for the first stage sample frame preparation by the identification and listing of PSUs allowing the collection of important variables to support the sampling selection.

The first stage sampling frame was built by a complete listing of vegetable growing areas (sites) in each district. Variables such number of holdings operating in the site, the types of vegetables grown in the site were collected to be used for the sample selection.

Once the site is selected, then a complete listing of vegetable holdings is done. This list was the Secondary Sampling Unit (SSU) frame. For sample selection purposes, variables were collected on holder name and sex, type of vegetable grown and specific date of the next harvest, number of employees, total acreage under cultivation. This additional information is used to perform effective holdings sample selection and also for operational use to ensure that the area and yield questionnaires are implemented at the right time particularly that yield data collection are planned during the right harvest time minimizing the survey personnel workload and costs of logistics.

During the listing of the PSUs, the following variables could be collected: a) Area Code b) Area Name c) Geographic Location-GPS Coordinates; e) Estimated Number of Vegetable Holders; f) Main water source; f) Types of vegetable crops grown.

The latter variable allows to build a sample, covering all the different crops. The estimated number of vegetable holders allow to calculate the probability of inclusion for the PSUs.

During the listing of SSUs, the following variables could be collected: a) Name of the Holder; b) Gender; c) the Total acreage under cultivation (acres); c) the number of beds (if applicable) d) The crop grown; e) the beginning of the period of harvest.

3.4. Sample Selection

The sample design could be the 2 stages sampling. At the first stage, the vegetable growing areas are selected with probability proportional to size (pps). The variable to be used for the pps sampling could be the number of vegetable growers in the area.

In the pilot test held in Ghana, 102 vegetable growing sites were identified and listed in the two districts (53 for Keta and 49 for Ada). 32 sample sites (PSU) were selected using PPS (16 for each district). The sample rate at first stage is 1/3. In the Ada District, one site was automatically selected since it was the only site where a specific crop, Zucchini, was recorded. The listing of vegetable crop holders in these 32 sites gave a total of 1814 holders. 10 sample holders were selected randomly in each of the 32 sites. The sample size for the field test was 320 holders. The workload of the enumerators and the budget limitation was taken into account in deciding on the sample size. A total of 16 enumerators were available for the field test.

4. Field Implementation and Innovation

The field implementation has allowed to identify several area of innovation:

- For staggered harvest crop, the enumerator can visit the field 3 times during the harvest period. Ideally, at the beginning, at the peak and at the end of the harvest. A harvest diary could be given to the farmer in order to record the production of the farm during the absence of the enumerator. The variables to be collected could be: a) the production on the bed/crop-cutting area in terms of number of measurement unit; b) Number of Harvested Beds; c) The date of the harvest. These variable should be kept simple as possible and well understandable by the farmer. Such collected would be useful to access the variability of the production within a single harvest period and to obtain better estimates of the production.
- The pilot test in Ghana has shown that, the growing of vegetable crops is not fairly distributed in various PSUs. For instance, zucchini was only cultivated in one PSU. During the sample selection, this PSU was automatically included in the sample. The estimation of the vegetable crop production grown in such production is done separately and then add to

the estimation on the remaining sample. This procedure allows avoiding the overestimation of the production for such "rare" crop.

- In order to assess the yield, a number of beds are randomly selected in the case the field is divided in beds. The enumerator will confine the field, whatever is its form, in a rectangle with sizes a and b. He will assign the four corners of the rectangle numbers from1 to 4. Using a calculator, he will select a number between 1 and 4. This number will correspond to a selected corner, which will be considered as an "origin point''. Then, he will select a random number between '0 and a' and between '0 and b', using a calculator. These selected numbers will be the coordinates (a, b) of a point in the field. When the point falls in a bed, this bed is selected. The operation is repeated until 3 beds are selected from this field. The sizes of the three beds will be recorded.
- Due to their correlation with the production, socio-economic variables, like availability of water supply, the demand, the equipment, etc. could be collected in other to assess the production. In the case of the pilot test, stratification was not necessary, since the listing of the SSU present a quite homogenous population. However, when stratifying the whole population of the farms the more recent information for each farm is used. It is therefore necessary, to keep update as possible all the information related to the farms. The listing is highly useful in this case.

5. Concluding remarks

Methodologies for measuring area and production for vegetable crop are under development. For instance, Remote Sensing Data are also used to estimate agricultural production; but their use is still at an early stage. Even in developed countries the use of remote sensing data in horticulture is scarce. However, some studies have been done on its implementation in horticultural census/survey (Avtar & Kamlesh, 2012 and Trout et al., 2008). Apart to the fact that it can be used to assess the area, it could be used to identify the harvest period and provide information on the growth status of crop. This information will facilitate the data collection work (Lee et al., 2014).

The pilot test survey in Ghana is currently under implementation, the result will allow to assess the various methodologies to measure area and production (farmer inquiry vs. objective measurement). It will also allow to access the variability of the production for staggered harvest crop.

However, the field implementation in Ghana done so far has allow to confirm what identified in the literature review about the use of bed for vegetable crop production and the use of a measurement unit for the measurement of the production by the farmer.

An adequate sample design has been also developed in order to estimate in an accurate manner the production. The data collected in the Keta district, will be compare with existing data on the vegetable production in order to assess the methodology.

CROP	Divided in Beds		NOT Divided in Beds	
	Area	**Production**	**Area**	**Production**
Leafy with single harvest • Lettuce • Cabbage • Cauliflower	Randomly select beds and: • Area by inquiry • Area by objective measure (GPS) • Simple geometric calculations for small beds • Number of beds harvested by inquiry over the last 12 months	Randomly select beds and: • Harvest bed, and weigh Or • Count plants • Randomly select plants, harvest and weigh • Production by farmer inquiry • Estimate yield of each harvest by farmer inquiry over the last12 months	• Area by inquiry • Area by objective measure (GPS)	Randomly select crop cutting area • Harvest and weigh • Production by farmer inquiry • Estimate yield of each harvest by farmer inquiry over the last 12 months
Leafy with staggered harvest • Spinach • Mint • Parsley • Celery • Potato leaves	Randomly select beds and: • Area by farmer inquiry • Area by objective measure (GPS) • Simple geometric calculations for small beds • Number of beds harvested by inquiry over the last 12 months	Randomly select beds and: • Harvest bed, and weigh • Production by farmer inquiry • Estimate the number of harvest over the last 12 months by farmer inquiry • Estimate yield of each harvest by farmer inquiry over the last12 months	• Area by inquiry • Area by objective measure (GPS)	Randomly select crop cutting area • Harvest and weigh • Production by farmer inquiry • Estimate yield of each harvest by farmer inquiry over the last 12 months
Root vegetables with single harvest • Carrot • Beet • Turnip • Bulb onion • Shallot • Leek	Randomly select beds and: • Area by inquiry • Area by objective measure (GPS) • Simple geometric calculations for small beds • Number of beds harvested by inquiry over the last 12 months	Randomly select beds and: • Harvest bed, and weigh Or • Estimate number of measurement units • Harvest randomly selected plants, weight measurement unit • Production by farmer inquiry in measurement units • Estimate yield of each harvest by farmer inquiry over the last12 months	• Area by inquiry • Area by objective measure (GPS)	Randomly select crop cutting area • Harvest and weigh OR • Estimate production by farmer inquiry in measurement units • Estimate weight of measurement units by farmer inquiry

Fruit Vegetables with single harvest • Pumpkin	Randomly select beds and: • Area by inquiry • Area by objective measure (GPS) • Simple geometric calculations for small beds • Number of beds harvested by inquiry over the last 12 months	Randomly select beds and: • Harvest bed, and weigh Or • Estimate number of measurement units by farmer inquiry • Estimate weight of measurement unit by harvesting, filling, and weighing • Estimate yield of each harvest by farmer inquiry over the last12 months	• Area by inquiry • Area by objective measure (GPS)	Randomly select crop cutting area • Harvest, and weigh Or • Estimate number of measurement units by farmer inquiry • Estimate weight of measurement unit by harvesting, filling, and weighing • Estimate yield of each harvest by farmer inquiry over the last12 months
Fruit Vegetables with staggered harvest * • Cucumber • Eggplant • Pepper • Hot pepper • Tomato • Okra *Methods are same regardless of whether or not fruit vegetables are cultivated in beds.	Randomly select beds and: • Area by farmer inquiry • Area by objective measure (GPS) • Simple geometric calculations for small beds • Number of beds harvested by inquiry over the last 12 months	Using fruit vegetables already reaped that are present at holding. • Estimate number of measurement units by farmer inquiry • Estimate weight of measurement unit by harvesting, filling, and weighing • Estimate the number of harvest over the last 12 months by farmer inquiry • Estimate yield of each harvest by farmer inquiry over the last 12 months	• Area by inquiry • Area by objective measure (GPS)	Using fruit vegetables already reaped that are present at holding. • Estimate number of measurement units by farmer inquiry • Estimate weight of measurement unit by crop cutting, filling, and weighing • Estimate yield of each harvest by farmer inquiry over the last 12 months

ABSTRACT

The structure of the agricultural sector evolves through the responses of individual farms to technological innovation, economic shifts and demographic trends, among other factors. In 2014, the Canadian Longitudinal Census of Agriculture (CL-CEAG) dataset was created to provide an additional tool for micro-level farm analysis. This initiative followed the example of the U.S. Census of Agriculture Longitudinal File. This paper describes the CL-CEAG dataset, the methodology for the record linkage and models of farm exits and farm profitability as examples of analysis using the CL-CEAG. Discussion on the features of the file and on how to access it concludes.

Keywords: Census of Agriculture, longitudinal data, farm exit, farm profitability

* Corresponding Author

1. Introduction[1]

[1] The authors thank their colleagues for valuable comments and suggestions, in particular Ray Bollman.

1

The primary purpose of the Census of Agriculture (CEAG) is to create a statistical profile of Canadian census-farms[2] at one moment in time. However, given that the CEAG includes the population of census-farms and that it provides a broad range of farm and operator characteristics with a high degree of continuity over time, the CEAG presents a unique opportunity for the creation of a longitudinal dataset for farm-level analysis of structural trends and the lagged impact of policies and external shocks. Thus, following the US example, where the US Census of Agriculture Longitudinal file was created in 1997, linking census records back to 1978[3], Statistics Canada created in 2014 the Canadian Longitudinal Census of Agriculture (CL-CEAG) dataset. The purpose of the paper is to present the CL-CEAG dataset as a new analytical tool, describing in particular the methodology for the record linkage, as well as providing models of farm exits and farm profitability as examples of analysis using the CL-CEAG. Discussion on how the dataset can be accessed while ensuring data confidentiality concludes.

2. Existing longitudinal files for the Canadian agricultural sector

The CL-CEAG micro-dataset complements already existing longitudinal data on Canadian farms from administrative data sources and surveys. Housed at Agriculture and Agri-Food Canada (AAFC), administrative data of from AgriStability and AgriInvest, two Canadian agricultural risk management programs, provide detailed longitudinal farm business revenue and expense data of over 100,000 participating farms, as well as detailed inventory information for about half of these, beginning in 2005. The population is limited to program participants and does not include all Canadian farms. The file does not include farm physical information or farm operator characteristics.

The Longitudinal Administrative Databank (LAD), housed at Statistics Canada, consists of detailed income, social transfer and demographic information of 20 percent of Canadian income tax filers and their families, beginning in 1982. Farm families can be identified as those with a non-zero value for Gross Farming Income and/or Net Farming Income. The LAD has been used to analyze the persistence of negative net farming income and the prevalence of low family income of farm families compared to non-farm families (Culver, 2012; Nagelschmitz, 2007). The file does not include any information on the farm business.

The sample overlap of the biennial Farm Financial Survey, which collects information on farm assets, liabilities, capital purchases, and capital sales, as well as some operator demographic information and program participation information, has been used for analysis, such as of the year-to-year changes in level of farm debt (Culver, 2012).

---

[2] In Canada, a census-farm - or “agricultural holding” - is any operation producing agricultural products that are intended for sale, which in addition to farms producing field and livestock products crops also includes mushroom houses and nurseries; farms producing Christmas trees, fur, game, sod, maple syrup or fruit and berries; beekeeping and poultry hatchery operations; operations with alternative livestock; as well as operations involved in boarding horses, riding stables and stables for housing and/or training horses (see http://www.statcan.gc.ca/eng/ca2011/gloss) (See http://www.statcan.gc.ca/pub/95-629-x/2007000/4123857-eng.htm). In this paper the focus is on all census-farms, and we use the term “farm” and “census-farm” interchangeably, always mindful that the majority of census-farms are small operations , which provide at most only a very small contribution to their farm operator’s income.

[3] See Hoppe and Korb (2006) for a description of the US Census of Agriculture Longitudinal file dataset; Ahearn et al (2009) and Katchova and Ahearn (2015) use the file for analysis of farm level dynamics.

In the past, CEAG files have been linked at the micro level in pairs of two succeeding census iterations to analyze the characteristics of exiting, entering and continuing census-farms (Kapitany and Bollman, 1983; Ehrensaft et al, 1984; Bollman and Ehrensaft, 1988; Bollman et al. 1994; Kimhi and Bollman, 1999). In addition, Shapiro et al. (1987) used as sample of micro-linked census-farm records from 1966 to 1981 to examine the dynamics of farm concentration.

The CL-CEAG complements these existing longitudinal administrative and survey data sources, by providing longitudinal data for all census-farms, as well as the possibility of including a wide range of farm and operator characteristics variables in micro-level models examining farm behaviour for up to 25 years.

3. The Canadian Longitudinal Census of Agriculture dataset

The Canadian Longitudinal Census of Agriculture (CL-CEAG) dataset links the micro-data of census-farms across the six censuses from 1986 to 2011, using the unique Agricultural Operation Identifier (AGOPID), which is part of each census-farm record. The AGOPID makes it possible to track the change in characteristics of individual farms over time, as well as to identify census-farm entrants and exits between collection years to measure the dynamics of structural change. The dataset provides a consistent set of industry- and geography-based classifying variables.[4] For the latter, the 2011 Standard Geographic Classification is applied, with the fundamental geographic unit being Census Consolidated Subdivisions (CCSs). CCSs can be aggregated, to form Census Divisions, Census Agricultural Regions, and Economic Regions, providing a high degree of flexibility.[5] The CL-CEAG dataset currently includes a number of variables that describe farm and farm operator characteristics that are consistent over the period covered by the data. Many more census variables can be added as research projects are developed.[6]

The AGOPID is fundamental to the creation of the CL-CEAG dataset and the interpretation of analysis that uses the data. The AGOPID is attached to each census-farm, which has been identified based on the definition of "agricultural holding" (see footnote above) and is therefore included in the Census of Agriculture. The AGOPID is largely based on the location of the farm's headquarter. A census-farm is treated as "continuing" if it responds to censuses under the same AGOPID across census years. By the same token, if a respondent associated with an AGOPID indicates that there is no longer an operation that produces agricultural products for sale or with the intent to sale, the census-farm with that AGOPID is considered to have exited[7].

Changes in farm ownership (whether it be an intergenerational transfer or an arms-length purchase from outside the family), change in operators, or change in headquarter location have the following impacts on the AGOPID: If a census-farm is sold or otherwise transferred as an on-going operation and the new operator's information (i.e. name and age) is available and is associated with the farm's location, the farm is considered continuing and its AGOPID is maintained. However, if a census-farm is bought by another existing farm, the farm is most likely treated as part of the new owner's existing operation and the farm's land, building and inventory are recorded in the Census of Agriculture questionnaires as an expansion of the buyer's farm. In that case, the AGOPID of the

[4] The CL-CEAG dataset includes industry variables of longitudinal farm type based on the North American Industry Classification System (NAICS; http://www.statcan.gc.ca/eng/subjects/standard/naics/2012/introduction#a8).
[5] http://www23.statcan.gc.ca/imdb/p3VD.pl?Function=getVDPage1&db=imdb&dis=2&adm=8&TVD=116940
[6] Some CEAG variables have evolved over time. Where feasible, a consistent variable is created. Some variables may not be found in all years, but may nonetheless be useful for analytical purposes.
[7] Note that a farm is not considered active if all land is rented out.

Table 1. Factors Related to Farm Exit between 2006 and 2011

	Likelihood of exit	Signifi-cance
One-period farm and operator characteristics [Reference in brackets]		
Macro-Region [Ontario]		
Atlantic		
Quebec		
Prairies	++	***
Alberta	+	***
BC		
Farm Type [Grain and Oilseed]		
Beef Cattle	---	***
Hogs	+++	***
Horticulture		
Mixed		
Revenue Class [Under $50K]		
Between $50K and $250K	-	***
Between $250K and $999K	--	***
Over $1M	---	***
Age of 1st Operator [Under 30 years of age]		
30 to 39 years of age	-	**
40 to 49 years of age	--	***
50 to 59 years of age		
60 years of age and older	+++	***
Off-Farm Employment [No Off-Farm Employment]		
Part-Time Off-Farm Employment		
Full Time Off-Farm Employment	+	*
Number of Operators [One operator]		
Two	--	***
Three	---	***
Multi-period Variables (1996-2006)		
Change in Value of Machinery and Equipment (Bottom tercile [reference]		
Middle tercile	--	***
Top tercile	-	***
Change in Farm Size [Bottom tercile]		
Middle tercile	-	***
Top tercile	--	***
Change in Gross Farm Receipts [Bottom tercile]		
Middle tercile	--	***
Top tercile	-	***

Notes: +/- indicates the direction and strength of the influence of the variable on the likelihood of exit and are only reported when statistically significant. *,**,*** indicate significance at .01, .001 and .0001 levels, respectively. For categorical variables, reference groups are noted in parentheses.

purchased farm is terminated and no new AGOPID is created. If a farm is sold and bought but the new operator or head quarter location cannot be identified with the farm under the previous owner, the old AGOPID is inactivated and a new AGOPID is created.

Entry and exit rates generated by the CL-CEAG are qualitatively similar both to entry and exit rates generated by the CEAG going back to the early 1900s of between about 35 and 50 percent over 10 years, and to the U.S. (Bahar and Brown 2014). They are also are in line with manufacturing firm 10-year entry and exit rates of about 40 percent (see Baldwin 1998).

4. Examples of Modelling using the CL-CEAG

Longitudinal datasets are useful tools for many types of analysis. Here we first highlight the use of lagged and multi-period variables in the modelling of farm dynamics, specifically farm exists, and then the analysis of the factors associated with change over time in farm performance (i.e. profit margins). It is important to keep in mind that, while instructive, the results of these simple models presented here should be viewed as correlative and not aimed at identifying causal relationships.

Example A: Farm Exits

Farm exit and entry dynamics in Canada have been modelled with various datasets in the past, including multiple panels of two-period CEAG panel data and a sample of longitudinal CEAG records (Ehrensaft et al. 1984; Kimhi & Bollman, 1999). The CL-CEAG allows the use of micro-multi-period variables of farm dynamics and behaviour on the whole population of census-farms, which could be related to future continuation or exit decisions of census-farms.

Building on Freshwater (2015), we use a logit model to estimate the relationship of farm and farm operator characteristics on farm exits, including three multi-period variables identifying the farms' growth behavior. Table 1 shows the results for census-farm exits between 2006 and 2011, (i.e., of AGOPIDs which existed in 2006 but not in 2011). The first multi-period variable accounts for the change of the value of machinery and equipment between 1996 and 2006, namely the ten years leading up to the anchor year (2006). The change in the value of machinery and equipment is assumed to be partly an observation of investment behaviour and reflective of the medium to long-term business objectives of the farm. The variable was created using terciles rankings within each farm type and farm size group in the anchor year, assigning each farm the value of Top, Middle, and Bottom Tercile, from greatest percent increase to greatest percent decrease in the value of machinery and equipment. The hypothesis is that farms planning on exiting are less likely to increase their investment in years prior to exiting than are farms in the other two categories. We also construct a similar variable of terciles of percentage change for physical farm size, using the number of acres for crop farms and herd size for livestock enterprises between 1996 and 2006, with similar a hypothesis.[8] Finally, a variable for change in annual gross farm receipts between 1996 and 2006 (in 2001 dollars) is included in the model to captures the trend of farm revenues in the years prior to the decision to exit or continue, which may have a different trend than physical size of the operation. In addition to these multi-period variables, the model also includes standard single-period variables in the farm exit model: region, farm type, gross farm receipts, off-farm employment and farm operator age.[9]

Given that the purpose of the paper is to illustrate the use of the dataset, it is sufficient to show the general tendencies rather than exact coefficient. This approach limits the impact of this analysis on the confidentiality of the dataset, as will be discussed further, below. The longitudinal farm growth indicators all have the expected signs with regards to the probability that the farm exits. Farms that were growing are less likely to exit than those that are decreasing in size. At the same time, the single-period variable farm revenue class (using farm gross receipts) is the strongest predictor of farm exits, and operator employment off the farm and the number of operators are also significant variables. The CL-CEAG enabled the modeling of the role of multi-period trends at the census-farm level on farm behaviour.

Example B: Farm Profit Margins

While the previous example shows the benefit of the CL-CEAG in enabling the use of multi-period variables for analysis in traditional regression models, this second example shows how the longitudinal dataset enables the modelling of change of farm attributes over the entire period (i.e. 1986 to 2011). This example models the factors impacting farm profit margins across the period.

The general linear mixed longitudinal model (GLMLM) is used because it is better suited to longitudinal analysis than the more common generalized linear model (GLM). While the GLM assumes that observations are independent of each other, the GLMLM takes accounts the fixed effects impacting observations of each subject, in addition to the random effects of each observation (Breslow and Clayton, 1993).

The dependent variable of the model is 'profit margin', calculated as Total Gross Farm Receipts minus Total Farm Business Operating Expenses plus Interest Expenses divided by Total

---

[8] The variables are change in farm acres (for grain, tobacco and horticulture farms); head of cattle (beef cattle farms); and number of pigs (hog farms).

[9] Since 1991, the CEAG allows for multiple operators, with no difference in status, i.e. there is no 'primary operator' designation. However, for this analysis we use the first operator that is identified, and assume that the first operator is most involved in the operator of the farm, i.e. the "primary" operator.

Gross Farm Receipts.[10] In addition to the one-period farm and farm operator characteristics, as in the farm exit model, the model includes CEAG variables associated with two farm management practices as a proxy for adoption of innovation: 'Use of computer for farm management' and 'Use of tillage practices', which references the adoption of no-till technology.

The results of the estimation are as follows. The coefficients of the farm and farm operator variables have broadly speaking the expected signs: Larger farms with older farm operators that dedicate their time to farm operations tend to have higher profit margin, after taking into account their farm type and location.[11] Farms with two operators are more likely profitable than those with either one or three operators. This might be a sign of the most stable farm management and farm size structure, perhaps due to husband and wife partnerships[12]. The variable 'Use of computer for farm management' has a positive and marginally significant effect of farm profit margins, while the variable 'Use of tillage practices' has no significant effect. Census year dummy variables were included in the model to account for external factors, such as market conditions and weather patterns; they were found not to be significant.

The model provides largely an intuitive set of associations. More work is required to develop a fully formed identification strategy. The longitudinal nature of the file, however, opens up several avenues of econometric analysis to pursue this, including the development of internal instruments, for instance using Systems- GMM (generalized method of moments) estimation.

5. Discussion

The CL-CEAG dataset has been developed to provide an additional tool for the analysis of the Canadian agricultural industry, given its broad range of farm characteristics and now the ability to use multi-period and lagged variables to identify the drivers of farm behaviour, including responses to macro-factors, such as changes in the infrastructure and cost of transportation, regional economies, and policies and regulations.[13]

However, the CL-CEAG is not free of limitations: The linking of farm records over survey time, like all firm-based data files, is not always clear-cut. Some changes occurring to the farm business require special consideration and judgement as to whether they represent the death and birth of a new business or the continuation of an on-going farm operation, such as the sale of the farm to new owner but without change of headquarter location or structure of the operation. Also, given the quinquennial nature of the CEAG, farm entries and exits which occur within the five year period are not observed and thus entry and exit rates may be underestimated (Katchova and Ahearn, 2015). In addition, the analysis of multi-period variables or the observation of dynamic trends is limited to those farm businesses that are in existence for at least ten years to be part of three censuses. Lastly, since the primary purpose of the CEAG is to provide information on Canadian

[10] Gross farm receipts include revenues from the sale of agricultural and forest products and agricultural custom work and machine rental, as well as payments from government programs and insurance proceeds. Operating expenses include business costs in the production of agricultural products plus wages and salaries paid to children and spouses. For incorporated farms, operating expenses may also include wages and salaries or rent paid to owner/operators (i.e. shareholders), while labour remuneration owner/operator of unincorporated farms is part of net operating income.
[11] The relationship with employment of other family members is not modeled and might have a different effect.
[12] Detailed results are available from the authors upon request.
[13] For example, Ferguson and Olfert (2015) used information for Census Consolidated Subdivisions in their work on the impact of the elimination of a grain transportation subsidy. Now, with the CL-CEAG the impact of individual farm characteristics can be analyzed.

census-farms at a point in time, the questions are not designed with the longitudinal dataset in mind. However, the development of future censuses might now take the longitudinal CL-CEAG dataset into consideration, so that lagged and multi-period variables could potentially become farm typology indicators.

The CL-CEAG dataset – like all micro-level data – must be managed in a manner that prevents residual disclosure of records, which repeated use of the data with slightly different methodologies can cause. Longitudinal business micro-datasets are inherently at greater risk of residual disclosure than datasets of populations, because the number of records tends to be smaller and the firms (farms) tend to be more easily identifiable than people, especially the larger firms (farms) in a given region or industry. The CL-CEAG is housed in Statistics Canada's Centre for Data Development and Economic Research (CDER), a centralized Research Data Centre at Statistics Canada headquarters that provides strictly managed access to business economic microdata for analytical research. Projects need to go through an approval process and are subject to extensive security requirements throughout the research process[14,15]. Due to the risk of residual disclosure, i.e. identification of respondents through combination of research results, steps have to be taken to limit the effect of published research projects subsequent work. Best practices, such as minimizing the use of descriptive data, have been employed to ensure the usefulness and availability of the dataset into the future.

6. Conclusion

This paper describes the CL-CEAG dataset and provides examples of this new tool for research of the dynamics of structural change of Canadian farms. The aim of Statistics Canada and Agriculture and Agri-Food Canada is that CL-CEAG will encourage much new research.

ABSTRACT

LACO-Wiki is an open access, online map validation tool that has been being developed by IIASA and GeoVille. Funded by the Austrian Agency for the Promotion of Science and originally as a prototype by the European Space Agency, the application is intended for a variety of stakeholders including map producers and public agencies, such as environment agencies, that need a land cover validation solution for their products. In addition, LACO-Wiki can be used by researchers and students who are interested in learning about land cover map validation and for examining different methods of accuracy assessment. A secondary aim of LACO-Wiki is to become

an open data repository for calibration and validation data as well as a repository for land cover and land use maps, which could become a valuable resource for the remote sensing and research community.

LACO-Wiki provides guidance that takes users through the full validation workflow from uploading the map to be validated, generating a validation sample, initiating a validation session and creating a customized report on accuracy assessment. The system currently allows crowdsourcing of the validation tasks to members of a team or to a wider set of participants where users can generate random or stratified random samples to validate existing maps using publicly available very high resolution imagery (VHR) such as Google Earth and Bing. New functionality is currently being added to allow for the creation of a systematic sample that can be used for applications such as crop area estimation. Following the methodology outlined in Kerdiles et al. (2014), LACO-Wiki will automatically suggest an indicative number of sample points required to calculate the crop area with a user-specified level of confidence. The system is currently being tested on area estimation of wetland rice in Madagascar. In countries where access to VHR ortho imagery and image processing technology are not available or where field work costs (i.e. ground-truthing) are prohibitive, LACO-Wiki could represent a highly reliable, low cost solution specifically for area estimation in categories that can be consistently identified (i.e. stable over time) in VHR images, but also more generally for map validation.

Keywords: LACO-Wiki, Area estimation, map validation, land use, land cover, crowdsourcing

1. Introduction

LACO-Wiki is a web-based platform allowing users to validate land cover and land use maps. It provides users with a sequentially guided interface where they can upload their own land cover and land use maps, generate samples, create validation sessions and obtain customized reports including an accuracy assessment and a confusion matrix. During the validation session, different reference layers can be used including satellite and aerial imagery from Google and Bing, and features from OpenStreetMap. This paper outlines new functionality that is currently being added to LACO-Wiki to allow users to estimate areas of selected classes, in particular cropland classes.

With regard to area estimation methods, Craig and Atkinson (2013) review classical and newer techniques, including censuses, described as rather expensive and time consuming, which can therefore only be used every few years in developed countries or even less frequently in developing countries. Some, site-specific studies have analyzed areas where the reference data are effectively covering the whole area, thus becoming a census (Hollister *et al*, 2004). Statistical sampling is more commonly used in order to reduce costs and allow for quite accurate inference on larger populations (Congalton and Green, 2008). List frame and area frame sampling are sound methods to gather information, each one suffering from particular problems, e.g. maintenance of lists is difficult or small area estimation by area sampling has been poorly done (Craig and Atkinson, 2013). Hence, area frames and list frames are sometimes combined to address these issues. Area frame sampling is used in several countries including the United States National Agricultural Statistics Service (NASS). In Europe, the LUCAS survey, carried out by EUROSTAT and the European Commission Joint Research Center (JRC), employs a point system sampling approach for land cover area estimation. The system is called the Land Use/Cover Area Frame Statistical survey (LUCAS), and is used to estimate areas and change over time of land cover more generally, among other uses (Gallego and Delincé, 2010). Additionally, Kerdiles et al. (2014)

estimated areas of cropland in North Korea by using a similar system, with a systematic sample of points stratified by slope that were interpreted using very high resolution satellite imagery (e.g. from Google Earth). From these sample points, the authors at the JRC were able to estimate the area of cropland in hectares for different slope strata along with the standard error and coefficient of variation. Following the methodology outlined in Kerdiles et al. (2014), LACO-Wiki will automatically estimate an indicative number of sample points required to calculate the crop area with a user-specified level of confidence. In the current paper, we will demonstrate how the system works on area estimation of wetland rice in Madagascar. Additionally, and following good practice recommendations (Olofsson *et al*, 2014), LACO-Wiki allows users control and transparency at each step as well as producing several measures of accuracy and uncertainty.

The next section provides an overview of the LACO-Wiki system and the methodology behind the extension of the functionality for area estimation. Some remarks on the openness and applicability of the tool conclude the paper. It should be noted that the most usual metrics for validating a land cover map also apply to area estimation problems. For example, computing the omission error for a given class is equivalent to estimating the area that should have been classified as that class, but has been allocated to a different one.

2. Tool description and methods

LACO-Wiki can be accessed online at http://laco-wiki.net. For first time users, a brief user registration is required via Geo-Wiki; alternatively, users can log in using their Google+ or Facebook accounts. Once inside the tool, a sequence of 4 + 1 steps can be performed. The four initial steps are sequential but can be revisited at any time.

The first step consists of uploading a map in either vector or raster format (Figure 1). The currently accepted formats are shape files and GeoTIFFs in a WGS84 or ETRS89 LAEA projection. Once a map has been uploaded, the legend can be customized for on-screen display. The system allows users to upload ancillary datasets (RGB images in the supported projections) that could be of use in the validation process.

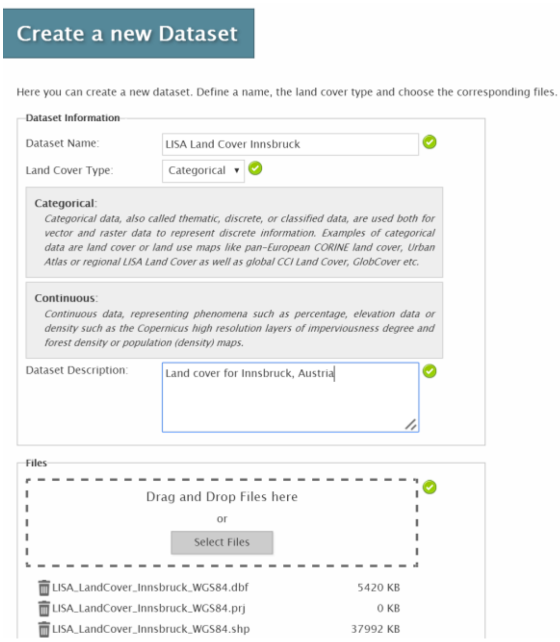

Figure 1. Step 1 – Example showing uploading of a vector dataset

The second step is the generation of a validation sample set (Figure 2). Here users can choose between completely random and stratified random samples for raster data and completely randomized for vector data. In the future, stratified random sampling for vector will be added along with systematic sampling for both types of data sources. The samples can be point, pixel (resolution-dependent) or geometric features (i.e. segments) depending on the type of map that has been uploaded and which sampling method has been chosen. Alternatively, in the near future, a validation sample set created in a previous session or generated in a different tool could be uploaded and used.

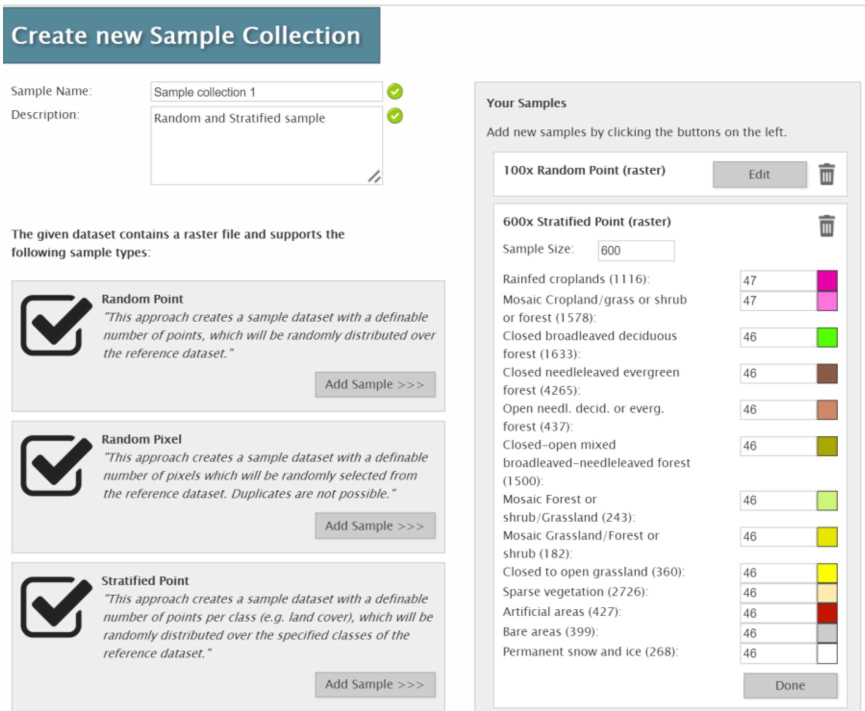

Figure 2. Step 2 – Selection of sampling methods for validation

The third step is the map validation or sample interpretation. With the use of reference data including satellite and aerial imagery from Google and Bing and a feature layer from OpenStreetMap, samples produced during the previous step can be validated. Users can employ the previously defined legends and the validation can be done in two ways: 1) Blind validation, where users interpret the reference data and then decide to which of the available land cover-land use classes the selected sample point, pixel or segment belongs or 2) plausibility validation, where users decide whether the land cover-land use class associated with the point or area of interest is correct or not (Figure 3). In both cases where a segment contains more than one land cover, dominance or majority of one is the deciding factor. In the future a third validation option will be added, called enhanced plausibility, which will allow users to correct the land cover-land use class if they think it is incorrect.

Figure 3. Step 3 – Plausibility validation using reference satellite and aerial imagery

The fourth step is the quality assessment and report generation. Here users can select what accuracy measures they want calculated including user, producer and overall accuracy but also Average Mutual Information (AMI) (Finn, 1993), quantity and allocation disagreement (Pontius and Millones, 2011), kappa (Congalton and Green, 2009) and Portmanteau accuracy (Comber *et al.*, 2012). An excel report is created that includes all this information. It is also possible to download the confusion matrix and the raw data.

More recently, we have been extending the LACO-Wiki tool by adding an additional piece of information and an iterative process as shown in Figure 4.

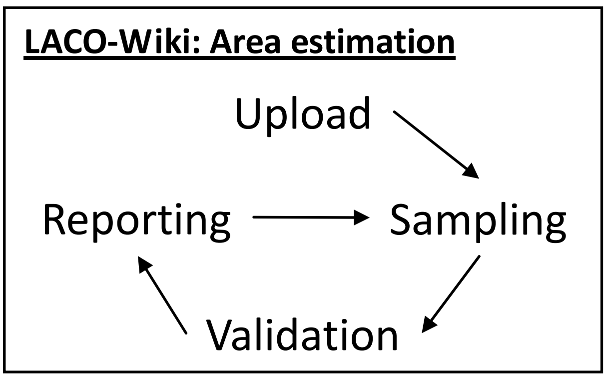

Figure 4. LACO-Wiki iterative process allowing re-sampling after obtaining area estimates reports

The iterative process allows for two-step sampling. The first report produced will include an initial estimation of the area A_c corresponding to each class *c* (e.g. overall cropland) computed by simply multiplying the total map area *A* with the proportion p_c of points classified as *c*.

$$A_c = A\, p_c \qquad \text{with variance} \qquad V(A_c) = A^2 \frac{p_c(1-p_c)}{n-1} \tag{1}$$

If we have a stratification, the estimates are:

$$A_c = \sum_h A_{ch}\, p_{ch} \quad \text{with variance} \qquad V(A_c) = A_h^2 \sum_h \frac{p_{ch}(1-p_{ch})}{n_h - 1} \tag{2}$$

and a coefficient of variation $CV(A_c) = sqrt(V(A_c))/A_c$ usually expressed in percentage.

In general, when a stratification is used for the first time, the available information is not enough to apply the usual Neyman rule for optimal allocation of a sample among strata (Cochran, 1977). A good strategy in this case is allocating half of the foreseen sample in a "reasonable" but subjective way, and applying a more formal optimal allocation to the rest of the sample at a later stage. The "reasonable" allocation applied by LACO Wiki will be based on coarse indications provided by the user on the possible values of p_{ch}. The user is asked about the possible proportion of class c in stratum h suggesting some values: (0, 10%, 20%, 50%, and 80%) and giving the option to provide a user defined value. The user is warned to choose "0" only if they are sure that p_{ch} is negligible. LACO-Wiki will propose a sample per stratum:

$$n_h^* = k^* A_h\, \dot{p}_{ch}(1-\dot{p}_{ch}) \qquad \text{where} \qquad k^* = n^* \frac{A_h\, \dot{p}_{ch}(1-\dot{p}_{ch})}{\sum_h A_h\, \dot{p}_{ch}(1-\dot{p}_{ch})} \tag{3}$$

This first lot allows better tuning the proportions per stratum, obtaining $\ddot{p}_{ch} = n_{ch}^* / n_h^*$ where n_{ch}^* represents the number of points interpreted as belonging to class *c* in stratum *h* in the initial sample.

Now we can make a better allocation of the overall sample of size *n*, provisionally provided by the user:

$$n_h = k A_h\, \ddot{p}_{ch}(1-\ddot{p}_{ch}) \qquad \text{where} \qquad k = n \frac{A_h\, \ddot{p}_{ch}(1-\ddot{p}_{ch})}{\sum_h A_h\, \ddot{p}_{ch}(1-\ddot{p}_{ch})} \tag{4}$$

The additional sample in each stratum will be $n_h - n_h^*$. If the initial selected values for $\dot{p}_{ch}$ were not adequate (i.e. not reflecting actual field conditions), it may happen that $n_h - n_h^* < 0$ for a given stratum. This will lead to an overall sample size slightly larger than foreseen and the user will be warned. The user will be also informed of the foreseen coefficient of variation CV computed by applying formulae (2) with the proportions $\ddot{p}_{ch}$ computed with the initial sample. The user will be asked if the foreseen accuracy and sample size are satisfactory. Otherwise a new value of *n* will be requested and the foreseen CV computed again until an acceptable trade-off is reached. A sequential approach to tuning the sample size and the accuracy is also possible (Carfagna and Marzialetti, 2009), but not implemented at the moment in LACO-Wiki.

For the classes where more samples are required, the system will randomly allocate them to each stratum and steps 3 and 4 would proceed as described earlier, producing a new validation and a report of accuracy and area estimates. If a pre-selected sample has been loaded in step 2, LACO-Wiki will then use this sample and the classification/validation done in step 3 to estimate the area. The results of the area estimation step will be displayed in the report produced in step 4. The system is iterative in the sense that if users are not satisfied with the area estimates obtained or their variability at any stage in the process, they could decide to run a sampling campaign again using the updated variance estimates.

Direct crowdsourcing or team support is implemented in the system since all validation tasks can be shared with several users in order to distribute the work and achieve faster results.

3. Discussion and applicability

The system is currently being evaluated by Madagascan experts and local experts at IIASA as well as local students. An overall agreement between these interpreters will be done and presented at the conference to demonstrate and compare current capabilities of the system. An increase in the accuracy of the area estimated for wetland rice is expected.

This system can be applied to different land cover classes. The main conditions for its applicability are:

- The targeted land cover class can be reliably identified on VHR images. If we think of crops, this may only be true in the case of paddy rice and some permanent crops, such as olive trees or vineyards, but this strongly depends on the complexity of the agricultural landscape. It can be also applicable in many cases to the overall area of arable land, of permanent crops or cropland.
- The dates of the images in Google Earth and Bing are recent enough to accept that few changes have happened between the image date and the reference date. In any case, the estimation obtained is some type of average of the yearly areas of the different dates of the VHR images considered.

LACO-Wiki was designed as a very straight-forward tool allowing users to easily validate their land cover-land use map and estimate the per-class area. As an online independent platform, it allows users from anywhere in the world to achieve fast map validation results. The calculations shown in the tool and the reports produced are standardized and therefore allow for comparison against different methodologies or even between different samples generated using LACO-Wiki.

The essential advantage of the tool is that validation and area estimation can be done entirely without ground-truth information. This is particularly valuable where field campaigns might be prohibitively expensive or where the areas are inaccessible. Additionally, if local knowledge exists, it can be incorporated as an extra layer in the system and visualized simultaneously with the satellite imagery. This would allow the user to produce a more refined interpretation of what land cover or land use exists at a given location.

ABSTRACT

The annual survey on the Structure of Agricultural Holdings (SAH) collects information on agricultural areas for cultivation type, type and quantity of livestock, agricultural production, structure and amount of labour involved in the holding. In the present work we describe and evaluate the results of the selective editing strategy used to identify the influential values of the SAH main numeric continuous variables (reference year 2013).

Keywords: selective editing, influential error, agricultural census, data modelling

1. Introduction

The survey on Structure of Agricultural Holdings (SAH below) collects information on Italian farms about land by type of cultivation, type and amount of livestock, type of production, structure and amount of family and not family labour (ISTAT, 2001). For the first post-census survey (reference year 2013), a new procedure for checking and correcting data has been designed, which integrates different methods and tools for the detection and treatment of different types of non sampling errors in the data. In particular, this work focuses on the description of the selective editing strategy designed to detect the possibly influential errors for the main continuous numeric variables from the survey (farms agricultural surfaces, livestock and some productions).

Within each data editing and correction strategy involving companies (in this case, farms), it is usual to investigate which are the units potentially affected by errors having significant impact (and therefore potential biasing effect) on the final estimates of the main target variables (see for example EDIMBUS, 2007, or MEMOBUST, 2014). One class of particularly effective methods in this area is known as selective editing (Latouche *et al.*, 1992), in which the units potentially affected by influential errors are selected to ensure a more severe control (generally manual/interactive revision) of their nature/source aiming at reducing their potential biasing effect on the final estimates. In the case of the SAH, the selective editing method adopted for the identification of influential errors is based on the latent class contamination models proposed by Di Zio and Guarnera (2013) and implemented in the generalized package Selemix (Guarnera *et al.*, 2013).

The work is structured as follows. Section 2 contains a description of the main features of the overall data editing and correction procedure implemented for the SAH numeric variables. Section 3 contains a brief description of the selective editing methodology and the Selemix software. Section 4 shows the results of applying the method to the most important survey variables of the SAH 2013. In Section 5 the results and efficiency of selective editing process are evaluated. Section 6 contains some concluding remarks and future work perspectives.

2. SAH survey: the data editing and correction procedure

The SAH 2013 responds to EU Regulation No. 1166/2008 of the European Parliament and of the Council of 19 November 2008. It aims to systematically produce statistics on the structure of agricultural holdings and on agricultural production methods. For numeric continuous variables, the final estimates are totals at National and regional level. The theoretical sample of the SAH 2013 includes 42,723[1] companies (D'Orazio, 2013), with a reference population of 1,138,214 companies active in the Country (about 70% of the 1,620,844 recorded at 2010 6th Census of Agriculture). A distinctive feature of this edition of the SAH is that this is the first survey conducted after the 6th General Census of Agriculture, which has made it possible to use the census as an auxiliary source, in order to make more efficient the survey process and more accurate the final results.

The survey was conducted by using web electronic questionnaires. Multiple factors contribute to the complexity of the data editing and correction strategy: the high number of observed variables, their types (both categorical and continuous), the complex relationships (both structural and statistical/mathematical) existing between the variables. With regard to non sampling errors, it is necessary to point out that some of them (for example duplication, skip items, balance) are already identified at the data entry stage, where some consistency checks are carried out at the time of entering information. This strategy ensures more accurate data with respect to a basic set of controls. However, the incompleteness of the controls means that collected data may still remain in situations of non-acceptability or inconsistency, to be properly treated at the subsequent data editing and imputation (E&I) stage.

As known, an error that occurs during collecting or data entry can have both systematic or random nature: these errors can be identified when they entail logical/statistical/mathematical inconsistencies, anomalous values, influential values on the target estimates. In order to identify the various types of error that are potentially present in the target variables (surfaces, livestock and farm productions), a complex procedure of E&I has been carried out. Its main steps are:

[1] In order to meet the Regulation requirements for some domain of interest the number of sample units was increased adding 2.030 small units outside the target population of the SAH: this kind of units are out of the purpose of this paper. The total number of sample units contributing to the estimates keeping into account also events like farms merge or split is 44552.

1 error localization in the phase of identification of the statistical units and/or coverage (errors in identification codes, merge/split of farms compared to the census, membership to the target population,…). This phase will be referred to as pre-editing;

2 identification of possibly systematic errors (in particular unit measure errors) on the basis of a deterministic approach, in order to apply proper automatic corrections;

3 identification of influential errors, with a presumably random nature, through selective editing, for subsequent manual/interactive review;

4 identification and automatic correction of not influential errors, with a presumably random nature, on the basis of a probabilistic approach. In particular, a data-driven type method, implemented in software Diesis (Bruni *et al.*, 2002), has been used.

In the following, the focus will be on the second and third phases of the procedure.

3. The selective editing approach for the identification of influential errors

Let X be a continuous variable and θ a parameter to be estimated on the X's distribution. We define as influential with respect to θ those X values which are potentially affected by a measurement error and have a possibly biasing effect on the θ estimate. Given their statistical relevance, these values need an accurate verification, which is generally performed by manual/interactive revision by well-trained expert clerks. In order to reduce costs and time of such data treatments, they have to be limited to the most critical units. All the residual errors could be eliminated by using less costly automatic data editing procedures. The main objective of selective editing is actually to limit the most demanding activities of data editing (manual reviewing, re-contact, etc.) to those cases where the expected benefit in terms of costs reduction is highest (Lawrence *et al.*, 2000). A score function (Latouche *et al.*, 1992) is used to rank the observed units, so that observations with the highest score are supposed to contain the most potentially influential errors on the target estimates (in the case of the SAH, the variables' totals). A specific value for the score function (threshold) is set in advance, and the m units with score above the threshold are selected for manual editing, where m depends on the expected estimates accuracy. The latter generally corresponds to the allowed residual error on the estimates computed on the not edited data. Since usually the estimates of interest (e.g. totals) involve several variables, a different score function is computed for each variable (local score) and a unique global score is obtained by suitably combining local scores. The selective editing approach allows to reduce not only the overall cost of interactive editing, but also the over-editing effect (that is the resources spent to manually check non sampling errors having low biasing effect on the target parameters estimates).

Typically, the score functions are based on the comparison of the observed values of the target variable with the corresponding predicted values obtained through some (explicit or implicit) model, taking into account the possible sampling weights. A key issue with this approach is that errors tend to be identified with residuals with respect to the assumed model, so that it is difficult to separate the natural variability of the investigated phenomenon from the extra variability due to the presence of errors in data. Moreover, it is not obvious how to define the threshold determining how many units have to be selected for interactive editing. A recent approach (Di Zio *et al.*, 2013 and 2008) tries to overcome this difficulty by explicitly modelling both true (i.e. not contaminated) data and error mechanism. In particular, in order to capture the intermittent nature of the model, a two-component mixture model is used, where the components are naturally associated with error-free and contaminated data, respectively. In other words, errors are assumed to affect only a subset of data in such a way that each unit in the dataset is corrupted by an error with an (unknown) a priori probability. Based on the appropriate conditional distribution, for each observed value the corresponding predicted "true" value is obtained, and the error component is determined as the difference between the observed and the true variable values. In this way, the number of units to be selected for manual revision can be directly associated to the required accuracy for the target estimates. It has to be underlined that the estimation of contamination models can be performed taking into account an appropriate stratification of the population units, that can be different by that one underlying the estimation domains (reference data partitions at the influential errors identification step). In practice, often the estimation domains correspond to a more detailed data partition with respect to the data stratification adopted at the contamination model estimation stage: this depends on the fact that in order to obtain "robust" and reliable estimates, a suitably large number of sampling units is needed in each strata. The described method is implemented in the R package SeleMix (SELEctive editing via MIXture models) available on the website http://www.R-project.org (Guarnera *et al.*, 2013). This package includes functions for the estimation of the model parameters via EM algorithm, computation of prediction of true values conditional on observed values, prioritization of units for interactive editing according to a user-specified threshold. If the analysis is performed on sample surveys, in order to select the most influential errors SeleMix uses the sampling weights. Missing values in the response contaminated variables are allowed. In this case SeleMix can also be used as a tool for (robust) imputation of incomplete data. The covariates included in the model are supposed to be error-free and not affected by non-response, therefore the efficiency of this approach also depends on the reliability of the available auxiliary information.

4. The selective editing procedure for the SAH

The aim of the selective editing approach implemented for the 2013 SAH survey was the identification of the potentially influential errors affecting a subset of key survey variables on firm surface (*Total Agricultural Surface, Utilized Agricultural Surface, Actually Irrigated Surface*) and livestock (*Total Number of Cattles, Total Number of Equines, Total Number of Cattle "Bufale", Total Number of Sheep, Total Number of Goats, Total Number of Pigs, Total Number of Rabbits*), Production of milk. For surface and livestock variables, auxiliary information from the 6th Census of Agriculture (reference year 2011) is available. However, no census information is available on milk produced by dairy cows, sheep and goats. Out of the 42.723 firms included in the SAH theoretical sample, the selective editing models have been applied to the subset of 38.330 respondents which resulted correctly identified (also in a longitudinal perspective) at the *pre-editing* stage[2]. Based on exploratory data analyses and the direct support of area experts, we defined: the contamination model at regional level, the approach to be adopted in order to predict the "true" values (model-based values vs census variable values), and the threshold on the target estimates accuracy. In particular, the choice of the contamination model for each single target variable as well as the specific auxiliary information to be used have been mainly based on the amount of available observed information and on the data characteristics (e.g., high rates of zero values in variables' distributions).

Before applying the selective editing strategy, some preliminary analysis and editing activities have been performed on the data in order to identify and possibly eliminate the systematic and/or measurement errors affecting the target variables. Different latent-class regression models have been developed for the different variables subject to selective editing (*Total and Utilized*

[2] Responding firms consistent with respect to Census units, e.g. splitted units are properly reconstructed in order to match with the Census generating units.

Agricultural Surface, Livestock, Produced Milk, Total Irrigated Surface), using as auxiliary information, when appropriate, the corresponding items observed at the Census of Agriculture and possible related survey variables. As some of the target variables (i.e., *Total and Utilized Agricultural Surface*) are observed in more than one item in the survey questionnaire, all the available information is simultaneously used in the corresponding estimated models. As mentioned, depending on the considered variables, the auxiliary information from the 2010 Census of Agriculture perform differently in terms of accuracy of predictions: i.e., the census provides good auxiliary information for the agricultural surfaces, on the contrary for variables related to the production of milk no reliable information is available from the census, therefore information from the survey itself has been used in order to exploit existing relations among variables for editing purposes. For each target variable, different stratifications are used at the model estimation and at the influential data identification steps, in order to guarantee the robustness of model estimates in each stratum and the efficient identification of influential errors at the most appropriate publication domains. Furthermore, different thresholds have been set for each target variable to properly tailor the balance between the expected estimates accuracy and the costs for manual revisions.

In Table 1, the number of observations identified as influential by variable and by region, is reported. As an example, 183 observations have been selected as influential for the variable Utilized Agricultural Surface (SAU2) and 129 ones for the variable Total Agricultural Surface (SAT2) (about 0.5% and 0.3% of the sample units, respectively): about 250 agricultural firms will have to be manually checked in this case, as there is an overlap of about 80 units in the two sets of potentially influential observations. In general, for the most part of the considered variables, the results highlight a not uniform distribution of potential influential errors in the Italian Regions: this suggests the need of most accurate preliminary data analyses aiming at identifying potential lacks or systematic sources of errors at the data collection and/or at the data entry stages.

5. Evaluation of the selective editing process

In this section the evaluation of the selective editing process with respect to the SAU2 and SAT2 variables is reported. Tables 2 and 3 show, respectively for SAU2 and SAT2, the number of: collected data (A), data corrected (imputed) through automatic or interactive editing procedures (B), data reported as influential (C) and, among them, corrected data using interactive editing (D), by Italian region. Moreover, Tables 2 and 3 show the following percentages:

- imputation rate (B/A): number of corrected information out of the number of collected data,
- rate of influential errors (C/A): number of data reported as influential out of the number of collected data,
- imputation rate by influential errors (D/B): number of data reported as influential and interactively corrected out of the total number of correct data,
- hit rate (D/C): number of data reported as influential and corrected by means of interactive editing out of the total number of data reported as influential.

Table 2 shows that out of the 44,552 SAU2 observed values in the final dataset, 97.18% is not corrected. Complementarily, the imputation rate is 2.82%, while the percentage of cases reported as 'influential' is 0.41% (183 units). Out of these units, only 20 (hit rate = 10.93%) were classified as errors and corrected. For SAT2 (see Table 3), similarly, the 96.53% of the observations is not subject to any correction. The proportion of units reported as 'influential' is 12.29% (129 cases). Out of these, only 24 (hit rate = 18.60%) were classified as errors and corrected.

Trentino-Alto Adige-Bolzano	808	27	7	1	3.34	0.87	3.70	14.29
Total	44552	1547	129	24	3.47	0.29	1.55	18.60

The differences between SAU2 and SAT2 variables are higher for the total number of corrections, than for the number of corrected influential cases. The hit rate values (10.93% and 18.60% for SAU2 and SAT2, respectively) can be interpreted as a measure of 'efficiency' of the procedure adopted in identifying, among the influential cases, actual errors. The low values of the index may be due to the fact that in the estimated models it was considered as auxiliary variable the information (measured in the census) of three years before the survey, so with low predictive power, and that this information could have quality defects. The imputation rate for influential errors exceeds 10% only in Valle d'Aosta and Molise, probably because of the low number of total cases. In Trento, there is only one reported unit as a possible influential outlier.

As a further element of evaluation, Table 4 shows, respectively for variable SAU2 and SAT2, the relative differences between the estimates calculated on the following sets of data: before the E&I phase (Raw), after the step of interactive revision of the influential errors (Semi final), and at the end of the entire process of E&I (Final). The estimates are computed using sample weights adjusted for non-response. In other words, Table 4 shows the impact on estimates obtained using Raw data of the corrections made on the only influential data and of the total corrections, respectively. The impact is measured on total estimates and, therefore, there could be possible compensations for different sign of the data corrections. Out of the (National) Total estimate, the corrections involve a change of less than one percent of the estimate using raw data.

Table 4: *Relative differences between estimates computed using different data, SAU2 and SAT2 variables*

Region	(Semi final-raw)/Raw (%)	(Final-Raw)/Raw (%)
Total SAU2	0.03	0.98
Total SAT2	-0.04	0.09

To better evaluate the impact of the corrections on the data reported as influential, Table 5 shows the sum and the average of the absolute differences between the data flagged as influential and corrected and the relative raw data in comparison with the same measures of the absolute differences between the corrected data but not reported as influential and the raw data. The corrections on the influential data are larger than those on non-influential data: 1.23 times for SAU2 variable and 2.8 times for the SAT2 variable. This underlines the capacity of the selective editing procedure to identify the most influential errors on the final estimates.

Table 5: *Sum and average of the absolute differences, SAU2 and SAT2 variables*

Variabile	Somma	N	Media	A Media/B Media % C Media/D Media %
A. SAU2 |Influent corrected– Raw|	402342	20	20117	
B. SAU2 |Not Influent corrected – Raw|	20179311	1236	16326	123
C. SAT2 |Influent corrected – Raw|	2104088	24	87670	
D. SAT2 |Not Influent corrected – Raw|	47493823	1523	31184	281

6. Conclusions

The aim of the selective editing approach implemented for the 2013 SAH survey was the identification of the potentially influential errors affecting the estimates of a subset of key survey variables to be subjected to a clerical review. For the 2013 SAH, the set of variables considered for the selective editing procedure includes total firm surfaces and livestock, and the auxiliary information is the same set of variables observed at the 2010 6th Census of Agriculture.

The obtained results differ when dealing with surfaces and livestock. Indeed, the variables relative to the total surface of a firm are more stable over the time and generally grant a relevant number of observations. This allowed to apply the selective editing procedure to quite detailed domains of estimates given by the combination of the variables (Region and OTE). The number of influential units to be subject to clerical checks results to be ‘adequate according to the available resources. As far as the livestock is concerned, observed figures changes easily over time. Consequently, the effectiveness of the 2010 6th Census of Agriculture as a source of auxiliary information resulted lower for livestock variables than for surfaces variables. This has probably led to identify a number of 'influential' cases higher than expected and/or desired for the purpose of containment of the interactive control, despite a careful definition of diversified thresholds for different animal types. Also the information on milk production, naturally depending from livestock numbers, has been affected by this instability. Moreover, the concentration of influential cases in some regions for some variables led to hypothesize the presence of systematic factors on the results. Further experiments are therefore needed in order to check on the one hand the effectiveness of the models and of the covariates used for this type of variables, on the other hand the existence of additional and more updated sources of auxiliary information. The assessment of the effects of selective editing procedure was focused on SAU2 and SAT2 variables. The share of cases reported as influential and actually corresponding to errors proved to be quite low. Nevertheless, the average number of identified errors is significantly higher for the cases reported to be influential than for the overall average of correct observations.

Overall, the selective editing process has produced satisfactory results, but its efficacy was lower than expected probably because of both the nature of the data and the absence of auxiliary information with a suitable quality. In subsequent editions of the survey, the use of alternative auxiliary information (other administrative sources, data from the current survey in a longitudinal perspective) will be evaluated. As far as the selective editing procedure is concerned, both a multivariate strategy for modeling data and the use of different thresholds of the estimates of accuracy on individual domains will be analysed. Finally, the results of the present work, will be used to plan the future survey edition with respect to the various phases of the entire process (for example, data recording) to identify and prevent any systematic error causes on the main variables.

ABSTRACT

Assessing the field level impact of Emerging Infectious Disease outbreaks such as the recentEbola virus disease (EVD) on agriculture and food security is challenging because such epidemics restrict access to farms and households, limiting the traditional means of direct measurements and field surveys. Therefore, a simulation model is developed and used to assess the impact of EVD outbreak on the 2014 agricultural production in Guinea, Liberia and Sierra Leone. Model results show that the impact of of EVD on the 2014 agricultural production was relatively small at the national level. However, it is significant at the sub-national level in affected areas. Furthermore, the impact on economic activities and livelihoods severely affected household food security in the main affected areas.

Keywords: Emerging Infectious Disease outbreak, Ebola, agriculture, simulation model, West Africa.

1. Introduction

Emerging infectious diseases (EIDs) are increasing in frequency, posinga significant threatto global economies and public health (Jones, K et al 2008;Pike, J. et al). Joneset al. (2008) found that EID events aredominated by zoonoses (60.3% of EIDs) with the majority of them (71.8%) originating in wildlife, for example, severe acute respiratory virus and Ebola virus. Infectious diseases account for a quarter to a third of all mortality and the outbreakscan easily cross borders and threaten economic and regional stability, as has been demonstrated in last decadeby HIV/AIDS, 2009 H1N1 influenza, H5N1, and SARS epidemics and pandemics as well as the recent Ebola outbreak (Verikioset al. 2011).

EIDs can be classified in two broad categories based on the nature of the outbreak and the main channel of impact. Estimates of the economic cost of outbreaks of the first category follow the standard “cost of illness” approach that focuses on the opportunity cost of resources consumed or lost as a result of disease. One example of such pandemic is HIV-AIDS, the economic cost of which arises mostly from the high mortality and illness caused by the pandemic. By contrast, outbreaks of the second category cause relatively little illness and death but short-lived and severe economic impact, driven essentially by the behavioral effects of these outbreaks. The last outbreak of Severe Acute Respiratory Syndrome (SARS) in 2003, the 1994 plague outbreak in Surat, India, or the 2014 Ebola outbreak in West Africa , fall in this category(Brahmbhatt, M;&Dutta, A; 2008). The SARS outbreak caused significant disruption and economic loss worldwide, and is estimated to have reduced worldwide GDP by USD 40 billion in 2003 (McKibbin, 2004). Similarly, the overall economic loss associated with the 1994 plague outbreak in Surat, India, were put at over USD 2 billion. According to the World Bank, the last Ebola virus disease (EVD) outbreak in West Africa caused GDP growth to fall drastically to 0.5 percent in Guinea from 4.5 percent expected before the Ebola crisis. Similarly, GDP growth fell by more than half, from 5.9 percent to 2.2 percent in Liberia and from 11.3 percent to 4.0 percent in Sierra Leone. The EVD outbreak caused severe disruptions that affect all economic sectors, notably the agricultural and food sector.Avian influenza outbreaks also cause serious disruptions to various economic sectors but the principal impact has occurred in the poultry sector. HPAI of the H5N1 strain has inflicted severe direct economist costs to affected countries, mostly in terms of losses of poultry due to the disease and control measures such as culling birds, with impacts extending not only to farmers but also to upstream and downstream sectors such as poultry traders, feed mills, breeding farms etc. Vietnam and Thailand lost about 15% of the stock of poultry (Brahmbhatt, 2005). The major affected South-East Asian economies have seen direct costs, in the region of 140 million birds culled and the stated costs of containing the epidemic of approximately USD 10 billion. In addition, trade restrictions led to a 36.8 percent decline in South-East Asian poultry trade (World Bank, 2005; Elci, 2006).

Recent years have seen a renewed interest in the analysis of the economic impact of EIDs. In the case of SARS for example, analyses have focused on the macro-economic impact including on GDPs, trade and Government budget, and most studies have highlighted the impact on sectors such as health, tourism, hotels, airlines, IT, etc(Keogh-Brown, M. R.&Smith, R. D.; 2008).Most analysis of the impact of EIDs on the agricultural sector has focused on describing changes in production and other parameters before and after the outbreak. For example, FAO conducted a number of studies on the impact ofHIV-AIDS on the agricultural sector (FAO, 2003), which found that the main channel of impact has been through loss of labour, which affects planted areas and yields resulting in reduced food production and resulting food insecurity.For example, in Zimbabwe, according to surveys conducted in 1997, agricultural output in communal areas declined by nearly 50% among households affected by AIDS in relation to households not affected by AIDS. A similar approach was used by Yalcin et al (2010) to analyze the impact of the highly pathogenic avian influenza H5N1 outbreak among turkey producers.

In case of an EID outbreak with potential serious impact on the agricultural sector, such as the recent Ebola virus disease (EVD) outbreak in West Africa, there is a need during the epidemic to provide an accurate ex-ante assessment of the impact of the outbreak on agriculture, livelihoods and food security, to support the design of effective emergency relief and rehabilitation programmes to minimize the impact of the outbreak on affected populations. However, assessing the impact of EID outbreaks such as Ebola on agriculture is challenging because the disease restricts access to farms and households, limiting the possibility to conduct direct measurements and carrying out interviews.

The purpose of this article is to outline a methodology for assessing the impact of Ebola on agricultural production. Asimulation model, the Disease Impact on Agriculture – Simulation (DIAS) model was used during the last Ebola outbreak in West Africa to quantify its impact on cereal production in Guinea, Liberia and Sierra-Leone. A limited amount of field survey information, where available, was used to fine tune and improve the model accuracy.

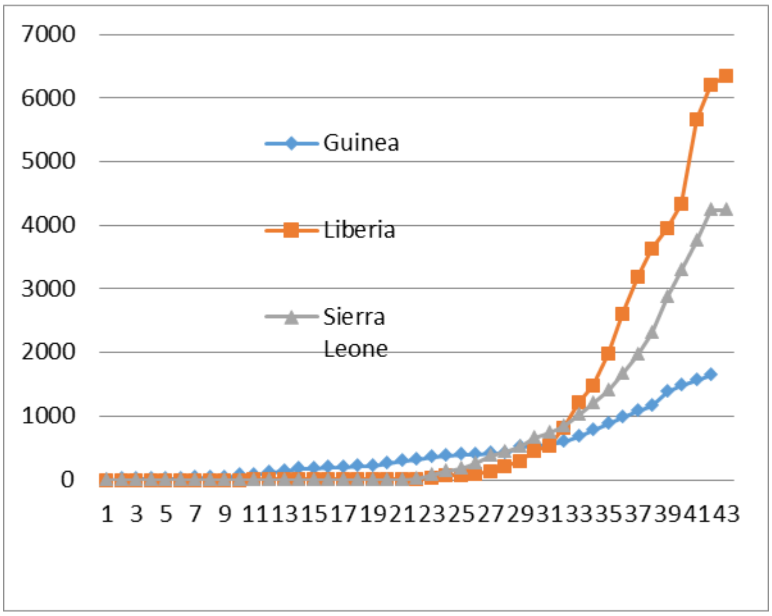
The reminder of paper is organized as follows: section 2sets out the channel of impact of EVD on agricultural production; section 3 outlines the methodology and the data used;section 4 presents and discusses the results. Finally, section 5summarizes the main conclusions.

2. Ebola virus disease (EVD) outbreak and agriculture

As outlined by the World Bank (2014), the impact of the Ebola epidemic on economic well-being operates through two distinct channels. First, there are the direct and indirect financial and human costs of the disease. Second, there are the behavioral effects resulting from peoples' fear of contagion, which leads to a series of disruptive actions and decisions by the population and public actors. These behavioral actions reduce labourforce participation and disrupt several economic sectors including transportation and trade. In the case of recent infectious disease outbreaks such as the SARS epidemic of 2002-2004 and the H1N1 flu epidemic of 2009, behavioral effects have been responsible for as much as 80 or 90 percent of the total economic impact of the epidemic (The World Bank 2014).

The last EVD outbreak in West Africa started in Guinea in December 2013, escalated the fastest in Liberia in early 2014 (see figure 1) and led to a sharp disruption of economic activities. The number of cases in Guinea were high during early part of the outbreak but remained relatively low during later part of the outbreak. In Liberia and Sierra Leone it led to the quarantining of the most affected regions, restrictions of internal population movement, as well as closure of markets. According to the figures from the World Health Organization (WHO), a total of 28 616 confirmed, probable and suspected cases were reported in Guinea, Liberia and Sierra Leone, with 11 310 deaths. The Public Health Emergency of International Concern (PHEIC) related to the outbreak was lifted in March 2016.

Figure1 : Evolution of the EVD crisis: number of cases as of December 2014



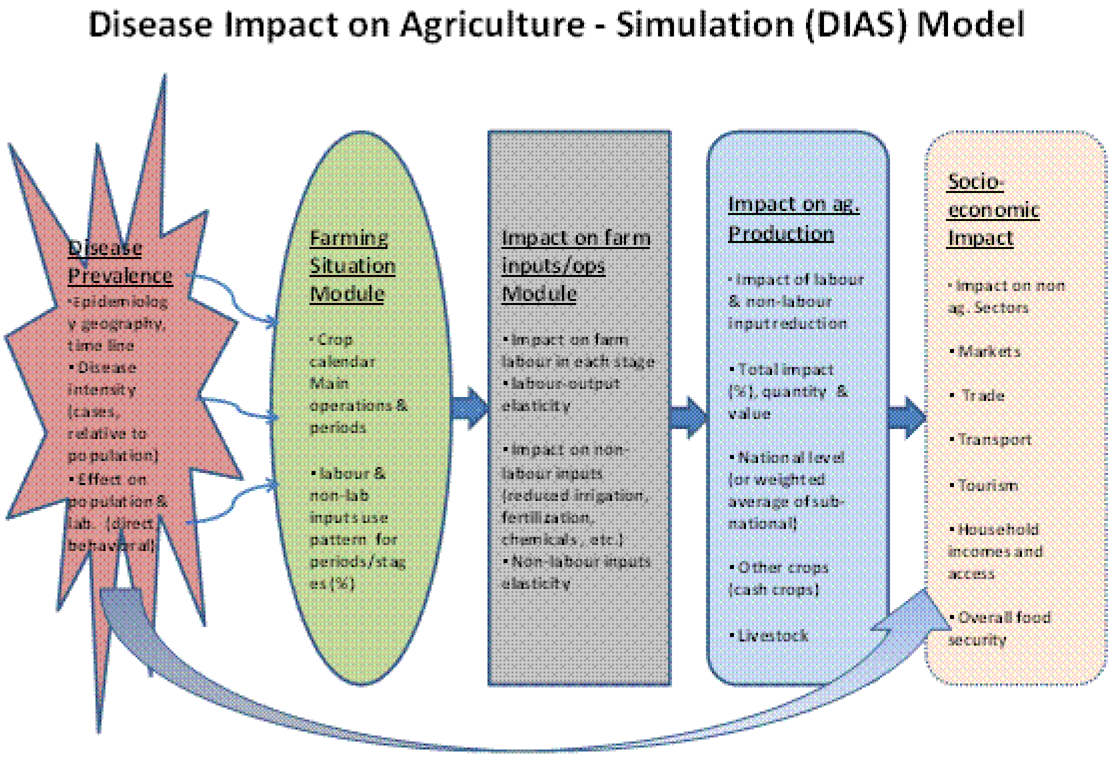
Rice is by far the most significant crop and it is grown on between 80-90 percent of all cereal-cropped area in the three most affected countries; it is virtually the only cereal grown in Liberia. Other food crops include cassava (in all three countries) and maize (in Liberia and Sierra Leone). In addition, the three countries grow cash crops, particularly cacao beans, coffee and rubber, which make up the bulk of their agricultural exports. In general, the EVD epidemic started to spread when crops were being planted and grew during the crop maintenance period, and then expanded rapidly during the critical harvesting period for the staple rice, maize and cassava crops.Farm operations, inputs and then harvestingwere affected in two ways. The main impact was seenthrough reduction in farm labour due mostly to aversion behaviors such as quarantines, border closures, restrictions/ban on people movement, people fleeing infected areas, reluctance to work in usual labour groups, etc. The disrupted/reduced farm labour affected land preparation/planting, crop maintenance/growth (weeding, fencing, application of chemicals, etc.), and harvesting. Secondly, through the labour associated non-labour inputs - reduced use of material inputs such as applied quantities of fertilizer, irrigation, chemicals, etc. Depending on their use and the relative impact these changes affect crop output.

3. Simulating the impact of EVD on crop production: the EVD Disease Impact on Agriculture – Simulation (DIAS) Model.

Quantitatively, the direct impact in terms of the number people infected in relation to the size of the population of the area is extremely small. Much of the impact observed has been of the behavioural type. The development of the DIAS model includes the following steps: (i) converting the relative cases of EVD infection into the impact on farm labour using a logistic function representing the S-Curve, (ii) assigning the labor use pattern and the labour associated non-labor inputs use pattern to each of the three major periods of crop production, (iii) establishingthe elasticity of labour and non-labor inputs and (iv) aggregating the impact of labor and non-labor input changes over different periods of crop production.

The most important component of the methodology is the use of the S-curve to quantify the impact of EVD on farm labour.

Figure 2: Schematic of EVD Impact on Agricultural Production Simulation



3.1. Using a logistic function (S curve) to calculate percentages of impact

Using a logistic function representing the S-Curve, the actual cases per 100 000 were converted to a percentage of population (and thereby farm labour) that may be considered affected. This follows a logic that as the number of cases of infection rise the impact is low at low number of cases but rises rapidly and then flattens out at some point. The formula adapted here is the following[1]:

I = f (X) = S/(1+K^(T+V/2-X)/V))

Where,

I = the percent impact on population (and by extension on labour) for a given value of X.

X = Variable X represents the number of relative cases of Ebola disease, for example per 100 000 of population.

S = Saturation point (maximum potential impact in % of labour disrupted completely, asymptotic limit of the S curve). An arbitrarily chosen value of 1/3 (or 33%) is used here.

[1] Modified from the following presentation of the S-curve:https://akapps.wordpress.com/2011/08/27/simple-s-curve/

.

Past studies on HIV infection rates have shown that the saturation points occurred at 39% for Botswana, 33.4 % for Swaziland and 31 % for Lesotho(see Whiteside & Erskine, 2002). A mobile phone survey carried out by the World Bank, with the Liberian Institute of Statistics and Geo-Information Services and the Gallup Organization, in October and November 2014, concluded that " ... 30 percent of respondents indicated that they were no longer working in agriculture compared to the baseline HIES. The majority cited worries about Ebola as the main reason they were not working.".

K = A constant used as a base for the exponential calculations (similar to log to the base 10 or the natural log to base e). It is set equal to 81 as in the original market study. In general, the smaller value of this constant, flatter the s-curve.

T = takeoff point; where on a severity scale of the infections the hyper growth in impact starts. The relative cases of infection at which the curve takes off and rises rapidly. The arbitrarily chosen value of 5 implies that when 500 cases are reported in a nation of 10 million people it will start having a significant general panic and the behavioral impact on population.

V = takeover level; it represents the number of relative cases when almost 90% of the impact is felt, for example at 100 in this case. Thus the steep rise of the curve is experienced between 5 and 100 relative cases.

Labour requirement varies depending on crop development stages. Rice being the predominant crop, the rice crop calendar was used as the main agricultural calendar. To accurately assess the impact of labour shortages at three different crop development stages, the crop calendar that covers about 9 months, was divided into three 3-month periods corresponding to land preparation/planting, growing/maintenance and harvesting in accordance to FAO/GIEWS crop calendar.

Figure 3: FAO/GIEWS average food crop calendar

WFP-compiled WHO data was used to input the cumulative cases. The first cases of EVD were reported in Guinea and Liberia in March 2014 and in Sierra-Leone in May 2014, but Liberia has been the hardest hit country (see figure 1). In Liberia, the incidence was later but steeper, affecting rice growing (labour and other inputs) and harvesting period; In Guinea, cases remained low through growing and harvesting period. Assuming a certain incubation period length of the EVD, the representative cases for each period were taken from the end of that period, i.e. the cumulative number of cases as of the last week in June, September and December for the three periods, respectively. To get the relative impact of the disease, the cases were expressed as per 100,000 people.

3.2. Assigning the labor use pattern to each period of crop production and simulating the impact of labor use reduction

Elasticities are important assumptions that affect simulation results.Hence, the second most critical set of information is about farm input elasticies and input use patterns. Based on relevant literature for various countries of West Africa (Olumbanjo, O and Oyebano, 2005; Kapsos, 2005; Vollrath D, 2009; Olujenyo, 2004), the labor elasticity for rice was set at 0.5 for the three countries.Labour elasticities for maize and cassava were set at 0.47 and 0.3, respectively.

According to Ngeleza et al (2011), the labor use pattern for rice is as follows: 38% of labour is used during land preparation and planting; 38% used during crop growth and 23% in harvesting. Requirement for cassava is typically 28% , 46% and 26% for these respective crop cycle periods. Using these rates of monthly labour use per operation, total labour use per three-month period from April-December was calculated. The labor use pattern for Maize is 59% 35% and 6% respectively.

In addition, the reduction in farm labour would also reduce the use of other non-labour material inputs such as fertilizer, chemicals, irrigation, etc. It is assumed that non-labor inputs such as fertilizer, other chemicals, irrigation etc. are applied during planting and crop growth periodsfor rice and maize. Thus weights of 50:50:0 areselected for the three periods as the pattern of their use during these three periods. Cassava production does not involve much use of these other inputs, hence only labour impact is calculated.

For simplicity the model groups all inputs into two, labor and non-labor. Using the implicit constant unitary elasticity of production such as the one used in the Cobb-Douglas production function, the sum of all input elasticities is assumed to be equal to 1. Given that we already have the labor elasticity value, the non-labor elasticity is simply calculated as one minus the labor elasticity. The elasticity is then applied accordingly to step 6.

Finally the impact of reduction in labour and non-labour, is calculated using their use patter and elasticities and summed across the three periods to get the final impact on crop production.

4. Results

The impact of Ebola was simulated at county or district level for each country and then aggregated at national level. Table 1 shows the aggregated simulation results at country level. Detailed results atcounty or district levels are shown in annex. As expected, rice was the most affected commodity due to its higher labour and inputs requirement. However, the impact on production was not as catastrophic as envisaged at the time of the outbreak. In Liberia, the most severely affected country, rice production is estimated to have declined by 12 percent from the without Ebola scenario (see Table 1). Output dropped by 7 percent and 4 percent in

Sierra Leone and Guinea, respectively. The relatively high level of impact in Liberia as compared to the other two countries affected by EVD, namely Guinea and Sierra Leone, is primarily due to the much higher intensity of the disease transmission. The infections grew rapidly during the crop growth and harvesting periods of the crop cycle. The sub-national level impact is even much higher in the counties hit hard by the disease, such as Lofa and Margibi in Liberia, where losses of paddy crop are estimated in the order of 20 percent and three others, Bomi, Bong, Monte Serrado, above national average. The simulated impact on maize was lower: maize production was estimated to decline by 3 percent and 4 percent in Sierra-Leone and Guinea, respectively.

Similarly, cassava being much less labour and input intensive crop than cereals, the impact on its harvest is estimated to be lower at 5 percent and 1 percent at the national level in Liberia and Guinea, respectively. In Liberia, cassava losses ranged from 1 percent in Grand Gadeh county to over 7 percent in Lofa and Margibi counties. It should be noted, however, that cassava roots can remain under ground and can be harvested as and when needed, hence the reduced harvest this year should not, necessarily be equated with the potential production of the commodity.

Table1: simulation results:

Country	Simulation Model
	Rice
Guinea	-4%
Liberia	-12%
Sierra Leone	-7%
	Maize
Guinea	-3%
Sierra Leone	-4.2%
	Cassava
Guinea	-1%
Liberia	-5%

In parallel to the modelling exercise, FAO and WFP, in collaboration with the Governmentsof Liberia, Guinea and Sierra-Leoneand other partners have carried out field level rapid assessments (RA) including surveys using questionnaires to analyse the impact of the EVD crisis on food production, supply situation and the overall food security. Results from theserapid assessments have largely confirmed the simulation results: For example, results from the Liberian field assessment indicated that rice production would decline by 10-15 percent at national level and up to 25 percent in hardest hit regions. Similarly, field assessments conducted in Guinea estimated a 3.4 percent decline in maize production and a 1 percent drop in maize harvest.

Other economic indicators confirmed that the impact of the EVD outbreak on national food harvest was not catastrophic. For example, price of imported and local food prices remained mostly stable at relatively low levels in all three countries, indicating that supplies were adequate.

The model produces results of with Ebola situation compared to without Ebola situation. These estimates are useful to indicate the extent of potential losses of agricultural production due to the crisis and can serve as a guide for the type of and the areas for response interventions.

5. Conclusions

The analysis presented in this paper suggests that the impact of of EVD on the 2014 agricultural production was moderateat the national level. However,the relatively low level of impact at the national level masks the subnational production and food security impacts. Moreover, beyond its impact on the agriculture and food sector, the EVD has seriously affected all other sectors of the economy with serious implications for household food security in the main affected areas. The mining, manufacturing and service sectors have been the hardest hit. According to the Economic Intelligence Unit (EIU), Sierra Leone's real GDP grew by just 4.6 percent in 2014, compared to 20.9 percent in 2013 before the EVD. In 2015, the effects of the EVD epidemic resulted in a sharp decline of 25 percent. With the EVD largely under control, real GDP is predicted to grow by 1 percent in 2016. Similarly,in Liberia, GDP growth is estimated at 0.9 percent in 2015, owing to the low output for Liberia's main exports and reduced harvests in 2014. A stronger rebound of 4.8 percent growth is forecast in 2016, well above the growth of only 0.5 percent achieved in 2014, but still well below the 6.8 percent forecasted before the Ebola crisis. In all three affected countries, the disruption of food chains due to the closing of markets, road blocks and quarantines, restricted cross border trading, as well as changes in traders' behaviour due to the fear of Ebola, has significantly reduced the income of EVD-affected communities including producers, consumers and traders. Specifically, income generating activities typically led by women, such as small trading, have been hit hard and the ban on bush meat has also deprived many households of an important source of nutrition and income. This has, in turn, negatively impacted on the food security situation of large numbers of people in the affected countries. Overall, about 2.2 million people, including 395 000 in Guinea, 720 000 in Liberia and 1.1 million in Sierra Leone, were estimated to be in need of urgent assistance due to the EVD crisis.

PLATFORMS FOR DATA DISSEMINATION AND DATA ANALYSIS

Session Organizer
O. Dupriez | The World Bank | Washington, DC | USA

ABSTRACT

The collection of agriculture statistics is an enormous enterprise largely supported by public funds. Access to agricultural survey and census microdata by the research community and other stakeholders is however limited. Opening up access to datasets would lead to increased engagement with stakeholders and in more diverse and innovative use of the data, which would result in better-informed policymaking in adding much value to the data. But disseminating microdata involves solving multiple technical, legal, and ethical challenges.
The past few years have seen the development of multiple standards and tools to preserve, document, catalog, anonymize, disseminate and analyze data in accordance with international best practice. Pushed by a movement towards increased transparency and accountability, government agencies are increasingly taking advantage of these solutions to share microdata. But the agriculture sector lags behind. Session [40] - Platforms for data dissemination and data analysis will focus on identifying and discussing the barriers, solutions and benefits of a more open access to, and use of, microdata from agriculture surveys and censuses.
We welcome submissions on this theme. Specific topics of interest include but are not limited to the following:

- Incentives and disincentives for microdata sharing
  - Costs, risks, and benefits of sharing microdata from agricultural surveys and censuses
  - Evidence of impact of agricultural microdata dissemination
  - Quantification and qualification of the demand for agricultural microdata (uses and users)
  - Respective roles of the public and private, national and international, stakeholders
- Technical solutions
  - Technical requirements for an efficient (shared?) infrastructure to support dissemination of data in the new, global data ecosystem.

1. ABSTRACT

In this paper, we examined approaches of disseminating agricultural statistics in Malawi. We used a desk research as well as secondary data from the National Statistics Office to review other ways through agricultural data could be disseminated to the public in Malawi. We found that agricultural data is disseminated through two main approaches that is through hard copy publications and website. However, we find that these approaches are traditional and do not meet the needs of the 21 first century era. In current circulations, there is a lack of display of simplified versions of statistical graphs, namely, pie charts, histograms, time-series plots, contour plots, scatterplots, and many more. The focus has largely been on standard line and tabular forms. On the other hand, we find that there are several means through which statistics in agriculture could be made available to the public, namely, radio broadcasting, mobile phones, televisions and social platforms. However, we also identify some interesting limitations that such approaches could have on agricultural data. We lastly combine these approaches with data visualization that could be easily implemented by journalists, spokesperson and other media community. This paper investigate that these other approaches would be easily combine with visual data. In addition, they could likely allow dissemination of technologies that could be transferred to the rural population of which 90% are farmers. In spite of the limitations that the other approaches to data visualization could have in Malawi, this paper suggests that the NSO has to swiftly move into social media as well other formal media dissemination models of agricultural statistics.

Key words: Agricultural statistics, data visualization, technologies, website

1 INTRODUCTION

1. Study Context and the Problem

High quality statistics are essential for designing and targeting policies to reduce hunger, malnutrition, rural poverty, and to promote the sustainable use of natural resources (http://www.fao.org/3/a-mk541e/mk541e03.pdf). Statistics provide the foundation for evidence-based decision-making and play a critical role in measuring and monitoring progress towards national and international development goals and targets. Improving country capacity for the collection, dissemination and analysis of basic agricultural data is essential. A coordinated approach to statistical capacity development, aligned to country strategies and priorities is crucial. In addition, this has to catch up with modern means of disseminating statistics.

In Malawi, agricultural is rural and cornerstone of the economy. It contributes about 40% of total Gross Domestic Product and provides above 80% of employment (NSO, 2016). The agricultural sector could only achieve its intended purpose only if it is disseminated to profit policy making frontier. Besides, technologies in agriculture could be beneficial if its related statistics can be made available to rural farmers. In our rural farmers will require technologies that is able to produce results on the ground.

Dissemination of agricultural statistics is increasing becoming a cost for most developing countries' central statistical systems. In Malawi, the agricultural statistical forum fails to meet annually because of lack of funds (MoA, 2015). This is despite its critical role in sharing successes that are generated in agricultural technology generation and dissemination value chain. Although the Central Statistical Office and the Ministry of Agriculture have attempted to disseminate agricultural data, their focus has been marginal. It has targeted government and donor community members only. The big question has always been do actual farmers know how the technology is fairing when compared within themselves and across communities.

World Bank, through paper written by Boyko and Hill (2009), isolated data as an input into knowledge and wisdom. If this is the case then data generated in Malawi does not result into knowledge and wisdom of farmers that are supposed to implement various technologies on the ground. If farmers are not aware of the modern ways of farming, how are they going to improve on the old tradition methods of farming practices for the better? It should be noted that many national statistical agencies disseminate microdata for public use. Reiter (2004) discussed two data dissemination strategies. The first is remote access computer servers, to which users submit requests for analyses and, in return, receive only the results of statistical analyses, such as estimated model parameters and standard errors. Confidentiality is protected, because the remote server never allows users to see the genuine data. The second is to release synthetic, possibly simulated, data that mimic the relationships in the real data. This approach has low disclosure risks since the released values are not the genuine data. Discussion of these approaches is framed by two key questions. First, to what degree can these approaches protect data confidentiality? Second, how do these approaches affect the accuracy and types of analyses users can undertake? These two questions are relevant for any method of data dissemination, including disclosure limitation techniques used currently by many agencies and organizations. To provide context and motivation, we begin by examining some of these current approaches.

Statistical Offices such as Malawi National Statistical Office cannot be blamed in its totality as disseminationdemands kwachas. However, it can be argued that dissemination of agricultural statistics is becoming costly because of use of traditional approaches to data sharing. On a good note, in the twenty first century, several global organizations such as the World Bank, Food and Agricultural Organization, UN Statistics Division, Organization for Economic Cooperation and Development (OECD) Global Strategy and others are developing technologies that can enhance dissemination of statistics at a very much reduced cost (http://www2.stat.duke.edu/~jerry/Papers/dissemination.pdf). For example, FAO induced development of CountrySTAT with financial support from Bill and Melinda Gate Foundation. It provides decision-makers with a one-stop Centre for easy access to statistics across thematic areas such as production, prices, trade and consumption (FAO, 2013). However, in most countries, the Country STAT is still idle as data is not regularly updated by the Central Statistical Offices and Ministries of Agriculture, Forestry and Energy. In this paper, we explore approaches that can be affordably used to cut costs on disseminating agricultural statistics. This is based on the call by Reiter (2004) that wide access to public use microdata has undeniable societal benefits

2. Research Methodology

In this paper, we first adopt a meta-analysis, which is a desk based research exploration, of tools of disseminating agricultural statistics. In other words, we adopted a revelatory case study approach following Fitzgerald and Fitzgibbon (2014). We basically review publishable articles of the Food and Agricultural Organization publications, World Bank technical papers, and World Class Universities that have provided a thorough discourse on data dissemination approaches. We have reviewed data disseminated through the following reports: Integrated Household Survey and Agricultural Production Estimate Surveys. Second, we combined desk research with secondary household survey data from National Statistical Office (NSO), phone and face to face key interviews with agricultural data custodians and media houses in Malawi. Lastly, this study had a discussion with statisticians at the NSO and Ministry of Agricultural on how the media could be partnered for easy publication of agricultural statistics.

2 DISCUSSIONS

Agricultural Statistics Stakeholder Analysis

Statistical Office and the Ministry of Agriculture are the major custodian of agricultural statistics in Malawi. These providers of agricultural statistics have varied policies on the dissemination of statistics (Kambewe and Banda, 2011). While some tend to be more comprehensive policies, other providers have simple policies. For example, NSO is governed by Statistics Act and detailed dissemination policy macro and microdata (NSO, 2013; 2014). NSO disseminates through two major methods, website and hard copy publications. Only basic tables without a link to micro-data set are disseminated by the Office. The reports are distributed for free to selected stakeholders. This in itself introduce bias and discrimination of who to access data from the data mother body. The following are the publications that the National Statistics Office provides a link on its website or in hard copy report forms (see Table 1):-

Table 1: Data Publications from the National Statistical Office

Publication	Outputs	Mode
Monthly Statistical Bulletin	Prices, agriculture, finance, industrial, production, transport, and external trade	*Report*
Quarterly Statistics	External trade, agriculture, industrial, production, transport, finance and prices	*Report*
Malawi in Figures	Short summary of available statistics	*Report*
Statistical Yearbook	Annual summary of all available statistics covering all economic and social sectors	*Report*
Statistical Data Bank	Databank of statistics for the country (monthly, quarterly and annual series)	*Website*
Malawi Socio-Economic Database	Presentation of Socio-Economic Indicators including agricultural data	*Website*
African Statistics Day	Presentation, Dissemination	*Report*
Agriculture Inputs Subsidy Survey	Recipients of subsidized agricultural inputs and the impact on the economy	*Survey Report*
National Census of Agriculture&Livestock	*Crop production, acreage, yield, livestock and land tenure*	*Report*

Furthermore, the NSO promotes dialogue with data uses through what is termed the National Statistical System. It regularly meet with sectoral officials and with members of the media. In agriculture, the NSO has developed and supported statistical user-producer technical working groups in the areas of agriculture through Agricultural Statistical Forum and Quarterly Agricultural Production Estimate Survey Meetings.

The Department of Climate Change and Meteorological Services considers data it produces as a public good which can be given free of charge. Summarized data can be accessed while access to raw data e.g. daily data is limited and access depends on how it will be used. Data can be sold to profit making organization such as contractors and insurance companies. The pricing is on cost recovery basis. For other organizations, the Director of the Department of Climate Change and Meteorological Services can give a waiver. Data given by the Department cannot be shared with other users.

The Department of Forestry does not have a policy regarding data dissemination. It normally releases its data through annual reports which are submitted to its parent Ministry, the Ministry of Natural Resources and Environment around June every year so that it is in time for the planning of the new government financial year.Agriculture and Fisheries data of the Ministry of Agriculture is for public use although there is no clear policy on that. Various reports (annual and quarterly) are prepared and meetings are held to disseminate the information. Annual meetings for the Ministry are held and progress of the previous year and plans for the following year are disseminated.

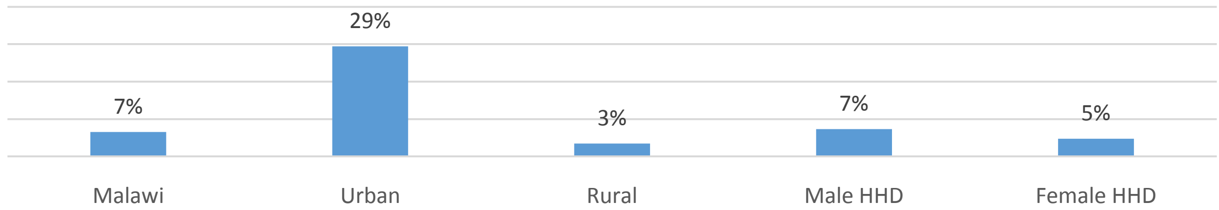
Statistical Database Platforms in Malawi

Malawi has various online databases for disseminating official statistics, namely, MASEDA, CountrySTAT, Data Portal, MDGs; Trade Portal and others. The NSO has a web-page http://www.nso.malawi.net. It is linked to the Malawi Socio-economic database (MASEDA) http://www.maseda.mw/ and the CountrySTAT website http://www.countrystat.org/mwi. The website has latest reports on National Census of Agriculture and Livestock (2006/07), Integrated Household Survey, Micro, Small and Medium Enterprise Report, Welfare Monitoring Surveys (Annual), latest statistical flashes (food crop prices) and Statistical Bulletins.

As regards to the data storage, most raw data is stored in SPSS or Stata format. Recent data is now being archived through the International Household Survey Network toolkit like the National Census of Agriculture and Livestock and the Population and Housing Census data sets. It can indicated that only 7% of

Malawians have access to internet (NSO, 2015) which means that the internet is only accessed by few individuals that are likely to be non-farming households. As shown by figure 1 below, only in the urban area are households able to access internet.

Figure 1-Proportion of household with access to internet in Malawi



The Ministry of Agriculture and Food Security also has a website, http://www.moafsmw.org/. This website is linked to the National Statistical Office website and a number of other government websites. The site has data on livestock census, farmers clubs, fertilizer consumption, fish statistics, rainfall, tobacco sales, farm gate price data and crop production data. However, the data on the website has not been updated in recent years. The Ministry disseminates its statistics through meetings, bulletins, leaflets and E-mail. The main products from the Ministry of Agriculture & Food Security are the Annual Agriculture Production Estimates which are disseminated at various for a (see Table 2).

Table 2-Types of disseminating agricultural statistics in Malawi

Data Type	*Data Dissemination Methods*
Crop estimates (Crop production, acreage, yield)	Publication
Tobacco Statistics	Annual reports, media and press releases and Website: www.tccmw.com/
Sugar Statistics	Press Release and Annual Reports
Smallholder Coffee Statistics	Annual Reports
ADMARC Purchases	Annual Reports
Livestock Census	Annual Reports
Horticultural Commodity Prices	Biweekly E-mail reports and through the Annual Agricultural Statistical Bulletin
Retail prices	Biweekly E-mail reports and through the Annual Agricultural Statistical Bulletin
Farm gate prices	Biweekly E-mail reports and through the Annual Agricultural Statistical Bulletin
Fishery statistics	Annual Agricultural Statistical Bulleting
Consumer Price Index	Stat flashes, Press Releases and Monthly, Quarterly and Annual Report
Trees planted	Annual Reports
Wood removals	Annual Reports
Daily weather forecasts	E-mail, on the web and the media

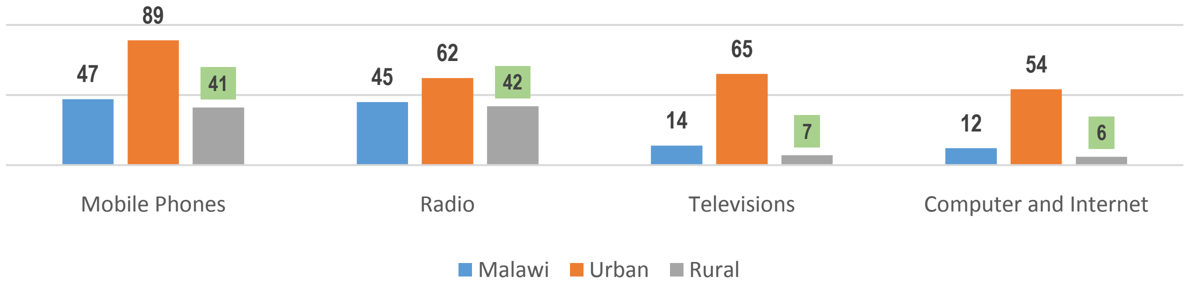
Seasonal Forecasts	E-mail, on the web and the media

National Statistical Office (2015) reported that above half of household in Malawi cannot afford internet services and 31% of households are reported that they do not know how to use internet. This implies that use of website in Malawi is challenged by barriers such as affordability, availability as well as technological know-how.Nevertheless, about 77% of individuals in Malawi are able to access social platforms such as Facebook and WhatsApp that do not require heavy tech-know (MACRA, 2016).

Data Visualization

Organizations of all types and sizes generate data each minute, hour and day. Everyone from decision makers to call center workers and employees on production lines hopes to learn things from collected data that can help them make better decisions, take smarter actions and operate more efficiently. Regardless of how much data you have, one of the best ways to discern important relationships is through advanced analysis and high-performance data visualization. If sophisticated analyses can be performed quickly, even immediately, and results presented in ways that showcase patterns and allow querying and exploration, people across all levels in organizations can make faster and more effective decisions.

Figure 2-Proportion Distribution of Households' Access of ICT equipments in Malawi



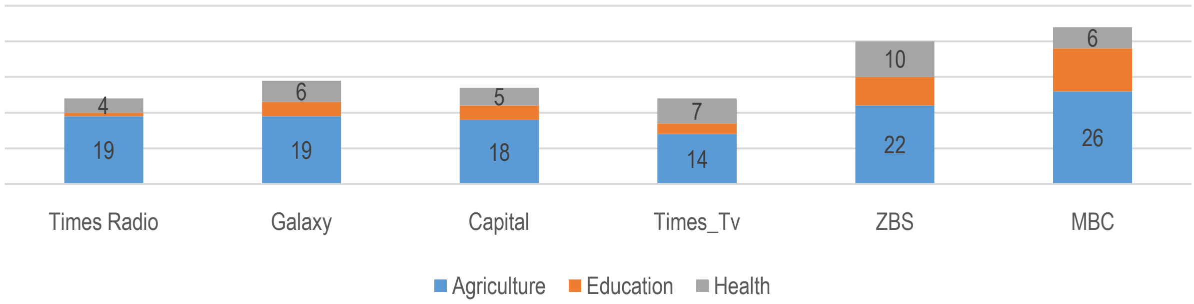
In today's on-the-go society, you may also need to make the results available quickly via mobile devices, and provide users with the ability to easily explore data on their own in real time (SAS, 2014; See Figure 2).

The Media Community

In collaboration with Malawi's National Statistical Office, media personnel, spokespersons from the national statistical system line ministries and sectoral statisticians from various Ministries were brought together to participate in the workshop titled 'Communicating Data through Visualization'. Some of the Ministries that were invited included Agriculture, Trade and Industry, Environmental Affairs, Energy, Mining, Forestry and Fisheries. The workshop aimed at promoting statistical literacy, ensure statistical materials target the right audience, foster networking amongst journalists and government spokespersons and ensure citizens understand better on the statistical information. Some participants highlighted how the workshop de-mystified data for them and taught them how to use official data sources and present information in a visual way.

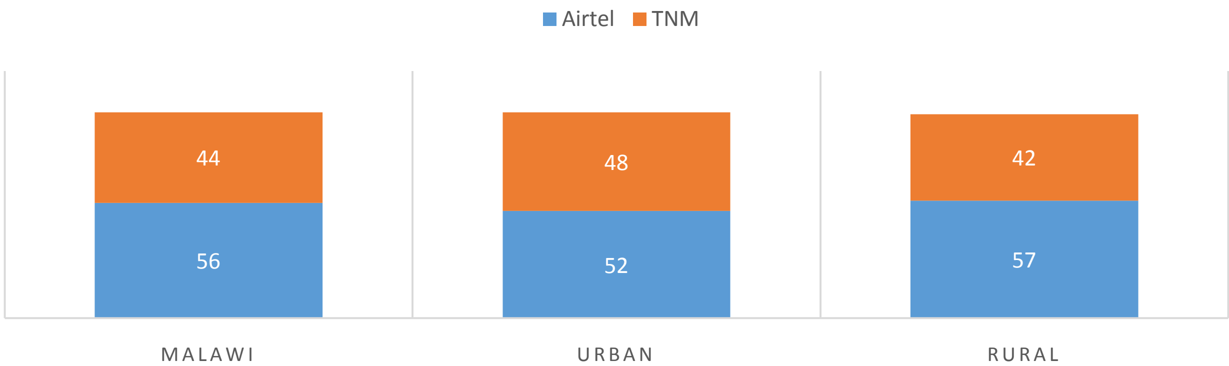
In terms of coverage of issues by the media, it is noted that out of main thematic areas of government, agriculture top the airtime given to broadcasting. This is a space that the Malawi statistical System can take in disseminating agricultural data and technology transfer. Figure 3 depicts issues that are broadcasted by Radio Stations in Malawi.

Figure 3-Issue based programmme by Radio stations



In terms of mobile service provider, we only find two providers that is Airtel and TNM (see Figure 4). This means dissemination of data can be channeled through any of these to households as well as individuals. MACRA (2015) found that about half of the population that owns mobile phones use dual sim which means they have access to both Airtel and TNM line. The growing popularity and global reach of Social Media like Facebook and Twitter presents an interesting new data source for social and economic research. Social Media and related methods and technologies, for example crowd sourcing and social collaboration, can also serve as a new data collection approach (Jug, 2014)[1].

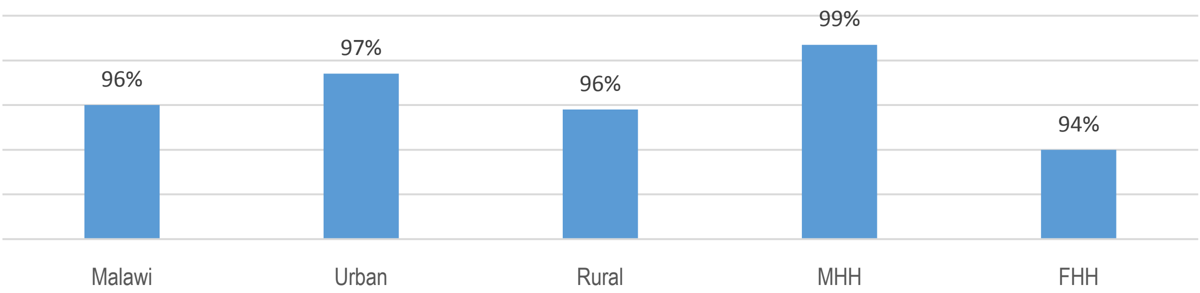
Figure 4-Proportion Of Individuals By Phone Service Providers



It is indeed imperative for the Malawi Central Statistical System to train the media community because of its coverage with the public. For example, Figure 5 shows that above 40% of the population in Malawi, urban and rural areas have a radio. This can imply that households listen to news that can be broadcasted on the radio. Assuming radio stations broadcast messages about agricultural technologies, almost 90% of the population in urban and rural areaslisten to radio programmes (NSO, 2015).

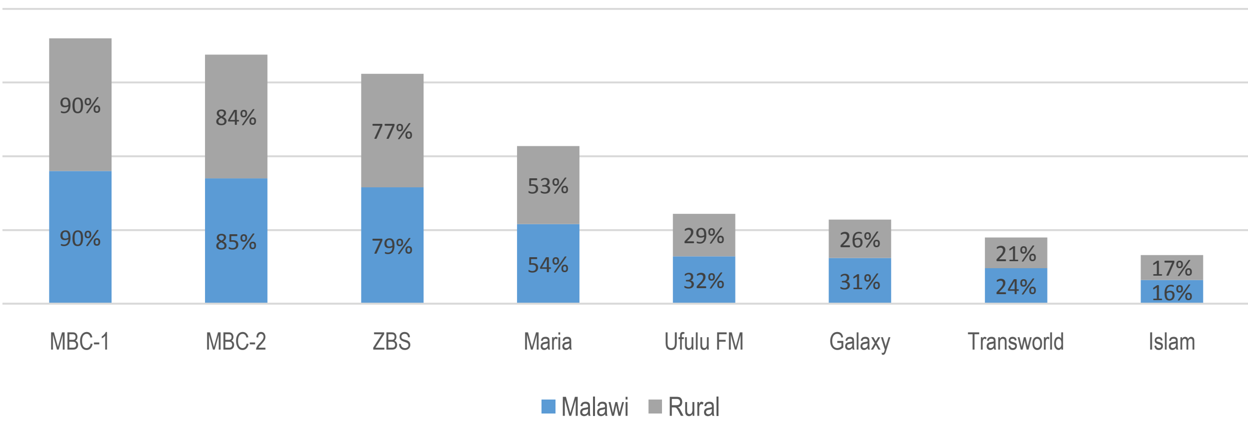
[1]Jug M. (2014). Information revolution: from data to policy action in low income countries: how can innovation help? PARIS21. France.

Figure 5-Proportion of households that listen to radio



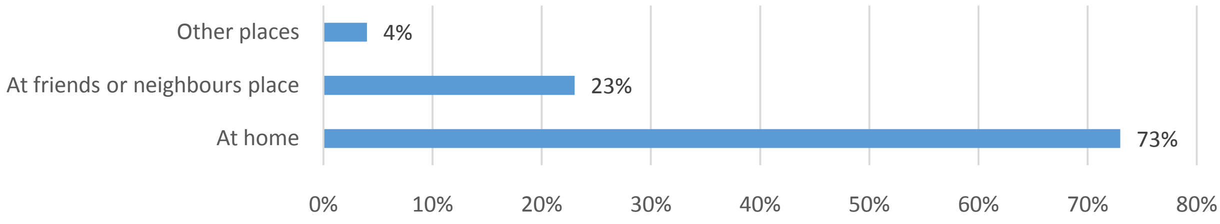
This is also vindicated by radio stations that reach out to households with new agricultural technologies. Nevertheless, among radio stations, Malawi Broadcasting Corporations (MBC) Radio 1 and 2 reach to most households in Malawi than other radio stations (see Figure 6).

Figure 6-Proportion of households that are reached by national radio stations



We however observed the multiplier effects that are generated when having or listening to the radio stations. Figure 7 shows that 73% of households listen from radio at home. This can be implied that about 4.6 people (NSO, 2008) at household level benefit from a single radio broadcasting. What is very interesting is that almost one in four households in Malawi listen from radio at neighbors or friend place. This also increases the multiplier effects from 4.6 people within a household to more than 9 individuals among households that may likely be reached out by national radio stations.

Figure 7-Proportion of households' multiplier Effects due to listerning to radio with others



In terms of newspaper, in Malawi, we have only two major Prints, namely, National Newspapers and Blantyre Daily Times. These newspaper circulate about 36000 prints in a day. They reach out to about 262000 households in a week that is on accumulative basis (see Table 3). However, most newspaper, do not include modern forms of statistical graphs, namely, pie charts, histograms, time-series plots, contour plots, scatterplots, and many more. And these could display an array of economic, social, medical, and physical data (Friendly, 2005). The focus has largely been on standard line, bar, and tabular forms over other types of data visualizations (Strecker, 2012)[2].

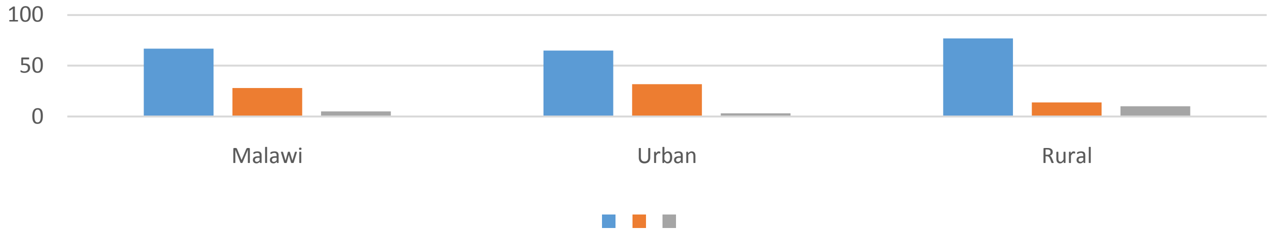
Table 3-Circulations by National and Daily Times newspapers in Malawi

	Mon	Tue	Wed	Thu	Fri	Sat	Sun
National Newspaper	16,000	16,000.00	16,000.00	16,000.00	16,000.00	25,000.00	12,000.00
Daily Times Newspaper	20,000	20,000.00	20,000.00	20,000.00	20,000.00	30,000.00	15,000.00
Total Circulation	36,000	36,000.00	36,000.00	36,000.00	36,000.00	55,000.00	27,000.00
Households Reached	36,000	36,000.00	36,000.00	36,000.00	36,000.00	55,000.00	27,000.00
Individuals Reached	180,000.00	180,000.00	180,000.00	180,000.00	180,000.00	275,000.00	135,000.00

Figure 8 shows households that subscribe to pay tv by location. It can be observed that 67% of households in Malawi subscribe with DSTv while only 5% subscribe with Zuku tv. In rural areas, we find a higher proportion of households subscribing to DSTv while only 10% subscribe to Zuku Tv. This may imply that dissemination of agricultural statistics through Televisions should be able to target pay tv that most households subscribed to.

[2]Strecker J. (2012). Data Visualization in Review: Summary. IDRC

Figure 8-Proportion of households with access to Televisions that subscribe to pay Tv by location



3 LIMITATION

Strecker (2012) highlighted that data visualizations in practice in most designs remain generally clear, but are generic. She stressed that there appears to be a lack of understanding about how to tailor design choices to ensure that visualizations are communicating a more focused and compelling message. In other words, most data visualization are generally at a novice level. More attention should be paid to the following three areas to help improve the effectiveness of the data visualizations currently being created:

- Document consistency: coherent color schemes and chart graphics should be selected and remain through the entire document.
- Titles and decks: supporting text should be used to draw attention to the main message or take-away of the visualization.
- Design choices: colours, positioning, and size should to be carefully incorporated into designs to help draw the reader's attention to the most important data points.

Refinements in these three areas would significantly strengthen the data visualizationsand would help improve their ability to communicate effectively. For example, most participants at the training organized by NSO spotted that they had a limited understanding of data visualization principles, but demonstrated strong enthusiasm for its potential and a willingness to learn and further engage with these tools. Therefore, they requested further knowledge and skills development around how to strategically use data visualizations (Strecker, 2012).

Brescian and Eppler (2008) results of field studies confirm and substantiate most of the concepts already collected from the literature. They have also surfaced a few new relevant issues on limitation of visualization, such as:

- the potentially misleading perception of reliability of a visualization (visualizations may appear more convincing and sound than they really are),
- the (multiple) implicit meanings inherent in visualizations (leading to ambiguous interpretations),
- the high prerequisites for diagram interpretation (a visualization's efficacy depends on the user's previous experience and visual literacy).

- The cause of a visualization disadvantage can be twofold: the designer(s) or the user(s) (that is, their interpretation) (Tufte, 1986). The designer can intentionally or unintentionally introduce mistakes or drawbacks in a visualization.
- Previous studies have demonstrated that visualization is costly to produce in terms of time and other economic resources (money, equipment, know-how, etc.). In this context, various authors emphasize the need for quantifiable measures of the quality of a visualization in order to determine whether it isfit for use (van Vijk 2006).
- The interpretation of a visual form can depend on the familiarity of the observer and on his or her previous experience with it.
- Visualization is actually one of the biggest barriers to insight because it places the burden of discovery on the user, hence any tool that places burden on the analyst is a game-stopper.
- Data visualization is defined as the study of the visual representation of data, meaning information that has been abstracted in some schematic form, including attributes or variables for the units of information. "Humans are better equipped to consume visual data than text.
- Given today's explosion of big data, Statistical Offices need more advanced methods for leveraging data methods that don't rely solely on tribal knowledge, personal experience or best guesses.

4 CONCLUSION AND POLICY RECOMMENDATIONS

In this paper, we examined approaches of disseminating agricultural statistics in Malawi. We used a desk research as well as secondary data from the National Statistics Office to review other ways through agricultural data could be disseminated to the public in Malawi. We found that agricultural data is disseminated through two main approaches that is through hard copy publications and website. However, we find that these approaches are traditional and do not meet the needs of the 21 first century era. On the other hand, we find that there are several means through which statistics in agriculture could be made available to the public, namely, radio broadcasting, mobile phones, televisions and social platforms. However, we also identify some interesting limitations that such approaches could have on agricultural data. We lastly combine these approaches with data visualization that could be easily implemented by journalists, spokespersons and other media community. In current circulations, there is a lack of display of simplified versions of statistical graphs, namely, pie charts, histograms, time-series plots, contour plots, scatterplots, and many more. The focus has largely been on standard lineand tabular forms over other types of data visualizations. This paper notes that other approaches would be easily combine with visual data. In addition, they could likely allow dissemination of technologies that could be transferred to the rural population of which 90% are farmers. In spite of the limitations that the other approaches to data visualization could have, this paper suggests that the NSO has to swiftly move into social media as well other formal media dissemination models of agricultural statistics.

Using Modern Technology to Make Metadata of Agricultural Statistics Available for Data Users

Waleed Mohammed
Statistician at Demographic statistics
Central Agency for public Mobilization and statistics (CAPMAS)
Nasr city, Cairo, Egypt
E-mail: kant2012xp@hotmail.com

DOI: 10.1481/icasVII.2016.h46b

ABSTRACT

Egypt's agriculture sector remains one of the most productive in the world, despite the small percentage of arable land, irregular and insufficient water supplies and problems with waterlogged and highly sainted soil. Although farmers do not have to pay for water used in irrigation, government drainage efforts have proved insufficient to counter problems in the sector's performance.

so Reliable and timely information about agriculture statistics such as crop area, crop production and land use is great importance to planners and policy makers for efficient agricultural development and for taking decisions on procurement, storage, public distribution, export, import and many other related issues.

Based on the above prospective this paper will discuss types of users for agricultural statistics , the experiences of CAPMAS (National statistics office in Egypt) in documentation Metadata of annual Bulletin of crop areas and plant production (ABCAPP) using Micro data Management Toolkit and disseminate it using National Data Archive (NADA) and the benefits which returns on users.

Keywords: Micro data Management Toolkit; National Data Archive (NADA); Dissemination; Crop areas; Plant production.

1- Importance of agriculture in Egypt

We can summarize importance of agriculture in Egypt in the following points:

1.1 Agriculture is considered a source of livelihood for a large proportion of people and food security.

1.2 In Egypt as most developing countries Agriculture is still a large proportion of GDP.

1.3 There are large numbers of households in Egypt involved in agricultural activities.

1.4 Most farms are small and performance depends on decisions taken by millions of farmers unlike industrial sector.

1.5 Agricultural production is unpredictable because of its heavy reliance on weather, particularly rain.

1.6 Food shortages may lead to political unrest.

1.7 **Agriculture in Egypt is different from other sectors for these reasons:**

1.7.1 Nature of agricultural production is different due to (Seasonality, Geographic spread, Risks and uncertainty: climate change, market forces, Source of technical change (depend on research by Government agencies).

1.7.2 Farm households both as producers and consumers.

1.7.3 There are intrinsic linkages with other rural economic activities such as agro-forestry, fisheries at the household level which are difficult to segregate. Studying or collect data on them together makes sense.

2- TYPES of USERS for AGRICULTURAL STATISTICS

The Official statistics are intended for a wide range of users including governments (central and local), research institutions, professional statisticians, journalists and the media, businesses, educational institutions and the general public. There are three types of users for agricultural statistics: those with a general interest, business interest or research interest (universities, consultants and government agencies). Each of these user groups has different needs for agricultural statistical information.

2.1 Users with a general interest

Users with a general interest include the media, schools and the general public. They use agricultural statistics in order to be informed on a particular topic such as "Crop statistics, Livestock numbers, Holder's legal status and ownership form ...etc ", to observe trends within the society of a local area, country, and region of the world.

2.2 Users with a business interest

Users with a business interest include decision makers and users with a particular interest for which they want more detailed information. For them, agricultural statistics are an important reference, providing information on the phenomena or circumstances their own work is focusing on. For instance, those users will take some agricultural statistics into consideration before launching a product which depended on agriculture, or deciding on a specific policy or on a marketing strategy. As with the general interest users, this group does not usually have a good understanding of statistical methodologies, but they need more detailed information than the general users." Annual and permanent crops: Sown areas, harvested areas, production, yield'.

2.3 Users with a research interest

Users with a research interest are universities, consultants and government agencies. They generally understand something about statistical methodology and want to dig deeper into the facts and the statistical observations; they have an analytical purpose in inventing or explaining interrelations of causes and effects of different phenomena. In this field, official statistics are also used to assess a government's policies such as:

2.3.1 The eradication of hunger, food insecurity and malnutrition;
2.3.2 The sustainable management and utilization of natural resources (land, water, air, climate and genetic resources) Reduce Rural Poverty.
2.3.3 Enable inclusive and efficient agricultural and food systems.
2.3.4 Increase resilience of livelihoods to threats and crises.

3- Documentation Metadata of annual Bulletin of crop areas and plant production(ABCAPP) using Micro data Management Toolkit and disseminate it by using National Data Archive (NADA).

3.1 Definition Meta data

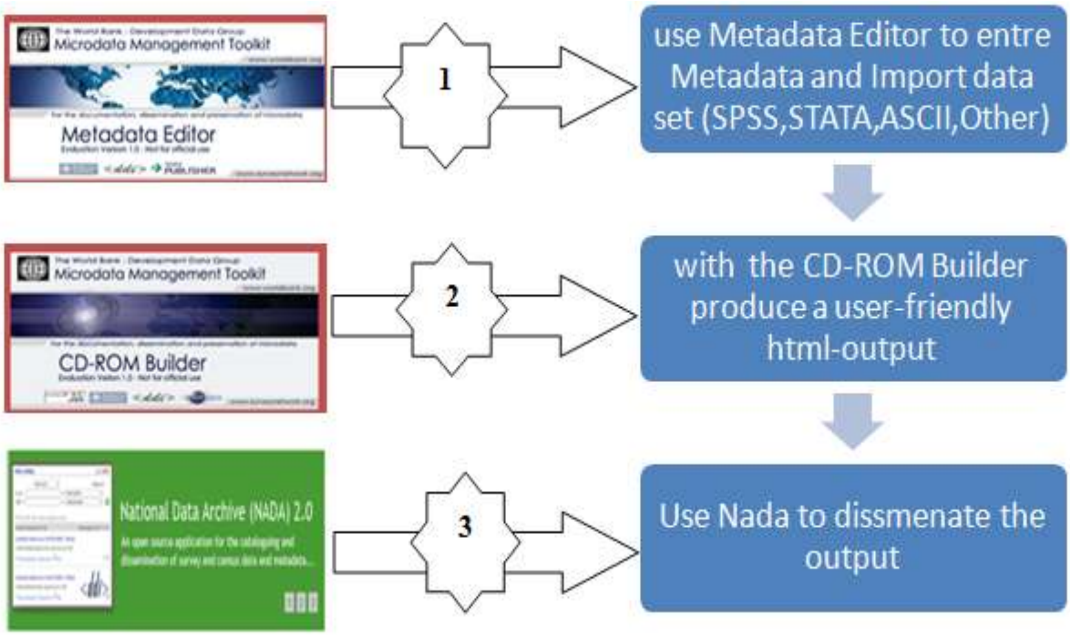
A very simple definition of metadata is that it is any information that helps users find, understand and use data and information. It is also referred to as documentation. Metadata helps us judge the quality of a survey and whether it meets their needs. It is also important for long term preservation.
The metadata should explain what was measured and how it was measured.

3.2 steps of using Toolkit in Documentation Metadata for annual Bulletin of crop areas and plant production (ABCAPP) 2012/2013

3.2.1 Use Metadata Editor to Document survey data in accordance with international standards (DDI-DCMI).
3.2.2 Use CD-Rom Builder to Generates user-friendly outputs, such as CDs, websites, for dissemination and archiving.
3.2.3 Use National Data Archive (NADA) For viewing metadata in website.

The following Figure summarized steps of using Toolkit :

***Figure 1 : Steps of Using Toolkit in Documentation Metadata** for (ABCAPP)*



3.3 Using NADA in Dissemination metadata for The annual Bulletin of crop areas and plant production 2012\2013

NADA is an open source microdata cataloging system, complaint with the Data Documentation Initiative (DDI) and Dublin Core's metadata Initiative (DCMI). It serves as a portal for researchers to browse, search, compare, apply for access, and download relevant census or survey datasets, questionnaires, reports and other information.

The NADA is designed to facilitate the process of releasing micro data to the user community, and support the analysis of this data by the provision of standardized information about the data (metadata). Proper micro data management utilizing the NADA software can have the following advantages for data producers:

3.3.1 Increased quality and diversity of research.
3.3.2 Improved reliability and relevance of data.
3.3.3 Reduced duplication of data collection activities.
3.3.4 Improved visibility of survey institutions as their data becomes more frequently.
3.3.5 Increased donor and public confidence in the survey data producers.
3.3.6 Improved publishing and dissemination efficiency of for data producers.
3.3.7 More efficient access to survey information such as reports, tables, and micro data.

The national statistical office in Egypt used NADA for Dissemination metadata for Agriculture surveys. The following figure shows that Metadata for the annual Bulletin of crop areas and plant production 2012\2013 in the website of CAPMAS.

Figure 2 : Data Catalog for the Bulletin of crop areas and plant production

For more details visit website of CAPMAS:
http://www.capmas.gov.eg/Pages/ShowPDF.aspx?page_id=http://www.censusinfo.capmas.gov.eg/Metadata-ar-v4.2/index.php/catalog/

3.4 Metadata for *the annual Bulletin of crop areas and plant production* (ABCAPP)

The following point some examples about metadata for (ABCAPP) from website of CAPMAS:

3.4.1 Objective

Provides users with indicators about (Holding location, Holder's legal status and ownership form, Data on the holder and composition of his/her household, Land tenure and land use (including areas under major temporary crops),Livestock numbers, Main purpose of production, Ownership and use of agricultural machinery, Land structure, Crop statistics ,Annual and permanent crops: Sown areas, harvested areas, production, yield.

3.4.2 Period of Data Collection :

Agricultural year beginning from the first of November and ends in October next year.

3.4.3 Data Sources

3.4.3.1 Ministry of agriculture

3.4.3.2 Central Administration of Agricultural Economics.

3.4.3.3 Research Institute for Lands, Soil , Water

3.4.3.4 Agriculture Departments in the Governorates.

3.4.3.5 website of Euro stat http://epp.eurostat.ec.europ.eu
EU POPA-Eurostat-Agriculture and Fishery

3.4.4 Methods of data collection

3.4.4.1 Interview

3.4.4.2 E-mail.

3.4.5 Indicators about crop areas and plant production

3.4.5.1 The total cropped area reached 15.48 million feddan in 2012/2013 versus 15.57 million feddan in the previous year, an decrease of 5.0 %.

3.4.5.2 The total cultivated area reached 8.94 million feddan in 2012/2013 versus 8.80 million feddan in the previous year an increase of 1.6 %.

3.4.5.3 The total area of wheat reached 3.38 million feddan in 2012/2013 versus 3.16 million feddan in the previous year an increase 6.9%and amount of wheat crop production reached 9.46 million tons in 2012/2013, versus 8.80 million tons in the previous year, an increase of 7.6%.

3.4.5.4 The total area of rice reached 1.42 million feddan in 2012/2013 versus1.48 million feddan in the previous year an decrease 3.7%. and amount of rice crop production reached 5.72 million tons in 2012/2013 versus 5.91 million tons in the previous year, an decrease of 3.2 %.

4- CONCULSION

Using modern Technology to Make Metadata of Agricultural Statistics Available for Users by NSO is very important, because metadata helps them to:

4.1 Find the data they are interested in. Without names, abstracts, keywords, and other important metadata element it might be difficult for a researcher to locate specific datasets and variables. Any cataloguing and resource location system—whether manual or digital—is based on metadata.

4.2 Understand what the data are measuring and how the data have been created. Without proper descriptions of the survey design and the methods used when collecting and processing the data, the risk is high that the user will misunderstand and even misuse them.

4.3 Assess the quality of the data. To know whether data are useful for a research project, researchers need information about the data collection standards, as well as any deviations from the planned standards.

Standards and tools for the dissemination of agriculture microdata: review and improvements

Matthew, Welch
The World Bank, Development Data Group
1818 H Street NW
Washington DC, 20433, USA
mwelch@worldbank.org

DOI: 10.1481/icasVII.2016.h46c

ABSTRACT

Large public and donor investment has led to an increase in the collection of microdata from surveys, census and administrative data. Preservation, discovery and access to these data are uneven and differ greatly by country and type of data. Extensive work by governments and the international community, through networks such as the International Household Survey Network (IHSN) and the Paris21 Accelerated Data Program (ADP), have provided the standards, guidelines and tools that have made it possible for many countries to preserve and disseminate microdata. One area, which is lagging, is in access to agriculture microdata. Agriculture microdata often possess both the characteristics of a household survey as well as an establishment survey, which can make the safe release of the data challenging. The paper discusses the tools developed by the International Household Network (IHSN) and the World Bank for microdata dissemination and includes recommendations on metadata standards as well as a discussion on guidelines and tools available for statistical disclosure control. Standards used for the documentation, preservation and dissemination of a typical household survey may not fit all types of data needed for the generation of agriculture statistics. The paper makes suggestions as to how the standards and tools could be improved to better suite agriculture surveys and in addition, non-survey sources of data for agriculture statistics.

Keywords: Metadata Standards, Disclosure Control, Dissemination, Tools

1. Introduction

There is a global movement towards more open access to data. Large public and donor investment has led to an increase in the collection of microdata from surveys, census and administrative sources. Many agencies provide access to aggregate, tabular or time series data. The preservation, discovery and access to the microdata underlying these sources are uneven and differ greatly by country and type of data. The release of the underlying microdata is important as it allows researchers and policymakers to replicate officially published results, provide feedback for improvement of future surveys, generate new insights into issues, avoid duplication of surveys and provide greater returns to the investment in the survey process.

Extensive work by governments and the international community, through networks such as the International Household Survey Network (IHSN), coordinated by the World Bank, and the Partnership in Statistics for Development of Statistics in the 21st Century (Paris21) have provided standards, guidelines and tools that have made it possible for many countries to preserve and disseminate microdata. These programs have resulted in the documentation of thousands of surveys by countries and agencies across the world. While these programs have ensured substantial improvements in the preservation of data and dissemination of good quality metadata, many agencies are still reluctant to allow access to the microdata. This is particularly true of agriculture microdata. The Global Strategy to improve Agricultural and Rural Statistics (2010) identifies six common areas where agriculture statistics in developing countries face problems. The last two are of particular interest in the context of this paper.

- Limited staff and capacity of the units that are responsible for collection, compilation, analysis, and dissemination of agricultural statistics.
- Lack of adequate technical tools, statistical methodology, and survey framework to support data-production efforts.
- Insufficient funding allocated for agricultural statistics from development partners and national budgets.
- Lack of institutional coordination, which results in the lack of harmonized and integrated data sources.
- Lack of capacity to analyze data in a policy perspective, which results in a significant waste of resources, as large amounts of raw data are not properly used.
- Difficulty for data users in accessing existing data with no metadata or indication of quality.

The Global Strategy acknowledges that building and maintaining technical capacity is a difficult task and requires a long-term plan. One of the recommendations includes that capacity building should include support to the dissemination of results. This could be extended to, or more specifically state, that capacity building to support microdata dissemination should be built. One of the key benefits of dissemination of the microdata is that it widens the pool of experts immediately who can analyze the data to gain the best and timeliest insights possible. It is not possible for the staff of statistical offices to respond to all analysis requests. Releasing the microdata frees up capacity for core activities by allowing users of the data to generate their own analysis.

In order to ensure that the released microdata are properly used they should be released with detailed metadata, which describes the full survey process, the data and any assessments of quality.

The following sections discuss the tools developed by the World Bank\IHSN to help countries and agencies disseminate microdata and discusses, and advocates for, the use of an international standard for the documentation and creation of metadata for survey data called the Data Documentation Initiative (DDI).

2. A Standard for Microdata Documentation

There are a number of reasons commonly cited for why the creation and agreement on standards has benefits. These include allowing the interoperability of systems, lowering the cost for developing tools, improving quality. The most commonly used standard for the description and documentation of survey data is the Data Documentation Initiative (DDI). The DDI had its origins some 20 years ago at the University of Michigan and is now an international standard developed by a large community of practice. The standard is used by most social science archives around the world as well as by a large number of international and country agencies that collect and disseminate survey data.

The DDI standard provides a structured checklist of what needs to be documented to fully understand the entire survey lifecycle, the microdata and its quality.[1] The comprehensive and structured nature of a survey documented according to the DDI standard helps agencies preserve data and makes it easier for users to understand what the data are measuring and how the data were created.

The DDI is comprised of two standards. The DDI Lifecyle and the DDI Codebook.[2] The Lifecycle accommodates the advanced documentation of the survey lifecycle from the conceptualisation of the survey through to analysis. The complexity of the DDI Lifecyle has meant that its uptake has been limited to only a few advanced archives and agencies. This led the World Bank\IHSN to champion an effort to simplify the standard. The DDI Codebook is based on feedback coming mostly from developing countries and as a result, the DDI Codebook is a more bottom-up standard.

The relative ease with which the DDI Codebook can be understood made it possible for the World Bank and IHSN to easily develop tools and guidelines for preservation and documentation of surveys. As a result, the standard is now being implemented in 130 national agencies in 88 countries, and 18 international or other organizations. National Statistics Offices concerned about preservation of their data and institutional memory combined with the World Bank\IHSN have documented over 5000 surveys using the DDI standard.

The standard is suitable for the documentation of any type of survey or census data and as such is suitable, and has been widely used, for the documentation of agriculture surveys and agriculture census data.

Looking forward, the core elements of the DDI Codebook will likely remain the standard of choice for the documentation of surveys from most of the agencies currently using it. Given though that the standard was designed for survey and census data and given that many agricultural statistics are now being generated from other sources of data or are merged with other types of data it will be necessary to adapt or add to the current standard in order to accommodate these sources. Examples

---

[1] The Quick Reference Guide for Data Archivists produced by the IHSN gives a description of key fields in the DDI and how the World Bank\IHSN have implemented it.
[2] The DDI Alliance: http://www.ddialliance.org/

of other sources of agricultural statistics are administrative data, remotely sensed data, satellite imagery, cadastral surveys, and time series data.

The DDI Alliance are currently working towards a new version of the DDI (DDI 4). The World Bank is working with the DDI alliance to ensure the standard meets the changing needs of users in developing counties, while still maintaining its relative simplicity for implementation. DDI 4 will incorporate all the elements from DDI Codebook and DDI Lifecycle in a simpler view. It will make it easier to use DDI for geospatial, administrative and time series data. This will be a major benefit to much data used for agriculture statistics. DDI 4 will come with a feature called profiles which will allow the user to pick a subset of elements for specific types of data. For example, for geospatial data, a DDI template (schema) could be created only for geospatial data or a combination of schemas could be created for multiple data types.

3. Tools for Documentation and Dissemination

The previous section discussed the needs for, benefits of, and the successes, which the World Bank and IHSN have had in rolling out standards for the documentation of microdata. A large part of the success in the adoption of the DDI by so many agencies has been the availability of easy to use free tools for the documentation and dissemination of surveys using the DDI standard.

The typical DDI document consists of an XML schema. While it is possible to write a DDI document directly in XML this is not easy nor convenient. To make the creation of DDI documents quick and easy requires software tools that allow the creation of DDI documentation without the user having any knowledge of XML. DDI documentation can be transformed into multiple human readable formats such as PDF reports and web based pages. The DDI lends itself most powerfully to the creation of online searchable catalogues. The World Bank and IHSN have been using and supporting a freeware DDI compliant editor as well as an open source online DDI compliant survey cataloguing and dissemination platform since 2006.

3.1 A DDI editor

The World Bank and IHSN contributed to the development of a DDI compliant metadata editor (The Nesstar Publisher) produced by the Norwegian Social Science Data Archive (NSD). This is Windows based software, which supports multiple languages. It is offered as Freeware by the NSD and has been the key vehicle through which the World Bank and IHSN have implemented the DDI standard since 2006. The availability of this easy to use free editor has led to the preservation and documentation of thousands of surveys, which might otherwise have been hidden or lost.

While the Nesstar Editor will continue to remain available for the near future, it is not anticipated that the NSD will develop the Editor any further. Given the earlier discussion on the need for further development of the DDI standard to incorporate other types of data there is a need to plan for and develop a new editor that can accommodate the new standard and new sources of data. While some advanced data centres have developed their own editors and some commercial editors are now available; there remains a need for the availability of a free, commercial-quality DDI compliant editor. To solve this problem The World Bank have begun the process of developing a new DDI editor. The new editor will support future versions of DDI and will have the added ability to support other standards such as Geospatial ISO 19139 and Dublin Core as well as custom designed schemas. The new editor will run on multi-platforms and will be distributed as open source software. The flexibility of the new editor combined with World Bank and IHSN support to countries is expected to broaden the ability for new types of data (relevant to the generation of data such as those used for agricultural statistics) to be documented, described, preserved and ultimately disseminated.

3.2 A Dissemination Platform

Data have their broadest use and utility if they can be discovered and used by a broad range of users. The most cost effective and efficient way to do that is to display the information online in such a way that makes it possible for users to discover, browse, search and download the metadata and microdata from a single online platform. Some advanced agencies have built their own custom microdata and metadata catalogues, and there are commercial products designed specifically for survey microdata available.[3] The success, which the World Bank and IHSN have had in helping countries, build capacity for the dissemination of data and DDI compliant metadata has however come through making available free (open source) catalogue software developed by the World Bank and supported by the IHSN partners. The software is called the National Data Archive (NADA). It is a multi-platform DDI compliant open source PHP application. The NADA allows users to browse, search, filter and download metadata and microdata. It also comprises a full featured secure administrative interface that allows managers of the system to apply access control polices at the survey level and to monitor and administer requests made by users. The full list of countries and organizations that the World Bank and IHSN have supported in implementing the NADA platform can be found in Appendix 1.

The NADA platform was originally designed to support only the DDI standard and survey and census microdata. User feedback and requests from users have always guided the development path of the NADA platform. The needs of users have changed over time as statistics are generated from new sources or combinations of sources of data. This is especially true of agricultural statistics where data come from many sources and where new data sources are augmenting or replacing survey and census data as a source. To address changing needs the World Bank have begun the development of new version of the NADA. The new version will accept and facilitate, in addition to new and existing versions of DDI, the display and dissemination of multiple metadata standards and data types. Of importance to agricultural statistics, this includes administrative data, time series data and geospatial data.

3.3. Tools for privacy protection

The release of microdata is important, as it allows researchers and policymakers to replicate officially published results, generate new insights into issues, avoid duplication of surveys and provide greater returns to the investment in the survey process.
The release of microdata poses privacy challenges to the producer. Agriculture microdata in particular often possess both the characteristics of a household survey as well as an establishment survey, which can make the safe release of the data more challenging.

The dissemination of agriculture microdata is poor in developing countries. One of the key reasons why these data are not widely distributed relates to the difficulty many countries face in applying statistical disclosure control (SDC) or privacy protection measures to the data. See the review by the Global Strategy to improve agricultural and rural statistics (2014).

[3] Two of the best known commercial products are the Nesstar Server and products from Colectica

While the release of microdata poses often-difficult disclosure control problems this is not the case for all types of data related to agriculture statistics. There are many examples where data from agriculture surveys have been released. One of the prime examples is the LSMS-ISA data produced by the World Bank. Also, a review of data catalogs in many developing countries shows that developing countries are successfully disseminating agriculture related data[4]. Where the data do present challenges for privacy there may be technical solutions and tools that could overcome some of these hurdles and allow the release of traditionally more sensitive microdata.

These strategies usually involve a combination of enabling legislation, the application of appropriate access terms and statistical disclosure control (SDC) methods.[5]

The World Bank and IHSN programs have provided considerable guidance to countries on the creation enabling legislation and dissemination policies for microdata dissemination. This has addressed part of the problem. Countries consistently list the lack of capacity and knowledge of SDC methods for privacy control as a remaining barrier to greater release of microdata. This is particularly the case for many types of agriculture data.

To help address this problem the IHSN, PARIS21 (OECD), Statistics Austria and the Vienna University of Technology and the World Bank has contributed to the development of an open source software package for SDC, called sdcMicro.

The package was developed for use with the open source R statistical software, available from the Comprehensive R Archive Network (CRAN) at http://cran.us.r-project.org. The package includes a comprehensive suite of methods for the assessment and reduction of disclosure risk in microdata. For users who are familiar with R, sdcMicro offers a very powerful and free tool to treat microdata for safe release. For those users who are not familiar with R the World Bank and the IHSN are developing a graphic user interface for sdcMicro that will remove much of the need to know R and free users to simply apply the methods as required. This should be available towards the end of 2016.

The proper implementation of SDC methods requires expertise and experience in Statistics and in the area of SDC. Many advanced agencies have expertise in this specialized area, but this is much less the case in developing agencies. The provision of the free tools will go a long way to improving the ability of agencies to apply SDC methods, but without guidance and capacity building uptake may still be low. To this end, the World Bank and IHSN have produced a number of guides to the SDC process and the practical application of the sdcMicro package. [6]

It should be stressed that SDC is only one part of the data release process, and its application must be considered within the complete data release framework. The level and methods of SDC depend on the laws of the country, the sensitivity of the data and the access policy (i.e., who will gain access) considered for release. The provision of the free SDC package and guidelines create an enabling environment for unlocking more microdata including agriculture microdata.

---

[4] See appendix 1

[5] For an in-depth summary of access polices, and dissemination of microdata files see The IHSN working paper written by Dupriez and Boyko (2010)

[6] See: http://www.ihsn.org/home/software/disclosure-control-toolbox

4. Conclusion

The success which the World Bank and its IHSN partners have had in assisting countries and agencies build capacity for the documentation, preservation and dissemination of microdata has, in large part, been due to a strategy of building, disseminating and supporting free tools. The thread linking the success of the tools has been the existence of an easy to understand and implement international standard – DDI.

These tools, and the support for them, have improved the accessibility to good metadata and microdata for thousands of surveys. There are still countries that despite having the necessary platforms and tools for dissemination do not release microdata for all or certain types of surveys. Agriculture microdata are one of the data types that are not widely disseminated and where solutions need to be found in order to maximize the investment in the collection of these data and for improvement in surveys and policy. A commonly mentioned reason for not distributing microdata from agriculture surveys has been privacy protection. To help solve this problem the World Bank and the IHSN have supported the development of a free tool for the implementation of SDC methods and developed guidelines to support this. This lowers the barriers to release and opens the door for more countries to release microdata.

With increasing amounts of data for agricultural statistics coming from sources other than surveys and census there is a need to adapt current tools and standards to incorporate these new sources. The World Bank and IHSN are constantly improving the available tools to ensure they accommodate the changing needs of producers and users of data. The World Bank is also actively working with the DDI alliance to ensure that documentation standards remain accessible and relevant.

ABSTRACT

Australia's agriculture, fisheries and forestry industries make an important contribution to Australia's economy, society and natural resources. The productivity, competitiveness, sustainability and profitability of these industries are enhanced by having access to timely, high-quality and reliable statistics to inform decision-making by both government and industry. Similarly, at the micro level, individual businesses use statistics to inform their management and investment decisions. Over time the Australian agricultural statistical system has evolved to support the information needs of decision-makers across government, industry and the broader community.

However, there has been criticism that the current Australian agricultural statistical system is deficient in providing quality, timely data to meet these needs. Like all national statistical offices, the Australian Bureau of Statistics (ABS) faces the ongoing challenge of meeting diverse user needs in an environment of fiscal constraint. In this context, it is essential that the datasets produced within Australia's agricultural statistical system are targeted at the highest priority needs and are produced, disseminated and used in the most effective and efficient way.

The ABS and the Australian Bureau of Agricultural and Resource Economics and Sciences (ABARES) are the principal producers of agricultural statistics in Australia. The two organisations initiated the National Agricultural Statistics Review (NASR) to hear directly from statistical users and producers across government, industry and the research sector about these issues, and to identify potential solutions. The NASR provided valuable stakeholder insights, and has identified a pathway to establish a contemporary, best practice Australian agricultural statistical system for the future. The NASR has enhanced the relationship between the two agencies and paved the way for further collaboration to provide stronger and more effective leadership across the system. Additional opportunities for partnerships have also been identified with other statistical users andproducers to better coordinate effort and investment, and to work collaboratively to improve data quality and reduce respondent burden.

This paper will briefly examine the context through which the NASR was initiated and its links to national policy in Australia. The paper will briefly explore the NASR process and the positive impacts of collaboration and partnership with a wide variety of stakeholders from across the agricultural sector. As the NASR has progressed into its implementation phase, the final section of the paper will outline progress against actions recommended during the review, and the additional outcomes and opportunities that have emerged as a result of continued engagement across the agricultural statistical system.

Keywords: statistical system; policy; collaboration.

1. Background

1.1 The two predominant producers of agricultural statistics in Australia are the Australian Bureau of Statistics (ABS), and the Australian Bureau of Agricultural and Resource Economics and Sciences (ABARES). ABARES, a science and economics research bureau located within the Australian Government Department of Agriculture and Water Resources (DAWR), collects, analyses and disseminates a range of agricultural information to support government policy development and industry bodies across the agricultural industry. As Australia's National Statistical Organisation (NSO), the ABS has traditionally produced a range of data on the production and value of agricultural commodities and on the land management practices used by farmers, to inform information needs and support policy, programs and decision-making processes across the agricultural sector. The ABS also produces a range of natural resource and energy statistics, including environmental-economic accounts.

1.2Outside of ABS and ABARES, agricultural statistics and information are also produced by a range of other organisations including other Australian Government and state/territory agencies, industry bodies, and academic research institutions. These statistics include not only data directly collected via surveys, but also administrative datasets collected as a by-product of other processes – for example data collected under the Government's legislated agricultural levies system, and data collected through trade records and biosecurity databases.

1.3The evolution of Australian agriculture in the past few decades has been accompanied by increasing concerns regarding land and natural resource use and growing interest inthe sustainability of agricultural production.Thishas amplified the pressure on the national agricultural statistical system to meet a range of emerging information needs whilstat the same timeresponding to demand for more accurate, timely and detailed data from industry stakeholders. A report by the Australian Farm Institute in early 2013 identified a range of concerns with the availability and quality of Australian agricultural statistics, including those produced by ABS and ABARES (Potard, 2013). A number of these concerns had also been reflected through stakeholder consultation conducted by ABS and ABARES as part of their respective stakeholder engagement programs. Stemming from these criticisms both agencies recognised an opportunity to collaboratively review the agricultural statistical system and jointly act to address emerging challenges.

1.4In July 2013 the National Agricultural Statistics Review (NASR) was initiated as the first review of Australia's agricultural statistics system which was jointly undertaken by ABS and ABARES. The Review considered all aspects of the national agricultural statistical system, assessed its ability to inform decision-making and identified opportunities to improve the system both now and into the future.

2. Undertaking the National Agricultural Statistics Review

2.1 The purpose of the review was to assess the agricultural statistical system in Australia and its adequacy for informing decision-making in the agriculture, fisheries and forestry industries both now and into the future. The review aimed to identify:

- the priority information needs of stakeholders;
- where information needs are not being met by existing sources of data;
- overlaps and inconsistencies in data; and
- opportunitiesto improve efficiency in the national agricultural statistical information system.

2.2 For the purposes of the review, 'agricultural statistics' was broadly taken to mean the data, information, statistics or other knowledge that could be used to provide insights into agricultural activity (which for the purposes of the review, included fisheries and forestry activity) (ABS, 2014). The agricultural statistical system was considered to consist of:

- agricultural statistical assets;
- the statistical infrastructure underpinning these assets – including standards, frameworks and classifications; physical systems; and coordination and governance frameworks; and
- stakeholders – including users, producers, custodians and providers of agricultural statistical assets and information.

2.3 The NASR was undertaken in two phases over 2013 and 2014, and featured extensive stakeholder engagement in recognition of the critical importance of stakeholder contributions in identifying potential issues with the agricultural statistical system and ways to address them. These stakeholders included not only government agencies (at both the Australian Government and state/territory government levels) but also industry bodies, farmer representative organisations, academic and research institutions, and the broader community.In total across the two phases of the review's consultation, 43 organisations participated in a series of targeted forums, and 42 formal submissions were received throughout the consultation process.

3. NASR final report

3.1 The NASR Final Report summarised the review's findings as regards to the current state of the agricultural statistical system and its capacity to inform stakeholder needs both now and into the future.

3.2 Findings from the review indicated that generally the Australian agricultural statistical system is effective in informing government and stakeholder information needs. Stakeholders reported that about two-thirds of the statistical assets they usemostly met their needs (ABS, 2015:39). Throughout the consultation phase of NASR, stakeholders indicated that the majority of the statistics they used were generated by national or state or territory government agencies, and that the agricultural statistics were a valuable asset.

3.3However,a number of deficiencies and stakeholder concerns were identified throughout the review, that if addressed would improve the capacity of the system to more efficiently meet current and emerging needs. These deficiencies were identified through an assessment of the Australian agricultural statistical system against a set of best practice principles that characterised well-performing statistical systems internationally. These deficiencies were found to be driven by a set of systemic issues, namely:

- A lack of strong governance and coordination across the statistical system to effectively coordinate the contributions of stakeholders and ensure a planned and coordinated approach to statistical production;
- The agricultural statistical system has evolved in a somewhat reactive manner, without a central plan or strategy to guide investment, leading to potential duplication and inefficiency;
- An over-reliance on surveys and an under-utilisation of alternative data sources such as administrative sources, leading to areas ofhigh respondent burden, potential data quality issues and higher costs;
- Under-utilised opportunities to harness innovative new technologies (e.g. 'big data') and statistical methods to produce statistics more efficiently and with reduced burden; and
- The need for a culture of open data to make the best use of existing sources.

3.4 The Report recommended a number of actions to address these systemic issues and stakeholder concerns identified through the review, and to position the Australian agricultural statistical system to better align with international best practice. These recommendations included:

- The establishment of mechanisms to improve coordination and governance across the statistical system, including targeted and purposeful engagement to consult, provide direction, and encourage better coordination of government statistical collection activities; and an annual calendar of statistical activities to improve transparency and encourage coordination of statistical activity;
- The establishment of a Foundation Dataset that applies existing frameworks to organise and present data from multiple sources that will assist toidentify the highest priority information needs across the entire statistical systemto better target investment and plan future statistical activity;
- Encouraging stakeholders to explore alternative data sources to surveys, including through establishing an Administrative Data Initiative to explore greater use of administrative data across the statistical system;
- Adoptingnew and emerging technologies in statistical use and production, including making greater use of internet-based surveys, and encouraging more coordinated approach to invest in innovative new technologies and methods throughout the statistical cycle that will reduce burden and improve data quality; and
- Establishment of a one-stop portal for agricultural statistics to maximise the value of existing data sources and encourage a culture of open data.

4. NASR progress to date

4.1 The NASR recommendations articulated a pathway for ensuring the Australian agricultural statistical system continues to meet information needs in the most efficient and effective way possible. In addition, the collaborative approach taken to the review by ABS and ABARES, and the goodwill and relationships built through the review's extensive engagement process have generated additional benefits. These include stronger relationships between ABS and DAWR/ABARES; and stronger relationships between ABS, ABARES and other stakeholders in the agricultural statistical system. At the same time, the NASR has generated expectations amongst statistical users, and these need to be carefully managed within the context of available resources.

4.2 The NASR report recommendations were aspirational in nature, however, and while warmly accepted in principle by the two agencies, their implementation has required some pragmatism and prioritisation. Some of these have been addressed through natural program developments, for example the adoption of an 'e-form first' strategy for the 2016 Agricultural Census. Since the release of the final NASR Report in mid-2015, while continuing to explore opportunities across all the recommendations,ABS and ABARES have focused their collaborative efforts on a number of priority actions including the implementation of structured, purposeful engagementprocesses for the purposes of greater coordination and governance; the concept of a foundation data framework; and exploration of potential high-value administrative sources.

4.3**Coordination and governance:** As noted above,findings from NASR demonstrated a clear gap in effective governance and coordination of the national agricultural statistical system. Stakeholders clearly identified throughout the NASR engagement process the high value they placed on opportunities to be continually engaged with ABS, ABARES and other representatives from across the agricultural industry to discuss a range of statistical issues and opportunities. As stakeholders endorsed the statistical leadership of ABS and ABARES within the system,both agencies are maintaining a high level of engagement across industry groups and related stakeholders, such as government organisations with responsibility for natural resource management. To make the most effective use of time and resource, and ensure the engagement processes are focussed on specific actions or issues, ABS and ABARES will convene regular summits and other events targeted at specific audiences and topics.

4.4An example of this coordination and governance role is the recent Agricultural Statistics Roundtable,convened with stakeholders from industry Research and Development Corporations (RDCs) and government agencies, jointly led by ABS and ABARES. The focus of the Roundtable was to explore alternative data sources and technologies that could be utilised to increase the quality and accessibility of data, and ultimately begin to reduce survey burden on farmers. Many industry groups within Australia, including RDCs, are custodians of large amounts of data, either through statistical collections or by-products of other activities. Discussion during the Roundtable highlighted the work already being undertaken by industry groups leading collaborative projects to generate and utilise existing datasets. The focus of these industry led projects align with themes contained in the Enduring Goals for Australian Agriculture framework, focussing on areas such as agricultural supply-chain efficiencies, management of natural resources, and sustainability of farming practices.

4.5As well as providing valuable information sharing opportunity for attendees, at the conclusion of the roundtable ABS identified six key actions where the organisational statistical leadership role could be employed most effectively to support or deliver outcomes to enhance existing data sources. These actions are currently being developed by ABS and ABARES, but broadly include:

- Supporting industry collaboration to develop and implement common data standards and data sharing protocols to improve quality and accessibility of existing data sources;
- Exploring the potential of farm management systems, satellite technology and precision agriculture to contribute to official statistics;
- Engaging in viable pilot projects with industry to use administrative data to replace survey content;
- Demonstrating the value of environmental economic accounting as a framework for information relating to sustainable agriculture;
- Establishing a collaborative project with ABARES to extract statistical value from the agricultural levy process; and
- Exploring potential to combine and consolidate surveys across industry and government.

4.6**Foundation data frameworks:** The NASR recommended a Foundation Dataset for Australian Agriculture be established to inform the Enduring Goals for Australian Agriculture, address data gaps and better target future investment across the national agricultural statistical system. This recommendation recognised the utility of agreed information frameworks to help focus and prioritise the collection and dissemination of agricultural statistics, and ensure a direct relationship to policy requirements.

4.7To assist in focussing the Foundation Dataset concept as a foundation data framework for agriculture, the ABS is applying the System of Environmental-Economic Accounting, including the sub-system for Agriculture, Forestry and Fisheries (SEEA-AFF) to the Enduring Goals for Agriculture. This enables analysis of the relationships and linkages between the Enduring Goals that provide the core elements of the foundation data framework. In this way the SEEA and the Enduring Goals can be used together to produce meaningful indicators to meet a range of industry and policy needs.,

4.8The SEEA-AFF has potential to inform a range of policy issues relating to agriculture and the environment, including:

- understanding trends in natural resource use by activity, such as agriculture or forestry;
- addressing information gaps relating to sustainability risk for investors;
- understanding the competing demands for resource use from different activities, for example use of land and water;
- exploring the potential productivity benefits arising from improved farm management practices in specific regions or commodities; and
- understanding the potential economic and environmental impacts of climate events and bio-security risks on particular industries or products.

4.9**Agricultural administrative data initiative:**The NASR proposed an Administrative Data Initiative to develop methods for broader use of administrative data sources within the agricultural statistical system. This initiative will include examining legislative, privacy and commercial barriers to the use of data collected by governments and industry with the objective of reducing survey burden on farmers, and implementing a "collect once, use many times" approach. Two potential areas of action have been identified by ABS and ABARES to progress this initiative:

- Utilisation of levy data: Following the release of the report of the Senate Committee inquiry into the agricultural levies system in mid-2015, ABS and ABARES have been working together to advocate for the statistical value of levy data to be recognised in any legislative change. As a consequence an amendment to the Primary Industry Levies and Charges Collection Act was introduced to Parliament in 2016 which enabled not only RDCs, but also ABS, to access levy data for statistical purposes. If this amendment is enacted, it poses an important opportunity for ABS, ABARES and RDCs to work collaboratively together to harness the statistical value in this important data source and explore the potential for it to supplement or replace survey collection, thereby reducing burden.
- Microdata and Data Integration: ABS has an increasing focus on enabling access to microdata (unit record data) and on data integration projects while maintaining privacy safeguards. The Business Longitudinal Analytical Data Environment (BLADE), held by the ABS, is an important example of a data integration methodology ABS has developed to enable greater access to business data for statistical purposes. BLADE enables integration of ABS business survey data with administrative data sources, such as tax information, using the ABS Business Register as the integrating spine. BLADE is designed to support analysis of the micro economic drivers of business performance, competition and productivity and provide innovative

responsive solutions to client data needs. Already ABS and ABARES are discussing how this might support ABARES analyses of the sector.

5. Next steps for a whole of sector approach

5.1 As a result of the NASR consultative process, NASR outcomes and ongoing work between ABS and ABARES, both agencies continue to be well-positioned to exercise joint statistical leadership across the Australian agricultural statistical system, marshalling support from and coordinating activity with a range of other stakeholders in both government and industry.

5.2 However to ensure that policy directions for Australian agriculture are maintained and supported long term through the provision of relevant statistical information, and to fully address the systemic issues identified through NASR, an increasingly whole-of-government approach will be needed. The combined demand for agricultural commodity data, as well as complementary information on environment, landand natural resource management, will lead to increasing pressure on the national agricultural statistical system to ensure statistics are collected and disseminated as efficiently and effectively as possible to continue to support evidence based decision making.The recent Roundtable was a step in this direction, where opportunities for collaboration were identified and currently being implemented into the ABS work program.

5.3 There are challenges in responding to the directions established through the NASR, however. Reducing dependence on surveys and transitioning to new data sources while maintaining key time series and the credibility of official statistics will require creating of new methodologies and statistical infrastructure. The increasing diversity of information needs and potential sources will also stretch the capacity and resources of the current statistical system.

5.4 To meet these challenges, further leveraging the collaborative relationships built with stakeholders across government, industry and the wider community will be critical. NASR has provided a model for a partnership approach to developing strategic, system-wide solutions to existing and emerging agricultural, land and other environmental policies. However, it is not feasible, or desirable, that the ABS as Australia's NSO lead or deliver in its entirety the leadership and statistical data required in achieving this goal.

5.5In an environment of fiscal responsibility, ABS is best placed to focus its capabilities on producing and disseminating critical data to support the highest-priority information needs, and on its statistical leadership role. This role includes coordinating the efforts of other users and producers of statistics, finding ways to unlock the value of administrative and other data sources for public good, developing and promoting standards and quality requirements, and providing the supporting capabilities for complex statistical products such as data integration.

6. Conclusion

6.1 Maintaining Australia's natural wealth, including the land on which agriculture occurs, is an ongoing challengefor government and industry both now and into the future. Meeting this challenge requires increasingly more complex information,which is putting pressure the national agricultural statistical system and leading to concerns at the capacity of the system to meet these demands. In this context ABS and ABARES took the opportunity to jointly undertake the NASR and identify and address these concerns.

6.2 While the challenges remain, the NASR has laid the foundation for joint coordination and statistical leadership across the national agricultural statistical system, with all stakeholders having a part to play. In this context and in collaboration with ABARES, the ABS, as Australia's NSO, will look to re-align and renew its role of statistical leadership, coordination and integration of high priority statistical information. As this occurs, other stakeholders will need to assume greater responsibility for the collection of relevant and valued statistical data to ensure the Australian national agricultural statistics system remains agile and policy relevant.

ABSTRACT

The economy of Pakistan is predominantly dependent on Agriculture, which is the largest sector of the economy and contributes about 21% to the Gross Domestic Product. Most of the population depends on agriculture either directly or indirectly as it accounts for half of the employed labor force and is the largest source of foreign exchange earnings for the country. The Agricultural sector is also one of the key determinants of social welfare. As such, agricultural productivity growth is essential for poverty reduction and the provision of food for the existing population. Due to its importance, agriculture poses various policy implications for policy makers and researchers. However, there exist several deficiencies in agricultural research. A survey study is conducted about the actual statistical facilities in agricultural research in Pakistan and found that there is no proficient system for the proper designing of experiments, data collection, statistical analysis, or interpretation and communication of results. Furthermore, the sector lacks an adequate mechanism for statistical advice to improve research projects or proposals, which are the basic ingredients in promoting food and agricultural research. Even those agricultural centers that have statistical facilities are either not functioning properly or lack sophistication with the use of statistical programs and packages. Agricultural universities/faculties/colleges are facing a broad deficit of adequate and highly qualified statistical personnel, except for a few statisticians on executive boards with many responsibilities. Agricultural and food research institutes and centers in Pakistan are not provided with expert statisticians. Both policy makers and researchers need timely and accurate official statistics, ranging from the data of annual rainfall to an average annual temperature, and statistical models and analyses that apply these data for planning purposes to make better decisions and policy. Thus, there exists a need to integrate the work of agricultural scientists

with statisticians. Hence, in this paper we propose to create a statistical collaboration laboratory to play this vital role in integrating statistical knowledge with agricultural research. The tentative name of this statistical laboratory will be the "**P**akistan **La**boratory for **S**tatistical **C**ollaboration (PLASCO)." The main objectives of PLASCO will be to provide an integrated platform for statisticians and researchers to collaborate to advance agriculture; to train the next generation of statisticians to become useful agricultural statisticians; to build the statistical capacity of agricultural researchers through collaborations with statisticians, seminars, workshops, conferences, and refresher courses; and to create a healthy statistical computing environment with access to statistical software. This laboratory will create bridges between statisticians and researchers (non-statisticians) from various departments and will play an important role in improving the quality of agricultural research. The support and mentorship provided to agriculture researchers at the laboratory will improve their ability to design experiments, collect and analyze data, and interpret and communicate the results. Establishing such a laboratory will require financial resources and commitments from agricultural researchers and administrators at the agriculture and food institutes in Pakistan. National and international funding agencies will be contacted and briefed about the importance of the project and how it will be conducted. Mutual funding from more than one agency may be possible if all the agencies adhere to a mutually agreeable standard. Moreover, because of the great need for improved statistics in agricultural research, many laboratories will be established on the same standard throughout Pakistan. This is not only a single project but can serve as a laboratory test case and a role model for other developing countries.

Keywords: Statistical Capacity Building, Agricultural Research, Research Integration, Statistical Collaboration Laboratory

1. Introduction

Pakistan traditionally is a country with an agricultural economy. The majority of its population (about 70%) heavily depends on agriculture or related activities with strong backward and forward linkages. Moreover, the food security for the masses and raw material production for domestic agro-based industries are also relying on this sector. As the largest sector of the economy, it contributes 20.9% for the Gross Domestic Product (GDP) and 43.5% of the employment (Economic, 2015). This sector has four sub-sectors namely: crops, livestock, fisheries, and forestry. It is also mentioned in the draft report of "Agriculture and Food Security Policy" that Pakistan's Government is really interested in value added growth of the agriculture sector in terms of domestic and export markets. According to the Ministry of Planning and Development, the agriculture sector needs to grow at 5 percent to reduce poverty and ideally should reach the growth targets of 7-8 percent to improve the national economy of Pakistan (MNFSR, 2016). A positive relationship between agricultural growth and GDP exists such that a one percent increase in the agriculture growth rate can bring a 0.34% increase in the GDP growth rate (Hussain & Khan, 2011).

This agrarian economy is moving towards industrialization with an advancement in technology and adoption of modern trends in agriculture. Therefore, there must be precise consultations, collaborations, and policy recommendations to lay down the foundation for agriculture-led growth in the country. On the other hand, several deficiencies exist in the agricultural research system of the country. There is no proficient system for the proper designing of experiments, data collection, statistical analysis, and communication of results. In addition, this sector lacks an adequate mechanism for seeking statistical advice to improve research projects or proposals, which are the basic ingredients in promoting food and agricultural research. The agricultural and food research institutes and centres are working in Pakistan, but there is a lack of expert statisticians in these institutes and centres. Both policy makers and researchers need timely, relevant, and accurate official statistics, ranging from the data of annual rainfall to an average annual temperature, and statistical models and analyses that apply these data for planning purposes and making better decisions. Thus, there exists a need to integrate the work of agricultural scientists with statisticians.

The current paper is a review of an attempt to bridge the relationship between statisticians and non-statisticians (researchers), especially agricultural researchers, with the proposal of creating a unique kind of statistical collaboration laboratory to play a vital role in the integration of statistical knowledge and capacity building with agricultural investigations. The trained statisticians of this laboratory will collaborate with agricultural researchers to provide innovations and ultimately solutions to raise the incomes of impoverished farmers. This idea of developing statistical collaboration laboratories in the agricultural research system was also proposed by Msemo and Vance (2015a). They describe that this type of laboratory can be considered to be a collection of statisticians that emphasizes building relationships with researchers that are collaborations rather than just consultations. The trained statisticians of such laboratories focus on helping their clients to answer their research or business questions (colloborations) rather than helping them just answer their statistics questions (consultations). Another beneficial feature of such laboratories is their ability to build statistics capacity by training young statisticians and to create new statisticial knowledge via research on applied problems (Vance 2015).

This is not an empirical study, rather it is a brief analysis of one of the problems plaguing agricultural research in Pakistan and a proposal of a potential solution to increase agricultural productivity in Pakistan. We are not attempting to reform the current agricultural research institutes. Instead we are proposing to introduce an innovative model to improve the essential statistical aspects of agricultural research. This model, if successful, will spread organically throughout the agricultural research enterprise to improve collaborations between statisticians and agricultural researchers and will, ultimately, lead to increased agricultural productivity and improvements in the livelihoods of Pakistani farmers.

Sections 2 and 3 in this paper describe the problems and current state of the agriculture sector in Pakistan. Section 4 describes the proposed model of a statistical collaboration laboratory to become part of the worldwide LISA 2020 network. Section 5 concludes with some of the challenges facing the agriculture section of Pakistan and our attempts to overcome them to achieve our goal of improving agricultural productivity through the creation of unique kind of statistical laboratory.

2. Problems of Agriculture Sector in Pakistan

The agricultural sector of Pakistan is the backbone of the country's economy. But the growth of this sector is facing many problems. This is the reason of very low per acre yield as compared to other developed agricultural countries, and it is true that the magnitude of the agricultural problems undoubtedly crippled the economy. In 1947, the share of this sector to GDP was 53% which has shrunken down to around 21% last year. These problems of the agricultural sector can be categorized into four main and 28 subsections as below in Table 1 (Mughal, 2016).

Table 1: Problems in the agricultural sector

Techno-Economic Problems	**Natural Problems**	**Socio-Economic Problems**	**Financial Problems**
Limited cultivable area	*Various plant diseases*	Consumption oriented	Lack of credit

Water logging and salinity	Natural calamities	Farmer's litigation	Poor financial positions of farmers
Slow growth of allied products	Scarcity of HYV seed	Joint family system	*Instability in market price*
Low per hectare yield	Under utilization of land	*Illiteracy and Ill-health*	Shortage of agricultural finance
Inadequate infrastructure		Political instability	
Uneconomic land holdings			
Old methods of production			
Inadequate supply of agriculture inputs			
Lack of irrigation facilities			
Inadequate agricultural research			
Lack of R&D and neglect in education & training of farmers			
Problem of land reforms			
Defective land tenure system			
Subsistence farming			
Low cropping intensity			
Improper crop rotation			

According to the Minister of Finance, Ishaq Dar, the Ministry of National Food Security and Research (MNFSR) has been running without a national agriculture policy since its creation in 2011. Both the World Bank and the Asian Development Bank pointed out that agricultural growth will miss its annual target of 2.7 percent due to a drop in cotton output, which partly offset the improvement in sugarcane and rice crops. Minister Dar also stressed that in order to meet the challenges of food insecurity and malnutrition, it was imperative to employ the latest technological advancements and innovative techniques to improve the productivity of this sector (Dar, 2014). The draft report of “Agriculture and Food Security Policy” has been submitted by this ministry to the Government of Pakistan (MNFSR, 2016). The above problems of the agriculture sector and their possible solutions are mentioned in this draft. The statistical laboratory we propose in Section 4 can play a very important role in most of the recommended solutions especially in those in italics in Table 1 above.

3. Current State of Agriculture Research and Statistics in Pakistan

Some important structural changes have taken place in the agriculture section in the recent years especially in the important subsector of livestock. This sector is contributing a great amount to agricultural GDP. Fisheries and forestry were also minor contributors to agricultural GDP in the past but are now growing rapidly. Cotton is also becoming as important as wheat in terms of value added, with a one-fifth share of total earnings. However, the rice and sugar crops have fallen from a 20 percent share in the early 1970s to 15 percent today.

The Food and Agriculture Organization (FAO) reported in the report of the Nineteenth Session of the Asia and Pacific Commission on Agricultural Statistics that Pakistan had a history of conducting the agricultural census every ten years since 1960 (FAO, 2003). Five agricultural censuses in Pakistan have been successfully conducted in 1960, 1972, 1980, 1990, and 2000. The latest, which is the sixth one in the series, was conducted in 2010 by the Pakistan Bureau of Statistics (PBS) of the Government of Pakistan with the objectives to generate basic information on the structure of agriculture; to develop detailed basic information about the agricultural resources, state of their utilization, and to find out the degree of acceptability of modern farming practices among the farming community for the purpose of regional, provincial and national development, planning, and research in the field of agriculture; to collect information about livestock population; and to fulfill data needs of the international agencies like FAO which require the country's information for a worldwide study of agricultural resources in order to formulate international policies in matters relating to the supply of food and raw materials on sustainable basis (PBS, 2010).

The first author conducted a telephonic survey study to know about the actual statistical facilities in agricultural research in Pakistan and found that there is no proficient system for the proper designing of experiments, data collection, statistical analysis, or interpretation and communication of results. Currently, Pakistan has a total of 92 agricultural research institutes, including 15 agriculture, animal, and textile universities; 4 agricultural facilities; 6 agricultural colleges and institutes; 64 agriculture research centers; and 3 other agriculture-related educational departments.

The research conducted, techniques taught, and skills imparted in these institutions rarely extend down to the level of small farmers. For example, farmers need to know how to make optimal use of land, how to use fertilizers and pesticides, and what amount of water is exactly useful and necessary for any crop. Lack of management on the part of farmer is another huge problem.

There are no statistical collaboration laboratories in the country similar the one proposed in Section 4. Even those agricultural centres that have statistical facilities are either not functioning properly or lack sophistication with the use of statistical programs and packages. Furthermore, agricultural universities/faculties/colleges are facing a broad deficit of adequate and highly qualified statistical personnel, except for a few statisticians on executive boards with many responsibilities. Agricultural and food research institutes and centres in Pakistan are not provided with expert statisticians. It is indicated that in the research institutions of Pakistan, a diverse nature of data are generated from various discipline, so the actual insights of these processes can only be well understood by applying the most relevant statistical techniques with advanced statistical programs. The correct interpretation of results obtained needs sufficient knowledge of statistical methods (Hussain, Murshid, & Safeeullah, 2014). It is also observed that a variety of statistical techniques have been used in published articles, but the frequency of advanced statistical methods applied was quite low as compared to journals in more advanced countries (Akhttar, Shah, Rafiq, & Khan, 2016). These gaps can be filled through this proposed laboratory by enhancing the basic skills of junior statisticians by imparting trainings, short courses, and workshops.

Improvement in agricultural research and education is a continuing requirement for development, not only for developing better seeds, improving cultivation methods, and better using other inputs, but also for finding out the best combinations of inputs for conditions in Pakistan. Unfortunately, this area has not received great attention and suffers from financial deficits and lack of skilled personnel. Moreover, there is lack of extension services which is very important in providing farmers with systematic access to new innovations in farming practices, multiple cropping, and use of physical inputs. This can be done through arranging dissemination seminars and other related activities through the proposed statistical laboratory. In order to raise the potential of agricultural production, continuous improvement in the research for agricultural growth is necessary. The specific areas of research include the development of high yielding, short duration, disease and drought resistant varieties of major food and cash crops in Pakistan tailored to the situation prevailing in different areas of the country.

4. Proposed Model of a Statistical Collaboration Laboratory

The LISA 2020 Program was created to build statistics capacity and research infrastructure in developing countries to help scientists, government officials, businesses, and NGOs use data to solve real-world problems and make decisions. In this program, statisticians from developing countries are trained to effectively communicate and collaborate with non-statisticians and helped to create statistical collaboration laboratories modeled after the University of Colorado Boulder's Laboratory for Interdisciplinary Statistical Analysis (LISA) at their home universities or institutions. These new statistical collaboration laboratories foster education in collaborative statistics and promote the proper application of statistics and data science to solve real-world problems (Vance, 2015b). This is important because, when implemented in Pakistan, the statistical laboratory will enable Pakistani agricultural researchers to collaborate with local statisticians to solve local problems and generate real-world impact for the agricultural sector.

The LISA 2020 network is based at the University of Colorado Boulder in USA and is comprised of four statistical collaboration laboratories in Africa and one in Brazil (Msemo & Vance, 2015) (Awe, Crandell, & Vance, 2015) (Goshu, 2016). The program's goal is to create a well-connected network of 20 statistical laboratories in developing countries by the year 2020, including a statistical laboratory in Pakistan to help agricultural researchers better apply statistics. The proposed model is detailed below.

4.1 Pakistan Laboratory for Statistical Collaboration (PLASCO)

Though many details remain to be worked out, we propose to create the **P**akistan **La**boratory for **S**tatistical **Co**llaboration (PLASCO) at Nuclear Institute for Food and Agriculture (NIFA), Peshawar, Pakistan a subsidiary institute of Pakistan Atomic Energy Commission. The overall vision of PLASCO will be to promote effective collaborations between statisticians and agricultural researchers that lead to improvements in agricultural productivity in Pakistan. The mission of PLASCO will be to train statisticians and data scientists to become effective interdisciplinary collaborators, provide research infrastructure for the agricultural sector to enable and accelerate high impact agricultural research, and engage with the agriculture community to improve statistical skills and literacy widely.

Currently, agricultural researchers in Pakistan may receive statistical support from isolated statistics professionals working in various places. PLASCO will be one point of consolidation of statistical resources to act as a bridge between statisticians and other researchers across the country. We envision PLASCO helping to achieve the following objectives:

i) Serve as a center for researchers and statisticians to collaborate to solve agricultural research problems and answer agricultural research questions.
ii) Enhance the existing statistical support services which are difficult to find due to their distribution in different regions.
iii) Develop new statistical methods to address emerging problems in science and technology.
iv) Raise the level of statistical skills and literacy through seminars, workshops, and short courses.
v) Become a source of statistical software for agricultural researchers to access.

4.2 Outline of Proposed Implementation Plan

A statistical collaboration laboratory is, in essence, a collection of technically trained statisticians who are also well trained in the essential non-technical skills of communication and collaboration to effectively work with researchers to answer research questions. It will be directed by a Ph.D.-level statistician and supported by other Ph.D. and M.S.-level statisticians as funding availability and demand from researchers dictate. A major source of statistical expertise and workforce in PLASCO will be statistics M.S. and Ph.D. students who are trained to collaborate with agricultural researchers in the designing of experiments, data collection, statistical analysis, and communication of results.

PLASCO will also be a center for applying statistics in agricultural research, and as such will require physical space for collaboration meetings between statisticians and researchers; workshops, short courses, and training seminars in various topics in statistics, and a computer lab equipped with sufficient computers and modern software for statistical analysis of agricultural data.

We envision that several agencies will be recruited to sponsor and fund PLASCO, including the Pakistan Science Foundation (PSF), Pakistan Agricultural Research Council (PARC), Pakistan Atomic Energy Commission (PAEC), Higher Education Commission (HEC), Pakistan Academy of Sciences (PAS), International Food and Agriculture Organizations. NIFA will be primarily responsible for executing the implementation plan and for operation and maintenance of PLASCO.

Leadership from the LISA 2020 Program will provide advice and logistical assistance to PLASCO. For example, members of the LISA 2020 network will provide software recommendations and trainings to build the capacity of the young statisticians in PLASCO. Decision making regarding implementation of this project will be carried out by the local official of NIFA in consultation with the LISA 2020 leadership.

After developing a final implementation plan, the equipment, materials, and commodities necessary for PLASCO will be arranged by NIFA via the support of proposed funding agencies. Likewise, NIFA will host and sustain this laboratory.

Because much of the infrastructure and physical space required to create and run PLASCO will be provided by NIFA, the budgetary requirements of PLASCO are relatively minimal. Initially, PLASCO will engage a full-time Ph.D.-level statistician to direct and manage the statistical laboratory, costing approximately US$ 12,000/annum. It will require an administrative assistant and an accountant to coordinate the lab’s activities, costing approximately US$ 12,000/annum. It will require several statistics students to work in PLASCO to gain practical training and experience. These students will be paid a nominal sum of approximately US$ 4,800/student/annum. PLASCO will also require the purchase of new equipment such as a multimedia projector and white screen for presentations and workshops; five computers, monitors, and associated software; statistical books and manuals; equipment for internet connectivity; and a backup electrical generator, costing approximately US$ 13,000, for a total estimate of US$13,000 in start-up costs and approximately US$ 48,000 in annually recurring costs.

5. Conclusion

Pakistan is an agriculture country but the agriculture sector is still facing many challenges. Therefore, the use of modern techniques, provision of credit facilities, basic infrastructure, and agricultural research facilities are needed to overcome them. We believe that some of these issues would be resolved through the creation of the proposed statistical collaboration laboratory (PLASCO). The statisticians within PLASCO will be trained to effectively collaborate with agricultural researchers of all types, including agronomists and agricultural economists, to respond to the practical needs of the agricultural sector in Pakistan. This laboratory will provide an integrated platform for statisticians and researchers to work together to advance agriculture; to build the statistical capacity of agricultural researchers through collaborations with statisticians, seminars, workshops, conferences and refresher courses; and to create a healthy statistical computing environment with access to modern statistical software. This laboratory will create bridges between statisticians and researchers (non-statisticians) from various departments and will play an important role in improving the quality of agricultural research. Establishing such a laboratory will require financial resources and commitments from agricultural researchers and administrators at the agriculture and food institutes in Pakistan. National and international funding agencies will be contacted and briefed about the importance of the project and how it will be conducted. Moreover, because of the great need for improved statistics in agricultural research, many laboratories may be established in the future on the same standard throughout Pakistan. This is not only a single project but can serve as a laboratory test case and a role model for other developing countries.

ABSTRACT

Official statistics, and the underlying datasets, are essential for stakeholders to take informed decisions. National Statistical Officers (NSOs), however, often have little systematic information on the use of official statistics by stakeholders. This makes it challenging to appreciate whether investments to improve the quantity and quality of official statistics are generating good returns or, rather, whether they represent a net cost for taxpayers. The lack of the feedback on the use of official statistics also prevents NSOs to allocate their scarce resources more efficiently, i.e. to generate statistical products that better suit the information needs of stakeholders.

This paper first analyses the extent to which public and private sector stakeholders in Tanzania and Uganda use official agricultural statistics as provided by the National Bureau of Statistics (NBS) and the Uganda Bureau of Statistics (UBOS) respectively. It builds on data of an online survey implemented by NBS and UBOS in the first quarter of 2016. Results show that stakeholders use only a minor share of the agricultural data collected by the NSOs. The paper then proposes two innovations to enhance the utilization of agricultural data and statistics, which have been tested and implemented using household level livestock data in both Tanzania and Uganda. The first is to complement investments that improve the quantity and quality of official statistics with investments that collect the information needed for decision-makers to design and implement policy reforms. Collecting data to depict, monitor and evaluate the situation on the ground, which is what official statistics largely do, is in fact not sufficient on its own to generate evidence to find effective ways to improve it. The second innovation is on data utilization: data can be disseminated not only in NSOs' reports and as statistical software files but also in simple spreadsheets with embedded statistical commands, which suit the need of stakeholders. This approach empowers stakeholders and is implementable with a more efficient allocation of NSOs' available resources.

Keywords: agricultural data utilization; data dissemination; evidence-based decisions

1. Introduction

The importance of strengthening the evidence base for policies and investments cannot be over-stated. Target 17.18 of the UN Sustainable Development Goals aims to "*increase significantly the availability of high-quality, timely and reliable data … relevant in national contexts*", and target 17:19 to "*develop measurements of progress on sustainable development*". The UN Report "A World that Counts: Mobilising the Data Revolution for Sustainable Development" reads: "*Data needs improving. Despite considerable progress in recent years, whole groups of people are not being counted and important aspects of people's lives and environmental conditions are still not measured*" (UN, 2014).

A number of initiatives and investments are currently being implemented for improving the quantity and quality of data for decision-making. Cases in point are the Partnership in Statistics for Development in the 21st Century (PARIS 21); the Global Strategy to Improve Agricultural and Rural Statistics (GSARS); the Living Standards Measurement Studies – Integrated Surveys on Agriculture (LSMS-ISA); and the May 2016 Bill & Melinda Gates Foundation's commitment to provide national statistical offices with USD 80 million in the next three years to collect gender-related data (BMFG, 2016). Underpinning these investments is the assumption that the generated information will contribute to better decision-making. However, there is so far little systematic evidence on the use of official statistics by stakeholders. This makes it difficult for National Statistical Officers (NSOs), and for other interested stakeholders, to appreciate whether investments to produce quality statistics are generating good returns; the lack of the feedback on the use of official statistics also prevents NSOs to improve the way they allocate their (scarce) resources.

This paper first analyses the extent to which public and private sector stakeholders in Tanzania and Uganda make use of official agricultural data and statistics, as produced by the Tanzania National Bureau of Statistics (NBS) and by the Uganda Bureau of Statistics (UBOS) respectively. It builds on an online survey on the utilization of NSOs agricultural data and statistics implemented by NBS and UBOS in the first quarter of 2016. Results suggest that stakeholders use only a minor share of the agricultural data collected by the NSOs, and notably only the statistics published in NSOs reports and websites. The paper then proposes two innovations to enhance the utilization of agricultural data and statistics, which have been tested and implemented using household level livestock data in both Tanzania and Uganda. The first is to complement investments that improve the quantity and quality of official statistics with investments to collect the information needed for decision-makers to design and implement policies and investments on the ground. Collecting data to portray, monitor and evaluate the situation on the ground, which is what official statistics largely do, is in fact not sufficient on its own to generate evidence to find effective ways to move forward. The second innovation targets data utilization: microdata can be disseminated not only in NSOs' reports and as statistical software files but also in simple spreadsheets with embedded statistical commands, which suit the need of stakeholders. This approach empowers stakeholders and is implementable with a more efficient allocation of NSOs' available resources, provided of course that all ethical and legal issues associated with microdata dissemination are successfully addressed

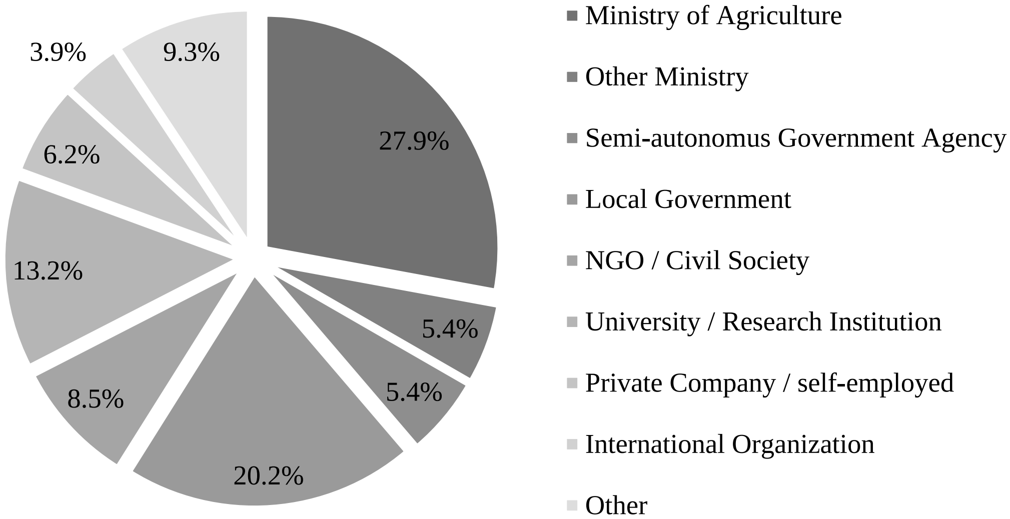
The next section presents the NBS and UBOS survey on stakeholders' utilization of agricultural data and statistics. Section 3 illustrates how NBS and UBOS innovated to improve stakeholders' utilization of livestock data and statistics in Tanzania and Uganda respectively. Section 4 presents conclusions.

2. The (under)utilization of NSO's agricultural data and statistics

In February and March 2016, the Tanzania National Bureau of Statistics and the Uganda Bureau of Statistics joined forces to undertake an online survey among agricultural stakeholders to appreciate their utilization of official agricultural data and statistics. The survey collected information on respondents' affiliation; relevance of agricultural data; sources of data; purpose of using the data; available statistical-related software; outputs produced; ease of access and ease of use of agricultural data; and other.

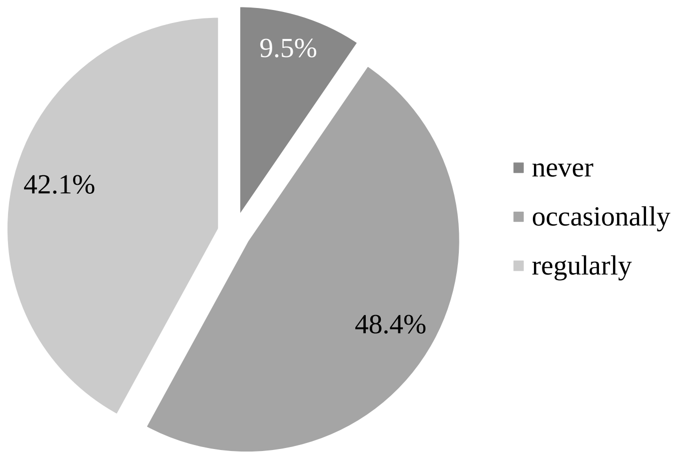
NBS and UBOS sent an email with a hyperlink to the survey to 491 potential respondents, of which 263 in Uganda and 228 in Tanzania. The target population included all UBOS and NBS agricultural-related contacts for which an email address was available. 149 stakeholders or 30 percent of the target population completed the survey, which is an expected response rate for online surveys (Nulty, 2008; Shih and Fan, 2008). Respondents largely include staff in national and local governments responsible to invest taxpayers' money for agricultural development (fig.1). In particular, 59 percent of all respondents work for the public sector, including the Ministry of Agriculture (27.9%); Other Ministries (5.4%); Semi-autonomous Government Agencies (5.4%), such as the Dairy Development Authority; and Local Governments (20.2%). Other respondents represent the private sector, the civil society, the academia, and international organizations.

Fig. 1. *Survey respondents by affiliation*



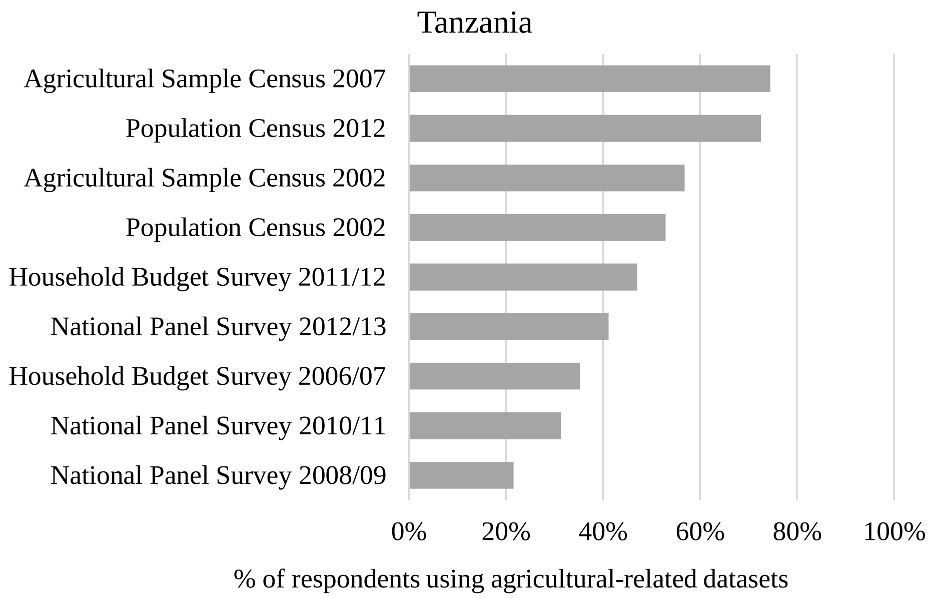
Respondents highly value NSOs' agricultural data and statistics: 76 percent and 35 percent of them indicate that agricultural data and statistics are "very important" and "important" for their work respectively. At the same time, 90 percent report to utilize NSOs' agricultural data and statistics: 42 percent use them on a regular basis, that is at least four times per year or more; and 48 percent use NSOs' agricultural data and statistics occasionally, i.e. less than once per quarter.

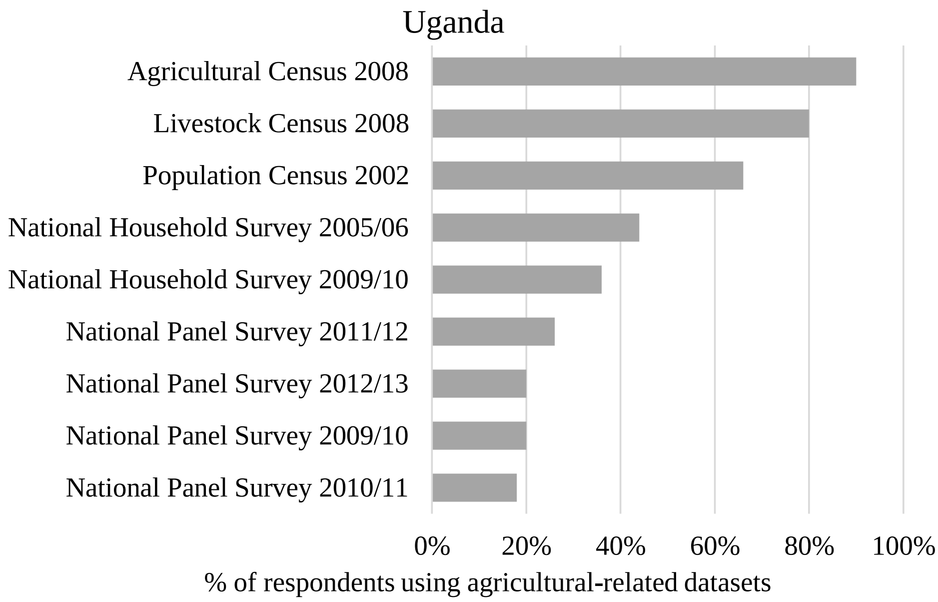
Fig. 2. *Frequency of use of NSOs' agricultural data and statistics*



Respondents primarily use census data, with 70 percent and 81 percent on average utilizing data either from the Population and Housing Census or the Census of Agriculture (Livestock) in both Tanzania and Uganda respectively. Fewer respondents utilize data from sample surveys, notably an average of 35 percent in Tanzania and 27 percent in Uganda.

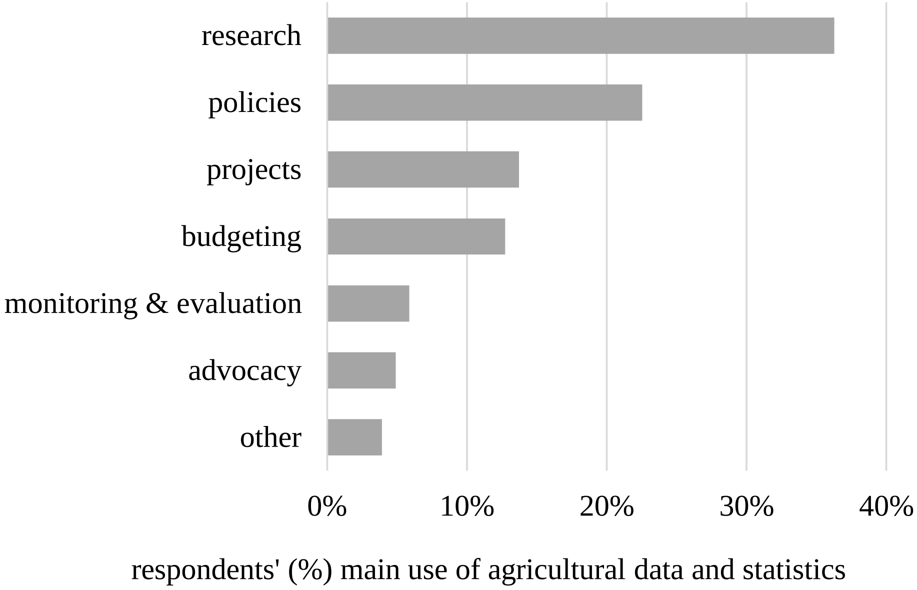
Fig. 3. *Main agricultural data and statistics utilized by stakeholders*





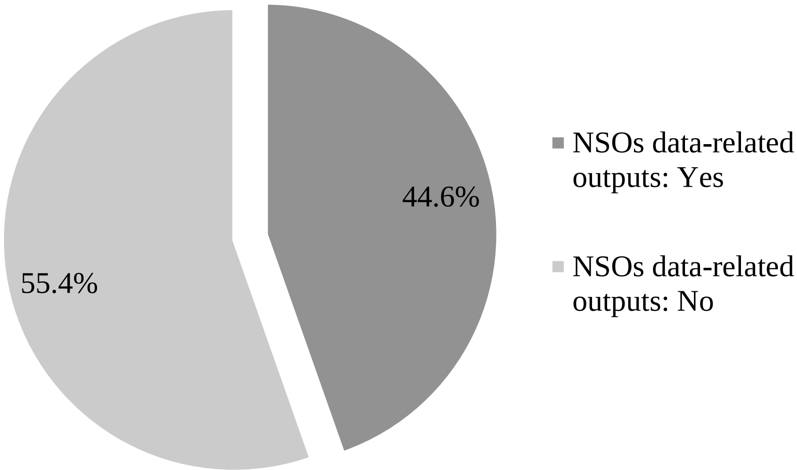
Research is the main single purpose for using official agricultural data and statistics (35% of respondents). However, the use of agricultural data and statistics for designing policies and projects, budgeting, monitoring and evaluation accounts for 55 percent of all uses. This is consistent with the finding that about 59 percent of all respondents are employed by the public sector.

Fig.4. *Purpose for using NSO' agricultural data and statistics*



The survey results also reveal that 45 percent of the respondents contributed to some outputs that build on NSOs' agricultural data and statistics, while 55 percent did not contribute to any. This is consistent with the evidence that about 42 percent of all respondents claim to use NSOs' agricultural data and statistics with regularity.

Fig.5. *Share of respondents producing outputs based on NSOs' agricultural data and statistics*



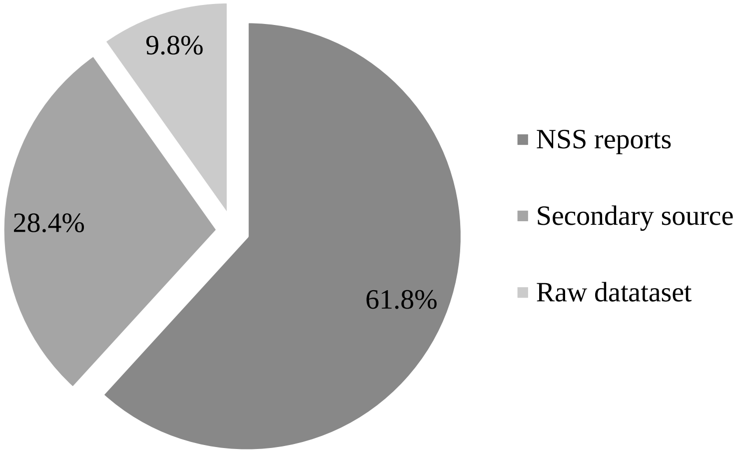
The story so far is one of a good use of NSOs' agricultural data and statistics. However, a closer look at the survey data reveals not only that over 58 percent of stakeholders do not make use or only occasionally use available NSOs' agricultural data and statistics (fig.2), but also that they only use a minor part of the collected data. Fig.6 displays stakeholders' source of NSOs agricultural data and statistics, including NSOs' reports; secondary sources, such as papers and documents that build on NSOs' data and statistics; and raw datasets. The figure indicates that 62 percent of all respondents find agricultural data and statistics in NSOs' reports; 28 percent find them in secondary sources; and 10 percent access the raw datasets for different use.

The Census Reports admittedly comprise a detailed analysis of the collected data – largely because Censuses gather relatively few information – but provide information only on those aspects of agriculture that change slowly over time. This information is valuable for policy makers when complemented with more detailed and frequent data on agricultural production practices, including on non-structural variables such as on type of fertilizers used or crop yield. Sample surveys are the tool that provide this information to decision-makers. The issue is that NSOs' reports of sample surveys only contain statistics for few of the collected data. For example:

a) The NBS Report of the Tanzania 2011/12 Household Budget Survey presents one table on land ownership by plot size and one on land ownership by type of tenure (NBS, 2014). The underpinning dataset, however, also includes information on the use of the plot (e.g. cultivated, rented out; etc.); on income from renting; on the value of in-kind production; on soil type; on the quality of the soil type; on irrigation; and on the value of the land parcel. Unless stakeholders analyse the raw data, all this latter information remains unexploited; and
b) The UBOS report of the 2011/12 National Panel Survey (NPS) includes two tables and one graph on animal rearing, which all focus on livestock ownership (UBOS, 2013). The NPS agricultural questionnaire, however, includes about 80 questions on livestock. Unless stakeholders analyse the raw data almost all of the collected information on livestock is not used for decision-making.

The evidence that only 10 percent of the stakeholders access and use NSOs agricultural datasets (fig. 6) indicates, therefore, that official agricultural data and statistics are largely unutilized for decision-making. This is an issue also because stakeholders often participate in survey design and would be eager to analyse available data. The implication is, at least for the agricultural data of Tanzania and Uganda, that the budget allocated for data collection and dissemination is not supporting a wide use of the data. The NSOs should innovate to facilitate the use of agricultural data and statistics by policy-makers and other stakeholders, thereby ensuring that the resources allocated for data collection are an investment with good returns for society and public at large.

Fig.6. *Source of agricultural data and statistics by share of stakeholders*



3. Innovations to enhance the utilization of agricultural statistics

Since 2011, NBS and UBOS have been collaborating with the Tanzania Ministry of Agriculture, Livestock and Fisheries (MALF), the Uganda Ministry of Agriculture, Animal Industry and Fisheries (MAAIF) and the FAO Livestock in Africa: Improving Data for Better Policies Project to increase the quantity and quality of livestock data available to decision-makers, while at the same time ensuring their use for policy purposes. There are two major lessons out of this process:

a) The first is that investments to improve the agricultural (livestock) statistical system generate good returns particularly when complemented with investments that generate the information needed for decision-makers to design and implement policies and investments on the ground. Collecting data to portray, monitor and evaluate the real situation on the ground, which is what official statistics largely do, is in fact all but sufficient to generate evidence to find effective ways to improve it; and
b) The second lesson is that NSOs can adopt simple and low-cost methods to disseminate entire or selected sections of complex datasets to stakeholders, which allows them to perform their own statistical analysis. In particular, as in most cases stakeholders only perform explorative data analyses, disseminating data in simple spreadsheets with embedded statistical commands is an effective way to empower them.

3.1. Evidence-based decision-making: beyond official statistics

"*The real value of data is that they can track performance and serve to indicate to decision-makers whether they have met their specified targets or not. While this is, of course, vital, they do not help decision-makers understand what they need to do in order to improve their performance going forward*" (UK Statistics Commission, 2007). This simple fact is poorly understood: investments to improve the statistical system, in fact, are rarely complemented with investments to generate data and information for decision-makers to effectively design and implement policies on the ground. For ease of clarity, let's assume that the decision-maker is the Ministry responsible for the agricultural sector; and that the Ministry's overarching goal is the design ex-novo of a comprehensive agricultural sector policy and associated investment plan. To this end, data and information needs span five main domains (Pica-Ciamarra and Baker, 2014).

a) ***Agriculture, economic growth and poverty reduction***. Data and information are needed to show that the development of agriculture, and in particular a given new initiative in the sector, contributes to one or more broader socio-economic development goals of the country. Statistics representative of the agricultural as a whole, of typologies of farmers and production systems, are necessary to this end. Official statistics serve this purpose, such as living standard measurement studies, agricultural / farm surveys and household budget surveys;

b) ***Productivity constraints***. Identifying the binding constraints that prevent different types of farmers from making efficient use of their productive resources is indispensable in identifying priority areas for policy reform and investment. Such constraints could include, for example, inadequate access to seeds and fertilisers, or animal disease prevalence. The agricultural census and/or sample farm and agricultural surveys are excellent sources of data to identify typologies of farmers and their productivity constraints;

c) ***Policy and investment priorities.*** Moving on from constraints, identifying their root causes is essential for establishment of policy and investment priorities. For example, the root causes of animal diseases could be a low vaccination rate; poor application of vaccines and drugs; use of counterfeited drugs; broken cold chain; uncontrolled animal movements across districts; contaminated water points or animal feed; uncontrolled livestock-wildlife interaction; and other. The NSOs are neither mandated nor expected to provide regular data and statistics on all the possible determinants of animal diseases, or of any other constraint for that matter. Indeed, it would be an inefficient use of resources for NSOs to regularly collect data on, for example, all possible intrinsic and extrinsic determinants of even one animal disease – including "living" agents such as viruses, bacteria, and other; "non-living" agents, such as temperature, nutrients, and other; and the multidude of climate, soil and man-driven causes. Only when animal diseases are identified as a main development constraints, therefore, decision makers should invest resources to identify their root constraints: they need to opportunistically engage and exchange information with a multitude of stakeholders, as well implement *ad hoc* statistical surveys targeting some detailed information that cannot be efficiently generated on a regular basis by the NSOs. This is necessary to identify policy and investment priorities;

d) ***Policy and investment design.*** Once the root cause of a constraint has been identified, decision-makers need data and information on the pros and cons of alternative policy instruments for easing and/or removing the root causes of one or more binding constraints. Data and statistics to identify the first best policy instruments are not immediately available, as the implementation of policy reforms usually co-occurs with some form of institutional change – new ways of doing things – which calls for changed behaviors of both implementers and beneficiaries. For example, it could be difficult to say ex-ante whether the system of animal health services is better improved through hiring additional animal health workers, or through providing transport allowances to existing extension agents. Stakeholder consultations and experimentations on the ground, possibly supported by some scientific data collection or survey, assist policy makers in gathering the information needed for identifying the first best policy instrument; and

e) ***Monitoring and evaluation***. Monitoring and evaluation are necessary to ensure that policies and investments be properly implemented and to provide guidance on adjustments. NSOs' data and statistics are a major source of indicators for both monitoring behavioral changes (e.g. farmers' utilization of extension services) and evaluating their impact (e.g. crop yields).

It should be clear from the above that official statistics, while an essential component of the decision-making process, provide on their own little guidance to policy makers to design and implement policies on the ground. And that any rational decision-maker, either for the public or the private sector, has little incentives to analyse NSOs' data and statistics unless s/he is sure that resources are also available to fill her/his information needs along the entire decision-making process. In Tanzania and Uganda, before embarking in any improvement of the agricultural (livestock) statistical systems, NBS, UBOS, MALF and MAAIF agreed to jointly generate all the evidence needed along the entire decision-making process, i.e. to complement investments to improve the agricultural (livestock) statistical system with investments to generate the additional information needed to design and implement effectively policies on the ground. This approach provided major incentives for the Agricultural Sector Lead Ministries (ASLMs) responsible for livestock to allocate more time and resources to analyze NSOs' livestock data and statistics.

3.2. Data dissemination in spreadsheets with embedded statistical commands

A major challenge encountered in the process towards the design of evidence-based agricultural (livestock) policies and investments was the difficulty for staff in the Ministries responsible for livestock to analyze NSOs' datasets, and in particular the livestock section of both the Tanzania 2012/13 National Panel Survey (TZ-NPS) and the Uganda 2011/12 National Panel Survey (UGA-NPS). Breeding scientists, feed specialists, veterinarians, epidemiologists and the like are rarely trained to thoroughly analyse household and agricultural survey data.

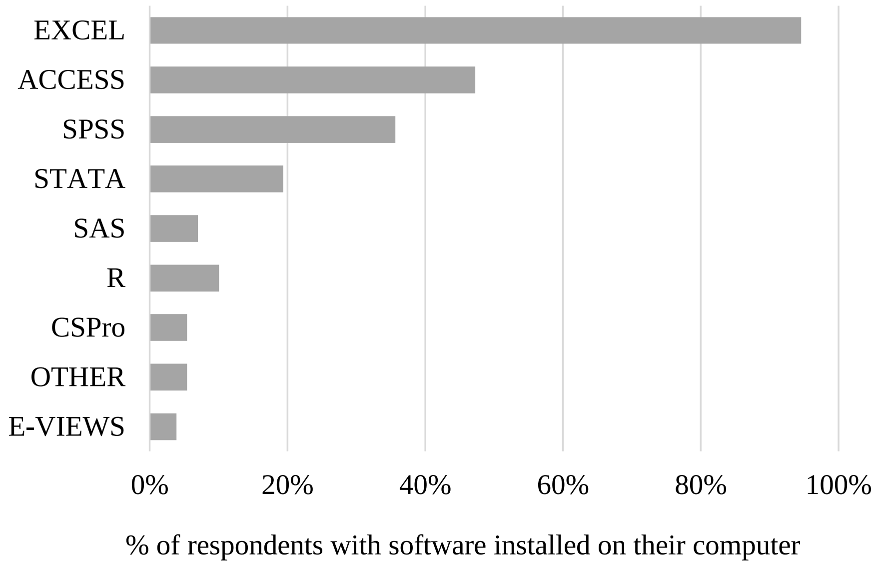
a) A tabulation plan proved ineffective at driving a constructive policy discussion: each produced statistical table, in fact, while in itself useful, led to unplanned questions that resulted in the generation of an endless cascade of tables. For example, once a table was produced on milk yield per cow; stakeholders started demanding tables by type of breed; by herd size; by household's access to veterinary services; by household's membership in livestock association; by availability of a processing plant in the community; and other. In other words, decision-makers were not able, but for a key set of statistical tables, to clearly define the information content of all the tables they would have liked NSOs to generate out of the available livestock dataset; and
b) Training in using statistical software was also considered as a poor investment to facilitate the use of official livestock data. Most stakeholders use NSOs data and statistics occasionally, and training makes sense only if the trainees make regular use of the acquired skills. In addition, data users concurred that an explorative analysis of NSOs data was largely sufficient for policy purposes and, therefore, that there was no need to use statistical packages to generate summary statistics.

NBS and UBOS agreed therefore, in close consultation with the Ministries responsible for livestock, to experiment with disseminating NSOs' livestock data in a simple spreadsheet with embedded statistical commands. The dissemination of microdata was possible in both countries as the data had been already disseminated in both STATA and SPSS, i.e. NBS in Tanzania and UBOS in Uganda had already succesfully addressed all the legal and ethical issues associated with micro-data dissemination (Dupriez and Boyko, 2010). Eventually, NBS and UBOS disseminated the livestock microdata in *MS Excel*, and for two major reasons: first, it was found that the majority of stakeholders have *MS Excel* installed on their computer (fig. 7); second, with respect to other possible forms of micro-data dissemination (e.g. CVS, text), *MS Excel* has embedded statistical commands that allow users to generate summary statistics straightforwardly, including weighted statistics. Of course, any other popular data spreadsheet with embedded statistical commands would be as good as *MS Excel* to disseminate microdata to users and provide them with some statistical power. The following is the procedure taken on board by NBS and UBOS Team to come up with datasets in *MS Excel* for the stakeholders.

a) First, the Ministries responsible for livestock, identified a set of livestock-related variables out of the Tanzania and Uganda National Panel Surveys of particular relevance for policy making, from animal ownership through animal vaccination to the utilization of livestock-related services;

b) Second, NBS and UBOS generated targeted datasets around those variables, including one dataset on key socio-economic characteristics of livestock-keeping and non-livestock-keeping households; one dataset on animal ownership and basic production practices for all livestock-keeping households in the country; and detailed datasets on livestock ownership and production practices for indigenous cattle-, indigenous goat-, indigenous sheep-, local chicken-, and pig-keeping households. NBS and UBOS generated also livestock sub-datasets by rural and urban households, and included in all datasets a dummy poverty variable and an annual income variable; and
c) Third, NBS and UBOS provided the Ministries responsible for livestock with the developed livestock datasets in *MS Excel* spreadsheets: this was doable given the sample size of the National Panel Surveys: it comprised about 1,800 livestock-keeping households in Uganda and about 2,100 in Tanzania. The distributed *MS Excel* spreadsheets included *ad hoc* commands to calculate representative statistics at different levels of aggregation, notably the weighted average, the median and the standard deviation.[1]

Fig.7. *'Statistical-related' software installed on respondents' computers*



With livestock data available in *MS Excel* spreadsheets, the Ministries responsible for livestock could:

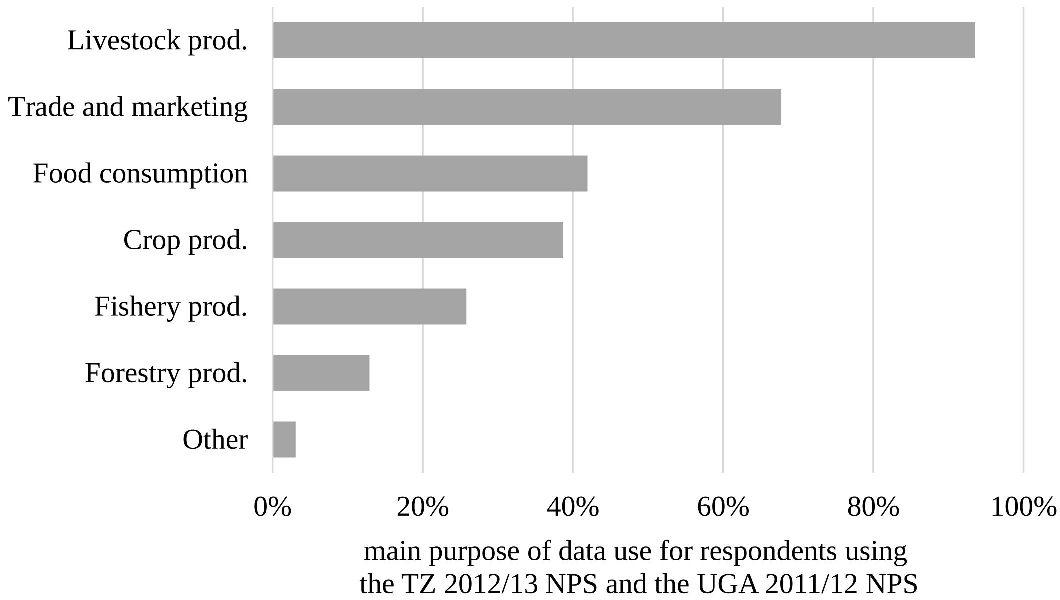
a) Correct few unambiguous data-entry errors, which could not be detected through standard statistical procedures (e.g. adjusting the weight of a live chicken from 13 to 1.3 kilos);
b) Generate additional variables to respond to specific policy questions (e.g. a dummy on household consumption of any type of animal protein); and
c) Perform an explorative analysis of the household-level livestock data, which is summarised in two reports on the Smallholder Livestock Sector in Tanzania and Uganda (MALF, 2016; MAAIF, 2016). It was one of the first times ever in which staff in the Ministries responsible for livestock generated representative statistics out of a NSO' dataset with no need of technical assistance or investments in capacity building.

Results from the 2016 survey implemented by NBS and UBOS on the utilization of agricultural data and statistics indicate that, disseminating datasets in spreadsheets with embedded

[1] The main challenges in exporting the NPS livestock data in a statistically usable *MS Excel* spreadsheet were to give codes 0 and 1 to all dichotomous questions and to split multiple response questions into different columns with codes 0 and 1. See UBOS (2016) *NPS 2011/12: Section and Datasets on Livestock – Basic Information Document* or NBS (2016) *NPS 2012/13: Section and Datasets on Livestock – Basic Information Document* for codes and commands to calculate the representative average, median and standard deviation in *MS Excel*.

statistical commands (*MS Excel* in this case) widely facilitates and motivates the use of data for various purposes. Among the respondents that utilized the Tanzania 2012/13 National Panel Survey and the 2011/12 Uganda National Panel Survey, 98 percent developed some statistical tables on livestock, with statistics on marketing and food consumption ranking second and third (68% and 42% of respondents respectively) (Fig.8). The analysis of the NPS livestock datasets undertook by the national governments suggested that, in both countries, limited access to livestock services is a binding constraint to livestock development: both MAAIF and MALF are currently gathering and analyzing additional data and information for designing an effective policy to improve the systems of animal health services in Uganda and Tanzania respectively.

Fig. 8. *Utilization of the Tanzania 2012/13 National Panel Survey and the Uganda 2011/12 National Panel Survey by purpose*



4. Conclusions

This paper analysed the extent to which public and private sector stakeholders in Tanzania and Uganda use official agricultural statistics as produced by the Tanzania National Bureau of Statistics and the Uganda Bureau of Statistics (respectively. It builds on data from an online survey implemented by NBS and UBOS in the first quarter of 2016. Results showed that stakeholders use only a minor share of the agricultural data collected by the NSOs, which promoted NBS and UBOS to innovate .

The paper presents two innovations to enhance the utilization of agricultural data and statistics, which have been tested and implemented using household level livestock data in Tanzania and Uganda. The first is to complement investments that improve the quantity and quality of official statistics with investments to collect the information needed for decision-makers to design and implement policies and investments on the ground. Collecting data to depict the situation on the ground, which is what official statistics largely do, is in fact not sufficient on its own to generate evidence to find effective ways to improve it. The second innovation is on data utilization: data can be disseminated not only in NSOs' reports and - when ethical and legal issues related to microdata dissemination are successfully addressed - as statistical software files, but also in simple spreadsheets with embedded statistical commands, which suit the need of stakeholders. This approach empowers stakeholders and is implementable with a more efficient allocation of NSOs' available resources. As the largest share of NSOs collected data currently remain unused, National

Statistics Offices could consider reducing the quantity of the data collected and allocate the saved resources to generate and disseminate targeted datasets, as demanded by stakeholders, in simple spreadsheets.

ABSTRACT[1]

Assessing the impact of agricultural research on sustainability targetsoften implies to face two main issues: the complexity of the causal path, and the lack of appropriate data. In this paper, we discuss which data would be necessary to measure short- and long-term impacts in Europe,and suggest a set of indicators to evaluate their quality, considering both metadata and collected data form the Eurostat database. An application isshown for a selection of 20 variables.In our results, qualitative and quantitative indicatorsoften provide conflicting information.We believe that such contrast is due to the fact that metadata can describe data quality only partially, while collected data can emphasize further quality features like the pattern of missing values and the presence of outliers.

Keywords: Data quality indicators;Data quality dimensions;Impact of agricultural research.

1. Introduction

Agriculture is an important target of EU and national policies. In particular, there is an increasing demand of knowledge on the effects of agricultural research on the EU sustainability targets. The achievement of suchknowledgedepends on two main factors: the complexity of the causal path, and the lack of appropriate data. Agricultural activities produce effects through a large number of pathways, from short-term impacts on agriculture production tolong-term impacts on people's sustainable well-being. Ideally, a unified analytical approach would jointly consider impacts across all the relevant sustainability dimensions at a local, national and over-national level.Methodologies in the literature range from disaggregate to aggregate analysis, from the assessment of economic rate of return to the assessment ofmulti-dimensional impacts.However, the extent of available statistical methods often contrasts with a general lack of appropriate data.This paper provides an insight into the quality of availablestatistics (Eurostat data) when analysing the effect of agricultural research on multiple targets in Europe.The paper is organized as follows. In Section 2, we concisely focus on the themes of interest of datarequired to investigate the short- and long-term effects of agricultural research in Europe. In Section 3, we suggest somesynthetic indicators for the quality of data.In Section 4,we compute suchindicators for a selection of variables representative of the themes of interest above. Conclusions are provided in Section 5.

2. Data: themes of interest

Following Bartolini et al. (2014), wedelineate the impact pathway from agricultural research expenditure to multiple sustainability dimensions through five interconnected levels: context/external drivers, investment, research activity, outcome andimpact.

The context/external driverslevel accounts for countries' specific characteristics, which may act as a confounder of the relationships among the other levels. Contextvariables includemacroeconomic variables (e.g. gross domestic product) as well as the disposal of agricultural resources (e.g. land and labour). External drivers take into account policies, regulations and laws, as

well as technology innovations from economic sectors other than agriculture (for instance, chemical and mechanic patent applications as pointed out by Thirtle et al., 2008).

The investment level includes the variables describinghow agricultural research is fundedwithin each country (e.g.,general government and business enterprise expenditure).

Outputs of research activity represent the first and most immediate results of research investments.Campbell et al. (2013) consider human resources (e.g., number of high qualified researchers), quality of research (e.g., number of EU funded projects), innovation (e.g., number of patent applications), research infrastructures, industrial specialization and publications.

The outcome level includes the immediate impact of research activity on farm production.Productivity of the agricultural sectoris the representative variable of this level.

The impact level contains variables non-immediately affected by research investment and encompasses multiple dimensions. This level includesfor instance, changes in farmers' economic conditions and wellbeing, changes in environmental conditions (pollution emissions; biodiversity; soil and water quality) and changes in social conditions (health, education, food security, poverty, migration, etc.).

Output, outcome and impact variables identifythe possible targets of European agricultural research. Applying textual mining techniques on the abstracts of EU funded research projectsin agriculture[2], Bartolini*et al.* (2016) analyse changes in the share of budget among different research targets from 1994 to 2009, and found that,during late 90s, economic competitiveness and reduction of environmental pressure were the highest priorities of research projects, while, since 2000, the larger share of budget was finalized to support projects having an expected impact on the health of European consumers and citizens.

Assessing the impact of agricultural research requires recovering adequate data for each theme of interest (level) above. Eurostat, FAO, OECD, ILO, the World bank and other international institutions disseminate data on most of them. However, due to the heterogeneity of the issues covered, availabilityand quality of data vary significantly across countries and time. Along with well- established and harmonized statistics (e.g., labour or national accounts statistics), we find poor quality data. Statistics seem adequate at first glance butsometimes concealmissing values, short time series or breaks in the series. In our view, it would be helpful if statistics were disseminated along with synthetic quality scores, in order to make immediately clear their actual usability. In the next sections, we suggest some quality indicators and present results for a selection of 20 variables representative of the impact pathway from agricultural research expenditure to multiple sustainability dimensions.

3. Quality indicators

Assessing the impact of agricultural research in European countries requires managing both time series and cross-section data sets. On the one hand, long time series for investment and research variables are required since their effects on target variables occur at different time lags. On the otherhand, complete and comparable cross section statistics are needed to allow international comparisons. Thus, comparability over time and among countries represent the most importantquality requirements.

Several institutions disseminate time series and cross-section data sets on the themes of interest detailed in Section 2, so that the identification of the best data source for each variable isanecessaryfirst step. In this paper, we focus on Eurostat statistics only,as Eurostat is the primary data source for European countries, anddisseminatesthe best metadata on data quality through single reports for each statistic (Euro-SDMX Metadata Structure files; ESMS files henceforth).

[2] 4th FP (1994-1998), 5th FP (1999-2002) and 6th FP (2002-2006) projects. Only projects with main topic 'Agriculture and food' or subtopic 'Agriculture'within the 'Biotechnology' topic were selected.

However, basing on Eurostat available metadata it is not immediateto detect the overall quality level of each variable, nor to understand for which analysis each variable could be fruitfully used (time series or cross sectional analysis, or both). In this section, we propose some quality indicatorsto beprovided along with data in order tomake users immediately aware of their actual usability.We consider both metadata and collected data.

3.1 Qualitative indicators based on Eurostat metadata

A detailed report on data quality (ESMS file) is available for all the statistics in the Eurostat database. ESMS reports contain very useful information but their length (no less than 5 pages) andtheirlevel of detail may discourage the user.

We summarize ESMS reports into four variables. The first variableconsiders the typology of data sources used to collect/produce data, assuming that the level of comparability and accuracy decrease going from Censuses to National Accounts, Surveys,Administrative data sources and Mixed data sources (such as inventories derived from various data sources). The second variabletakes into account the 'Institutional mandate'section of ESMS files, which specifies if statistics are produced/collected on behalf of EU regulations and if they are disseminates on a mandatory, gentlemen's agreement or voluntary basis. In this case, we assume that data quality improves if the collection, production and transmission of data are regulated. The third and fourth variables assign a quality level(low, medium, good and high) on the temporal and the geographical comparability, respectively. The quality level is derived directly from the assessments given in the 'coherence and comparability' section of ESMS documents.

3.2 Quantitative indicators based on data evidence

We develop several quality indicators on the basis of the evidence stemming from collected statistics. We considered two features of quality: missing data and outlier data. First, we focus on missing values, providing measures of their incidence both in time and space (i.e. across countries). Then, we consider the incidence of contiguous values in each time series. Finally, we focus on the detection of outliers, once all the time series are made stationary. The value of each indicator varies from 0 (minimum quality) to 1 (maximum quality).

Notation is the following. The set of countries is denoted as $j = 1, \dots, J$, and $X_{i,j,t}$ denotes the i-th variable ($i = 1, \dots, I$)in the j-th country at time slice t ($t = 1, 2, \dots, T$).

Missing data incidence

Let $o_{i,j,t}$ be a dummy variable such that $o_{i,j,t} = 1$ if the value of $X_{i,j,t}$ is available (not missing), otherwse $o_{i,j,t} = 0$. We define three indicators measuring the incidence of missing data.

- **Spatial Availability Index**. Proportion of available data for a certain variable in a certain country:

$$SAI_{ij} = \frac{1}{T} \sum_{t=1}^{T} o_{i,j,t}$$

- **Temporal Availability Index**. Proportion of available data for a certain variable at a certain time slice:

$$TAI_{it} = \frac{1}{J}\sum_{j=1}^{J} o_{i,j,t}$$

- **Contiguity Index**. Contiguity of available data for a certain variable in a certain country, computed as the proportion of available data adjacent to an available datum:

$$CI_{ij} = \frac{1}{T-1}\sum_{t=1}^{T-1} o_{i,j,t}\, o_{i,j,t+1}$$

Outlier data incidence

The distribution of a time series may change through time, that is it may contain an unit root or may not be stationary. If this is the case, the detection of outlier data does not make sense. For each variable$i$ and for each country j, denote the order of integration as d_{ij}, that is the minimum number of differences required to obtain a significant result of the Dickey-Fuller test (rejection of the unit root hypothesis). Consider the *Skewness-adjusted Outlyingness* (Brys et al., 2005), a robust measure of outlyingness for skewned distributions:

$$\zeta_{ijt} = \begin{cases} \dfrac{\tilde{X}_{i,j,t} - M_{ij}}{R_{ij} - M_{ij}} & \tilde{X}_{i,j,t} \geq M_{ij} \\[2ex] \dfrac{M_{ij} - \tilde{X}_{i,j,t}}{M_{ij} - L_{ij}} & otherwise \end{cases}$$

with:

$$L_{ij} = \begin{cases} Q_{ij} - 1.5e^{-4MC_{ij}}(QQ_{ij} - Q_{ij}) & MC_{ij} \geq 0 \\ Q_{ij} - 1.5e^{-3MC_{ij}}(QQ_{ij} - Q_{ij}) & otherwise \end{cases}$$

$$R_{ij} = \begin{cases} QQ_{ij} + 1.5e^{-3MC_{ij}}(QQ_{ij} - Q_{ij}) & MC_{ij} \geq 0 \\ QQ_{ij} + 1.5e^{-4MC_{ij}}(QQ_{ij} - Q_{ij}) & otherwise \end{cases}$$

where $\tilde{X}_{i,j,t}$ represents $X_{i,j,t}$ after applying d_{ij} differences, whereas M_{ij}, Q_{ij}, QQ_{ij} and MC_{ij} are the median, the first quartile, the third quartile and the medcouple (an adjusted measure of skewness: Brys et al., 2004) of the i-th variable in the j-th country after applying d_{ij} differences, respectively. According to such outlyingness measure, $\tilde{X}_{i,j,t}$ is an outlier if $\zeta_{ijt} < L_{ij}$ or $L_{ij} > R_{ij}$. If this is the case, let $u_{i,j,t} = 0$, otherwise $u_{i,j,t} = 1$. We define the **Outlyingness Index** as the proportion of non-outlier data for a certain variable in a certain country:

$$OI_{ij} = \frac{1}{T}\sum_{t=1}^{T} u_{i,j,t}$$

4. Results

We selected a total of 20variables representative of each level of the research impact pathway from agricultural research expenditure to multiple sustainability dimension,excepting the Output level, aswe were not able to find Eurostat statistics on total factor productivity for Agriculture. Actually, according to Schreyer (OECD, 2015), in Europe only Statistics Denmark, Statistics

Finland, Statistics Sweden and ONS deliver estimates of total factor productivity for the A and B sectors of NACE classification.

We downloaded data and metadata from Eurostatwebsite (http://ec.europa.eu/eurostat/data/database) in May 2016. We considered15 EU countries (AT, BE, DE, DK, EL, ES, FI, FR, IE, IT, LU, NL, PT, SE and UK) in the period 1980-2015. For each of the selected variables, we computed quantitative (columns 4, 5 and 6) and qualitative (columns 8, 9, 10 and 11) indicators as defined in Section 3.2. Also, we derived anoverall quantitative indicator I1 (column 7) and an overall qualitative indicator I2 (column 12). Indicator I1 is obtained as follows: quartiles of each quantitative indicator are computed, then values from 1 to 4 are assigned to each quantitative indicator for each variabledepending on the nearest quartile (1 for the first quartile, 2 for the second, and so on), andfinallysuch valuesare averaged for each variable.Indicator I2is subjectively derived from the values taken by qualitative indicators. Results are shown in Table 1.

Figure 1 compares the I1 and I2 values after the variables under analysis are clustered into four groups:blue dots correspond to Economic variables, grey dots to Research variables, yellow dots to Social variables and orange dots to Environmental variables.We see that indicators I1 and I2 do not provide unanimous indication on data quality (Pearson correlation coefficient equal to -0.09): Research variables are characterized by low values of I2 and high values ofI1, Economic and Social variables show a balance between the values taken by the two overall indicators, Environmental variables exhibit a heterogeneous combination.

Figure 1. Comparison of overall qualitative and quantitative indicators for a selection of variables.

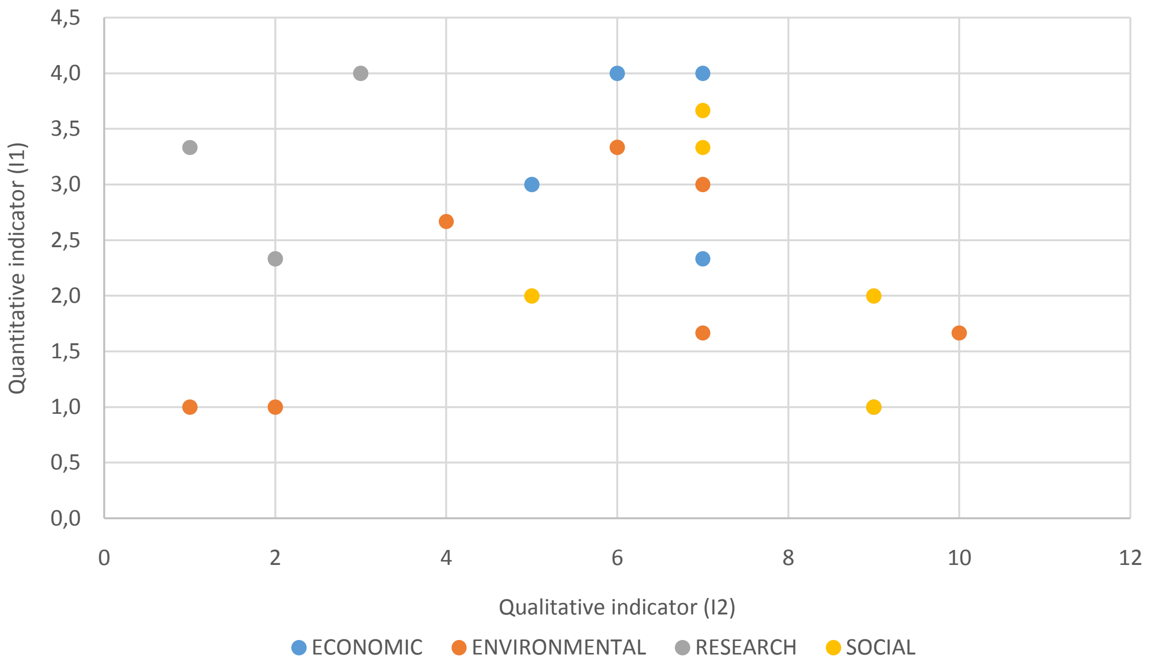

Table 1.Quality indicators based on collected data and quality reports from the Eurostat database on the 20 selected variables.

Description	Level of the impact pathway	Indicators computed on collected data				Indicators based on Eurostat ESMS files				
		Non-missing values	Contiguous over time	Non-outliers	I1: Overall quantitative	Primary data source	Institutional mandate	Comparability over time	Comparability across countries	I2: Overall qualitative
HA of arable land	ECONOMIC	0.86	0.83	0.99	4.0	Mixed sources (Economic Accounts for Agriculture)	EU Regulations (2004) sets harmonized methodology. Provision is on gentlemen's agreement	good	high	7
Business enterprise research expenditure for Agriculture	RESEARCH	0.31	0.29	0.98	2.3	Survey/Administrative	From 2004, collection is mandatory and regulated	Medium	Low	2

5. Concluding remarks

The evaluation of the short- and long-term impacts of agricultural research in Europe is an important theme for EU decision-making. To investigate thisphenomenon, it is necessary to dispose of high quality time and cross section data for a large numbers of variables. At a first sight, official statistics supply a plenty of information on the themes of interests (levels of the impact pathway from agricultural research expenditure to multiple sustainability dimensions). However, quality deficiencies due to missing values, outliers, short time series and break in the series may considerably affect the reliability of statistical analysis.

In this paper, we propose some quality indicators to be provided along with data in order to make users immediately aware of their actual usability.We compute such indicators on a subset of variables representative of each levels of the researchimpact pathway from agricultural research expenditure to multiple sustainability dimensions. These measures combine qualitative information on data quality published by Eurostat with quantitative evidence stemming from data. By comparing the values of overall quality indicators I1 and I2, we find contrasting indication: quality level stemming from metadata does not to match the one stemming from collected data.We believe that such contrast is due to the fact that metadata can describe data quality only partially, while collected data can emphasize further quality features like the pattern of missing values and the presence of outliers.

ABSTRACT

The growing awareness of the importance of evidence-based decision making in governments and organizations at all levels emphasises the role of statistics in monitoring and achieving national and international development targets. The Food and Agriculture Organization (FAO) of the United Nations plays an essential role in monitoring global food and agriculture statistics by developing methods and standards, providing capacity building support to member countries, and disseminating global databases.

This paper aims to propose a methodology to assess, monitor and report on FAO's statistics work, by evaluating the quality of agricultural data at country level and of their use in evidence based decision- making. FAO's statistics work was last assessed as part of the Corporate Outcome Assessment in 2014 and 2015. Changes in the international policy environment and lessons learned from the previous assessment, led to a revised FAO Results Framework. The 2017 Corporate Outcome Assessment will leverage the last assessment while incorporating some significant improvements. The methodological revisions include the harmonization of the results chain and outcome formulation for FAO's statistics work across Strategic Objectives, alignment with the Sustainable Development Goals (SDGs), and changes to the survey design and sampling methodology.

Keywords: agricultural statistics, evidence-based decision making, policy monitoring, results framework, strategic planning, corporate assessment, Sustainable Development Goals, balanced sampling method.

1. Introduction

In September 2015, the United Nations General Assembly formally adopted the universal, integrated and transformative 2030 Agenda for Sustainable Development, along with its 17 Sustainable Development Goals (SDGs) and 169 associated targets. Agriculture plays a central role in achieving these goals, which include eradicating hunger and poverty, ensuring sustainable management of natural resources, and combatting climate change.

At the same time, evidence-based decision making (EBDM) is becoming increasingly recognized as an important tool for change on the national and international levels. Within the context of EBDM, policy decisions are informed by rigorous analysis using relevant and accurate data. High quality statistics play an important role, not only in designing new policies, but also in monitoring progress towards national and international development goals and targets, and in evaluating policy impact. FAO is positioned to play a crucial role in achieving the SDG targets and influencing positive change, as it sits at the intersection of statistics, policy, and agriculture. , FAO has been identified as the *custodian agency* for 21 indicators and as a *contributing agency* for an additional 4.

This paper presents the methodology developed and used by FAO to assess, monitor and report on both the quality of agricultural statistics at country level, as well as the level of their use in evidence-based decision making. The paper is organized as follows: Section 2 provides an overview of FAO's role in food and agriculture statistics; Section 3 describes the new FAO Results Framework to support monitoring; Section 4 presents FAO's methodology, experience, and lessons learned in monitoring Outcome level progress in the *Medium Term Plan 2014-2017*; and Section 5 illustrates some of the methodological improvements defined so far for assessing the results of FAO's statistics work as part of the next *Medium Term Plan 2018-21*.

2. FAO's Role in the Production of Food and Agriculture Statistics

High-quality statistics are essential for designing and targeting policies to reduce hunger, malnutrition and rural poverty, promoting sustainable use of natural resources, and increasing resilience to threats and crises. They provide the foundation for evidence-based decision making for governments, the private sector and the international community and play a critical role in monitoring progress towards national and international development goals and targets.

FAO's statistics work is comprised of three main functions: (a) to assemble, analyse, and provide access to data for national, regional and global monitoring, including for the SDGs; (b) to develop the required statistical methods/tools for food and agriculture statistics; and (c) to provide technical assistance and capacity building to member countries for the implementation of international standards in agricultural statistics. In the new FAO Strategic Framework, statistics plays a dual role by directly contributing to specific outputs of the five Strategic Objectives (SOs) and by creating the internal and external enabling environments to facilitate delivery of corporate results under Objective 6 (O6), the FAO internal objective to ensure technical quality, knowledge and services. The FAO Medium Term Plan 2014-17 (MTP 2014-17) results framework identified a specific Outcome within Objective 6 to ensure the quality and integrity of FAO's Statistical work.

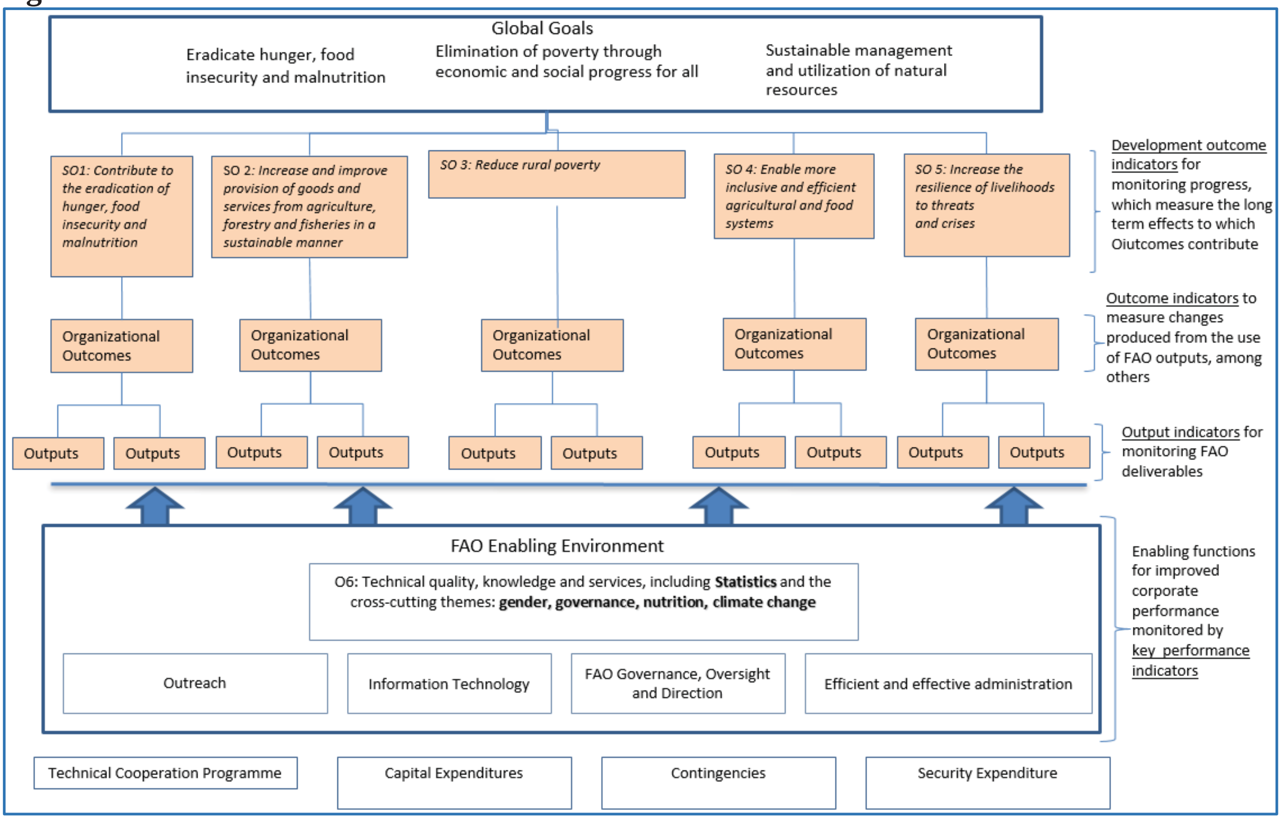
In a decentralized statistical system, such as that of the FAO, this can only be guaranteed through a strong governance system and corporate accountability framework that defines the responsibilities of the different units involved in statistical work. To this end, FAO has recently adopted a comprehensive Quality Assurance Framework, providing guidelines on best practices to be applied to all statistical processes and products in order to ensure corporate consistency, to avoid duplication and fragmentation of statistical activities, and to guarantee the quality of FAO data, whilst making the most effective use of resources. The Chief Statistician at FAO oversees FAO's statistical work across all SOs, and is responsible for delivering results under O6. The

Interdepartmental Working Group on Statistics (IDWG), along with representatives from all technical divisions involved in statistical work, support the Chief Statistician in these efforts.

The FAO Statistical Work Programme is developed by the FAO Chief Statistician with the support of FAO technical divisions and the IDWG on Statistics and it mainly focuses on:

a. Supporting the production and dissemination the 21 SDG indicators under FAO custodianship, in addition to the established compilation/dissemination of food and agricultural statistics;
b. Strengthening the statistical capacity of member countries, including on SDG monitoring, through the provision of training, technical assistance and support in the adoption of new and cost-effective survey methods.
c. Improving communication with countries and development partners on the importance of high quality data, and advocating for the increased use of statistics in decision making and for its proper inclusion in country programmes;
d. Ensuring that the FAO Statistical System is able to respond promptly and effectively to new data demands.

Figure 1: *The FAO results chain model*



3. FAO Results Framework

The Director General's Medium Term Plan for 2014-2017 and the Programme of Work and Budget for 2014-2015 outline FAO's new result-based model and monitoring framework (FAO, 2013). In the FAO results-chain model, each of the five SOs links to a set of Organizational Outcomes (OOs), which are underpinned by Organizational Outputs.

Outcomes reflect the changes in the country-level enabling environment needed to achieve each specific SO. For each SO, the Outcome indicators measure the main determinants of success. These indicators include factors such as relevance of policy and programming frameworks, level of committed resources and investments, level of coordination/partnerships, and availability/use of information and data for decision making. The indicators measure countries' progress in making reforms and developing capacity in order to achieve the SO. A set of indicators is defined for each Outcome within each SO.

Outputs are a set of deliverables that result from FAO's intervention (tangible products and services) and for which FAO is directly accountable. In this case, indicators are selected to reflect the key outputs of the Organization, those which have the most important influence on the outcomes at country level.

3.1 Statistics in FAO Results Framework

Statistics contributes in two ways to the implementation of the MTP 2014-17. Under each SO, statistics produce outputs and services at the country level to help inform EBDM. Under Objective 6, statistics serve as a global public good, ensuring technical quality for the analytical and policy work of FAO and other external stakeholders. The second outcome of Objective 6, Outcome 6.2 is therefore entirely devoted to statistics with the aim to ensure quality of FAO Statistics to support evidence-based decision making at all levels. This outcome covers the quality and integrity of FAO's statistical work, and is measured using two indicators:

Outcome	Indicator
6.2.A: Use of statistics for evidence-based policy making in the fields of food security and nutrition, sustainable agriculture, rural poverty and resilience to threats and crises	Number of countries in which statistics is available, accessible and used for evidence-based decision making
6.2.B: Level of statistical capacity development in member countries	Number of countries having shown significant progress in statistical capacity

Outcome 6.2 in Objective 6 is supported by the following four distinct ***Outputs*** and indicators:

Output	Indicator
6.2.1: Methods for the collection, compilation, dissemination, analysis and use of data under different data domains are developed and shared	Number of new guidelines and technical standards published
6.2.2: Support provided to strengthen national statistical institutions and to improve the competencies of national statisticians in collecting, analysing and disseminating data.	Number of new statistics capacity building projects in countries
6.2.3: High quality and internationally comparable data are produced and accessed by all countries	Number of FAOSTAT visits
6.2.4: Strengthened governance and coordination of FAO statistics and improved internal capacity to evaluate the results of FAO's work.	Number of new datasets included in the corporate Statistical Working System

Finally, most of the SOs incorporate an OO-level indicator to monitor country capacity to generate and use statistics for analysis and decision making within the specific SO.

OO level indicators measuring the existence and use of information systems, data and statistics	
SO1	Countries with high quality analytical products generated through functional information systems in support of food security and nutrition policy and programming processes
SO2	Countries that use statistics extensively in policy making processes pertaining to agriculture and natural resources management.
SO3	Capacities to monitor and analyse social protection policies and programmes
SO5	Countries with capacity to deliver regular information and trigger timely actions against potential, known and emerging threats to agriculture, food and nutrition

4. Monitoring Progress in the Medium Term Plan 2014-2017

Monitoring and reporting for the Medium Term Plan is conducted every two years at the Outcome level, and every year at the Output level. Given the nature of the Outcomes, very few data are currently available in the public domain on the selected indicators. Moreover, no information is currently produced on FAO's direct contribution to the achievement of the Organizational Outcomes (OO). Consequently, the data to inform the Outcome indicators are only partially obtained through secondary data, while the main source of information is the Corporate Outcome Assessment. This includes a review of key national policy documents, and a perception survey on the quality, availability, and accessibility of data that are needed to inform the FAO SOs.

The first assessment was conducted in 2014, and was used to establish baselines for the indicators. A second assessment was conducted at the end of 2015 to measure progress made on the indicators since baseline, and to assess FAO's direct contribution to these results. The next assessment will be conducted at the end of 2017, as part of the Medium Term Plan 2014-17 monitoring and reporting cycle.

4.1 The Design of the Corporate Baseline Assessment (CBA 2014)

The Corporate Baseline Assessment (CBA) was conducted in 2014, and assessed those countries where FAO delivered a meaningful programme of work during the 2011-2012 biennium. In total, 148 FAO member countries satisfied this criterion, and were included in the target population. In order to limit the length of time, costs, and human resources needed to conduct the assessment, the CBA analysed a sample of 80 countries, rather than the entire target population.

Countries were selected for inclusion in the CBA in order to obtain a representative sample of the population, taking into consideration factors such as geographical region, performance within each of the five SOs, and importance to FAO delivery. The key indicators reflecting the country's performance within the SOs are:

Indicators reflecting country performance within each of the five SOs	
SO1	Prevalence of stunting among children under 5
SO2	Average arable land per person
SO3	Poverty headcount ratio at $1.25 a day in PPPs
SO4	Proportion of agriculture value added over the GDP
SO5	Vulnerability Index and Crisis Index Final Index Rank

The main criterion used to select countries for the sample was the level of delivery (in USD). This ensured that countries with larger FAO programmes had a higher chance of being included in the sample. In addition to level of delivery, sample countries were also selected based on a set of six stratification variables, based on geographical region and the five SO indicator groups[1]. In this context, some countries were included in the sample with certainty, as they were assigned an inclusion probability equal to1[2]. The amount of delivery was used to allocate the sample among the strata and to define the selection probabilities.

In order to ensure the representativeness of the sample at global level for the entire work programme of the Organization, the sampling design was based on a random selection procedure that accounted for all the SOs simultaneously. Due to the small size of the population (and consequently of the sample), the sample was selected using the balanced sampling method (Deville and Tille, 2004). This method is the most efficient methodology designed for the selection of a

[1] For each of the five indicators, the countries have been classified into two groups on the basis of the median value of the distribution of the indicator. A third group for each indicator was defined reflecting the countries with missing values.
[2] The list of self-representative countries includes: Somalia, Afghanistan, Pakistan, Sudan, DR Congo, Zimbabwe and Bangladesh.

random sample in terms of marginal allocations (Falorsi and Righi, 2008). Therefore, the randomly selected sample ensures all the marginal allocations as well as the total sample size.

In the first phase of the fully-fledged survey, the sample size was fixed at 39 countries. Subsequently, in order to satisfy the need of the SO Teams to obtain data for all FAO focus countries, the final sample size was increased to a total of 80 countries. Given that the list of focus countries changed SO by SO, the total number of countries surveyed was different for each SO[3] (55 countries for SO1, 50 countries for SO2, 58 countries for SO3 and 55 countries for SO5).

Data were collected through a structured questionnaire with sections dedicated to each SO. The specific questions in each section were defined based on the data requirements of each SO Team. When possible, data were obtained from existing data sources (secondary data) and were therefore not included in the survey questionnaire.

The respondents in each country were identified, with the support of the FAO country offices, as senior representatives of six stakeholder groups: government, UN agencies, international donors and International Financial Institutions, research institutions/academia, civil society and the private sector. This diverse group of perspectives ensured a comprehensive assessment of each country's capacity for and commitment to achieving the Strategic Objectives. Given the broad range of respondents involved, the survey was conducted through a facilitated data collection event. At this event, facilitators explained the assessment's objectives and questionnaires, and then respondents individually completed their relevant sections. A total of 1474 questionnaires (334 for SO1, 346 for SO2, 490 for SO3 and 304 for SO5) were collected.

The estimates of the Outcome-level indicators and sub-indicators for the whole population were obtained using adjusted sampling weights. The initial sampling weights, calculated as the inverse of the inclusion probability of the 39 sample countries of the initial CBA, were adjusted to take into account non respondent countries (2 for SO1, SO2 and SO5, 3 for SO3). These weights allowed the indicators' values to be expanded from the sample countries to the target population.

After broadening the sample to include all SO focus countries, different weighting systems were defined to provide representative estimates for each SO. Two domains, unplanned for in the original sampling design, were also considered for each SO: the set of the focus countries and the set of non-focus countries. The weight adjustment was performed taking into account regional differences.

Finally, each Outcome-level indicator was derived by combining the values of sub-indicators derived from the CBA and those taken from secondary sources. Survey data for a specific country were firstly aggregated by group of respondents (through a simple mean), and then aggregated at country level (also through a simple mean). A score was calculated for each indicator, ranging from zero to one, as a result of an average of the values of the sub-indicators.

4.2 The Design of the Corporate Outcome Assessment (COA 2015)

At the end of 2015, another assessment was conducted to assess changes at the country and global levels at the end of the 2014-2015 biennium. COA 2015 was very similar to the CBA and surveyed the same set of countries to obtain estimates of the changes that occurred in the national enabling environment during the two year period. The COA planned to collect data on the same set of respondents, to obtain an evaluation of the change during the two year period not affected by the variability due to a change in the respondent.

The questionnaires were expanded to include two additional sections: a) FAO's perceived role in *contributing to change*; and b) a more articulated *assessment of the use of statistics for evidence-based decision making*.

In parallel to the primary data collection, secondary data were updated whenever possible. The COA obtained reliable estimates of the following three variables at aggregate level:

[3] The CBA did not cover SO4. Therefore the OO indicators for SO4 were obtained only through secondary data.

a. Values of the Outcome-level indicators in 2015;
b. Changes in the values of the Outcome-level indicators between 2014 and 2015;
c. Percentage of FAO contribution to this change, based on responses to specific questions inserted in the questionnaires

Data collection took place from December 2015- January 2016, and differed somewhat from the CBA. While the CBA collected all data at data collection events, the COA data collection differed by country: some countries still collected data through organized data collection events; for others the respondents received the questionnaires and national consultants followed-up to ensure coverage and timely response.

In the COA, two different sets of weights were used to develop global indicator estimates. The first was used to obtain the 2015 estimates of the Outcome indicators and FAO's contribution to the change, while the second was used to estimate the differences between the Outcome indicators at the two points in time.

The first set of cross-sectional weights were used for expanding the sample of the respondent countries to the target population. The second set of longitudinal weights were used for estimating the differences of Outcome indicators by expanding, to the whole population, the countries responded both to the CBA and COA (co-present countries). Thus, four weighting systems were obtained (one for each SO) following the same procedure used for the weights of CBA and a weight adjustment was carried out, taking into account regional differences in the rate of non-responses.

4.3 Challenges and Lessons Learned

The biggest challenge that emerged during the COA was attrition of respondents. Many of the CBA respondents could not be found for the COA, or, to a lesser extent, declined to be interviewed. These respondents had to be replaced by other stakeholders at short notice, which caused reduced comparability between the two assessments and a decline in the quality of results. Since many of the survey questions were based on respondents' *perceptions*, the change in respondents introduced variability into the survey results, thus reducing their overall reliability and accuracy.

Moreover, a set of sample countries were excluded from the final estimates[4] because the number of respondents by stakeholder groups was not sufficient to ensure unbiased results. Table 2 compares the number of countries included in the theoretical sample by SO, and the number of those that actually participated in both the CBA and the COA. A significant decline was registered, especially for SO1.

Number of countries in the sample of the CBA and the COA by SO

	Theoretical sample	Actual sample		
		CBA	COA	Co-present in CBA and COA
SO1	*55*	53	41	40
SO2	*50*	48	43	42
SO3	*58*	55	51	49
SO5	*55*	53	46	45

The challenges faced in the data collection phase were primarily caused by a few issues in the survey implementation:

a. *Short interval between the two assessments:* Due to organizational issues, especially the countries added in the enlargement stage completed the CBA questionnaires with almost one

[4] The criteria used for including countries' data for the estimation of the final results were to have valid questionnaires for at least 2 stakeholders' groups and a minimum of 3 questionnaires in total.

year delay (September 2014). The COA questionnaires for all 80 countries were completed in November-December 2015. This meant that many respondents were requested to complete almost identical questionnaires after just one year, which led to a lower response rate in some countries. Furthermore, some OO indicators did not show any significant change in such a short time period.

b. *Timing of the COA*: Data collection began in November 2015 and the deadline to return the questionnaires fell during the holiday season (December 2015 - January 2016), which affected the actual time dedicated to complete the exercise, and the possibility of subsequent follow-ups to try expand the number and diversity of respondents.
c. *Length and complexity of the questionnaires:* Due to the large number of sub-indicators, the CBA questionnaires were lengthy and complex. The COA questionnaires were even longer, as they incorporated additional questions on stakeholders' perceptions about the FAO contribution to change, as well as an additional section on the use of statistics. Moreover, the heterogeneity of the topics covered made it difficult for a single respondent to have the knowledge and experience to answer all sections with the accuracy required.
d. *Time lag of secondary data.* Secondary data are normally published with a time lag (for e.g. 2014 data is available only after 2015) with variable delays among different sources. Due to the short period of time between implementation of the CBA and COA, few indicators could be updated.

These issues affected the quality of the COA results, and increased the difficulties in conducting meaningful data analysis across the assessments at country level. In the comparison between the CBA and COA, some of the changes detected over time were likely due to measurement errors, especially considering the limited time elapsed between the two surveys.

5. Looking Ahead: The New COA Design for Medium Term Plan 2018-21

5.1. Review of the FAO Results Framework

FAO's programme of work is constantly evolving to respond to changes in the international policy environment. The new trends and challenges emerging at global level, as well as the new international policy frameworks recently adopted (2030 Agenda for Sustainable Development, the Paris Agreement on climate change, the COP 21 and 22, the follow-ups to the ICN2 and to the World Humanitarian Summit), provide the opportunity to adjust FAO's focus and work programme in order to integrate new priorities and the resulting demands from member countries.

There is also clear recognition of the need to refine the FAO results framework on the basis of lessons learned during the implementation of the MTP 2014-17. The technical adjustments identified for the next MTP include improvements in the theory of change, the clarity and consistency of outcome and output formulations, and the measurability and relevance of the indicators. This review of the FAO Strategic Framework and Results Framework is currently being carried out as part of the Medium Term Plan 2018-21 planning phases.

Finally, regarding Statistics, the results framework is being revised to avoid overlap between outcomes in Objective 6 and the SOs and the information compiled under various SOs will be used to feed the assessment of Objective 6. Moreover, the use of statistics in decision making is not directly linked to the current statistical capacity development work of FAO, which focuses mainly on helping countries to produce new and better quality data, not on helping them to transform data in key messages and communicate them well to the media and the decision-makers. Data access itself is only one component of EBDM. Therefore, capturing the impact of FAO's statistics work on decision making requires the consideration of different layers and different actors in those processes related to decision making. This helps explain the multi-stakeholder approach to monitoring and reporting on level of availability and capacities in the use of statistics.

5.2 Methodological improvements in the design of the COA

The lessons learned from the implementation of the COA 2015 coupled with the opportunity provided by the mid-term review of the FAO Strategic Framework and Results Framework, have led to following changes:

1) Increased harmonization in the Outcomes formulation and Results Framework across SOs;
2) Alignment to relevant global SDG indicators, to work towards a unique monitoring system;
3) Simplification of the overall structure of the Outcome indicators to facilitate the assessment;
4) Improvements in the methodological design of the COA 2017 survey. In particular:
    a. Improve the identification of relevant stakeholders groups by SO, and increase the number of respondents per stakeholder group to better measure variance within groups;
    b. Improve the data collection process by revising and simplifying the questionnaires and using an online form;
    c. Replace the current manual approach for policy reviews, which is subjective and very resource intensive, with a web-scraping tool to assess whether national policy documents utilize FAO's recommendations/frameworks;
    d. Reduce the proportion of secondary data;
    e. Use retrospective questions to allow for comparison of results over time and address attrition in respondents between surveys;
    f. Change the sampling design of the COA 2017 to address the need to produce estimates of the indicators by SO and by Region, in addition to national estimates for the focus countries.

5.3 Improving the Measurement of Results of FAO's Statistics Work

In developing the COA 2017 questionnaire, special attention is being dedicated to the harmonization of the indicators measuring the availability and use of high quality data, information and statistics at country level for improving evidence-based decision making with regard to every SO. A set of standardized questions is being added to each SO's questionnaire. More precisely, questions that clearly address data *availability*, *quality*, *accessibility* and *utilization* (at the policy/program design stage and monitoring stage) will be included.

A new stakeholder group in the pool of key respondents will also be introduced to obtain the views of those more closely associated to data generation, availability, use and assessment of quality of statistical information at country level. Senior officers in government agencies which produce official agricultural statistics (typically the National Statistics Office and some line ministries, including the Ministry of Agriculture) will be asked to fill in only relevant parts of the questionnaire, i.e. those related to the quality of agricultural statistical data at country level.

The data collected for different SOs through the new questionnaires will allow FAO to develop a composite indicator on the availability and quality of national statistical data in the statistics fields covered by FAO.

ABSTRACT

Agricultural statistician as others statisticians use statistical methods to collect and analyze data and solve real-world problems in the fields of agriculture. The World is changing, agriculture also. There are many mutations even in subject matter and methodological skill. The role of statistician is changing, through both the availability of large volumes of data and the recognition that informed decisions are sometimes best made by those who understand how such data might be used. There is so a need of a profile of modern agricultural statistician to come up with challenges.

This paper discusses the role of the subject matter and the methodological skill in the profile of modern agricultural statistician. We argue that facing new methodological developments, changes induced by ICT and current issues (economic, social or environmental), adaptation and retraining of researchers or practitioners or revision of training curricula remains a must. The interest of the issues discussed in this paper lies in the desire to meet the needs of the professional world and research to meet the thematic analysis requirements not only to current issues but also in the conceptual aspects related to the agricultural sector. Indeed, gender issues, sustainable resource management, poverty ... are specific analytical aspect that must be addressed and adapted to the agricultural sector. There then arises the question of the methodological approach, appropriate to identify the said aspects in conducting research and agricultural surveys.

Keywords: Statistician, methodological skill, curricula

"We need to build National Statistical Systems, in fact National Information Systems, consisting of official statistics, geospatial information and other non-traditional data, that are relevant for a multitude of purposes, and yet organised in a solid, coherent and integrated manner."

Stefan Schweinfest, Director, UN Statistics Division
Keynote address World Statistics Day 2015.

Introduction

Statistical science has undergone various changes over the years. Its development went hand in hand with the needs of society. Responding firstly to the provision of administrative data, statistical methods was developed with the methods of descriptive statistics (Sir Ronald Fischer 1890-1962) which has extended its application in various fields including econometric modeling, sampling techniques, etc. Its use is further enhanced with the development of computer technology, the increase in calculations power.

Today, more than ever, there is a new revolution in the use of statistics with information technology, the development of large masses of data, the growing need for evidence based decision on statistical data.

In the modern world of computers and information technology, the importance of statistics is very well recognized by all the disciplines. Statistics has originated as a science of statehood and found applications slowly and steadily in Agriculture, Economics, Commerce, Biology, Medicine, Industry, planning, education and so on. As on date, there is no other human walk of life where statistics cannot be applied.

The role of statisticians is changing, through both the availability of large volumes of data and the recognition that informed decisions are sometimes best made by those who understand how such data might be used.

This poses challenges both in terms of quality and topics covered in the training of statistician. This is particularly true for the agricultural sector. Indeed the importance of the agricultural sector is well established especially for developing economies. For example, in Africa the agricultural sector occupied at least half of the population and plays a key role in economic growth in reducing poverty. Also, it is crucial to have reliable and updated statistics for appropriate economic policies. This requires therefore well trained and qualified statisticians to address these issues. So there is a need of a profile of a modern agricultural statistician in line with technological and methodological developments.

This paper shows that the profile of modern agricultural statistician is shaped by new methodological skills related to technological developments, new subjects matter and business needs in this sector. Therefore, there should be a revision of training curricula and an adaptation and retraining of researchers and practitioners.

The argumentation is organized into sections. The first section recalls the challenges in the agricultural sector and in agricultural statistics. The second section presents the main methodological and technological developments affecting the profile of modern agricultural statistician. Before conclusion the final section discusses the implications for training and capacity building of researchers and practitioners.

1. Agriculture and it's challenges

The place of agriculture in the economies is well established. Representing between 30 to 50% of developing country GDP, the agricultural sector is an important source of income for the population and a factor in reducing poverty. The expectations for this sector are important in terms of reliable and timely available statistics, both for the population and for policymakers. These expectations are reinforced by recent technological developments: social networks, high flow velocities of information, new technology development, etc.

Particular attention is thus paid to issues of agricultural policy which poses various challenges including that of the availability of reliable data itself connected to data collection problems in agriculture, methodological issues and research in the area of agricultural statistics.

Challenges of data collection in agriculture

Diverse challenges, consequence of the mode and the type of agriculture practised in developing countries, arise in term of quality and personal characteristics of the farmers, the diversity of the cultures and the agricultural practices between regions, the type of practised agriculture and the methodological questions relating thereto.

In developing countries, agriculture is mainly a family type of agriculture practiced on small surface. Farmers are generally of a low level of education and use a combination of farming practices and techniques.

The diversity of regions, the agricultural calendar and types of culture according to these regions requires appropriate estimation methodologies of the main aggregates.

The sub sectors of agriculture pose specific challenges in evaluation of livestock, small animals, for fishing and aquaculture.

The sub-sector of the fishing poses the challenge of measuring production both inland fisheries and non-continental, traditional fishing and non-traditional. At the forest level, the same challenges exist in terms of estimation of wood production, deforestation surface, etc.

Also, the agricultural sector is highly dependent on weather conditions. These climatic conditions represent external factors to consider for the treatment and estimates of agricultural statistics.

In many developing countries, most producers are also consumers and collecting relevant data for understanding the decision making of smallholder producers where they are making both production and consumption decisions simultaneously are another challenge. Other problems that affect statistical activities are the extent to which agricultural activities are determined by the environment in which they take place and the impact of external events, especially weather conditions. There is a requirement, therefore, for detailed time series data that are disaggregated by agro-ecological zone, which is a major challenge for data collection.

Meeting these challenges of agricultural statistics entails having technical and adequate instruments for measurement. This is very important especially for statisticians because with the recent technological development, decision makers and more generally populations demand accurate statistics that is available in time.

Statistical methods in the agricultural sector have evolved over time and have taken to supporting new technologies and social networking.

2. New methodological developments and subject matter

The development of information and communication technologies have revolutionized the collection, storage, processing and dissemination of data. For example the development of mobile telephony and popularization of smartphones enable the collection and transmission of data. The tasks with paper and pen are increasingly abandoned as well as data entry steps after collecting paper. The information and communications technology (ICT), especially mobile phones and tablets, applications for creating digital investigations and software that allow users to upload data to real-time storage, reduced conventional problems facing the activities of data collection and analysis.

The technology itself is not sufficient to meet the project objectives. Even a platform to collect data for free does not guarantee that the right data be collected efficiently. A team that can design the collection, implement and evaluate the data is as important as technology. Training is an important element in the data collection operations through ICT tools.

We are in a dynamic and rapidly changing era in the field of production and processing of information, especially statistics. The change agents can be grouped into four classes. There is first the data revolution that operates through the digital transformation, new data sources and competition between data providers. Then there are the new metrics that should consider globalization, reality growing complexity, geodata. Then there is still the values imparted to statistics that led to arbitration between quality and resources, simplification of procedures accompanied by reduced budget. Finally, the need to propose policies based on the facts in the requirements of quality and cooperation.

These drivers of changes can be broken in the thematic domain of agricultural statistics as noted by the global strategy of agricultural statistics. Defining a framework should help integrate agricultural statistics into the national statistical system to meet the needs of users and stakeholders in a coherent framework.

A master sample frame for agriculture which will be the foundation for all data collections based on sample surveys or censuses is required for the integration of agriculture into the national statistical systems. The master sample frame must provide the basis for the selection of probability based samples of farms and households with the capability to link the farm characteristics with the household and then connect both to the land cover and use dimensions.

Update data collection methods should include complete survey framework that also takes into consideration the data sources in addition to sample surveys that provide input into the survey framework. Improved methods are required for producing food security data, market information that affect agricultural activities and farmers' decisions.

Table 2 shows the thematic domains and of the corresponding training and research topics.

3. The implications for training

The challenges in agricultural statistics, technological development and thematic of interest for the agricultural statistics influence the profile of the modern agricultural statistician.

The combination of technological development, agricultural statistical challenges and topics of interest question the profile of the new agricultural statistician. The profile of the classical statistician does not seem now quite appropriate.

The profile of these statisticians is modified according to the skills they should acquire in connection with the thematic as noted in Table 1.

The modern statistician should dominate the challenges posed in conducting the work of the statistician.
In the scope of the specification of requirements, skills should cover the demand for data on small area and disaggregated data, real-time data request and in connection with a multi-sector programming.

In terms of design, the modern agricultural statistician should be able to mobilize the satellite data and technology related in term of methodological and technical practice.

For data collection, he should mobilize modern technologies for data collection and electronic technologies including applications for collection and transmission of data.

More generally, the technological skills will be adapted in all areas of processing, analysis, dissemination and evaluation of data.

Table 1 : Challenges in statistical process model

Key business process	New challenge in business process
Specify needs	Streamlining and Joint Programming of Multisector Needs; Demand for Small-Area and Disaggregated Data; Demand for More Current Data, Real-Time Demands
Design	Integration of Remote-Sensed Data; Leveraging Other Authoritative Data Sources; Changing Paradigm of Data Gathering Pilot-testing of census and/or survey instrument
Collect	Use of State-of-the-Art Technology for Data Collection; Georeferenced data collection Electronic data collection and transmission
Process	Integration of Scanning and Machine Intelligent Data Capture Technologies; Innovative Transfer of Mobile Electronic Data into Master Data Files Automated Preemptive Data Quality Checks and Data Cleaning Applications
Analyse	Multisector Thematic Analysis of Census and/or Survey Data Linked to National and Sustainable Development Goals; Needs of Citizen and Private Sector; User-Friendly Data, Easier to Understand Generate Reports and Maps
Disseminate	Electronics dissemination Web services, APIs, Cloud based Electronic storage and retrieval
Evaluate	Real-Time Census and/or Survey Monitoring Demand for real time analysis Historic comparison and measure

Source: author

Also, other more transversal skills should be mobilized for modern agricultural statistician. These complementary skills relate analytical and IT Capacities, process management capabilities, communication skills and the development of analytical expertise.

4. Issues to be addressed

Training programs

Training and capacity building programs will be adapted to these topics and technologies. There will be a combination of different modes that are

- Shorter duration training leading to certificate programmes
- Longer duration training leading to degree programmes
- Customized training programmes
- Training for corporate sector
- Ad hoc training programmes

These types of training will thus integrate a heavy dose of technology and technique. That is the use of GPS data in statistical production, the use of satellite data, changing data collection methods incorporating electronic technologies for collecting and transmitting data. A prominent place should be given to the mastery of statistical software in agriculture.

Table 2: Thematic domain for agricultural statistics

Thematic domain	Training and research topic
Reference framework	• Framework for development of an integrated agricultural statistics programme • Mainstreaming agriculture into NSDS • Implementation of an Integrated Survey Framework
Master frame for integrated survey	• Use of GPS in the production of agricultural statistics • Linking area frames with list Frames • Use of remote sensing
Data collection methods	• Improvement of estimation of crop area, yield and production • Methods for estimating crop area, yield and production (mixed crops, repeated cropping, continuous cropping) • Methods for estimating yield of root crops • Cost of production • Methodology for enumerating nomadic livestock, estimating livestock products • Adoption of new technologies • Forestry and deforestation • Crop forecasting and early warning • Inland fishery, aquaculture • Interaction between climate, environment, global warming and agriculture • Land cover monitoring
Food security	• Methodology for the estimation of supply utilization account, food balance sheets, food stocks, edible forest products • Nutrition indicators • Use of households surveys / LSMS for food security indicators
Market information	• Estimation of farm gate prices • Collecting data on agriculture rural and border market prices • Collecting data on factors and product markets affecting agricultural

	activities
Data analysis	• Reconciliation of census data with survey data • Determination of user's information needs for decision making • Use of small area estimation methods for improving agricultural statistics
Improvement and use of administrative data	• Improvement of administrative data • Use of administrative data for improving agricultural statistics • Estimation of informal cross border trade data

Source: author

Indeed, gender issues, sustainable resource management, poverty ... are specific analytical aspect that must be addressed and adapted to the agricultural sector.
The new agricultural statistician will be a sort of combination of classical statistician and information influenced by challenges in agriculture and in technologies.

Conclusion

The world changes, technologies are evolving in line with the needs for statistical information and policy management. There is an exponential increase in the volume and types of data available, creating unprecedented possibilities for informing and transforming society and protecting the environment. The agricultural statistician like the others statisticians is at the heart of the process and use the techniques and methods of collecting and analyzing data to provide solutions to problems in the agricultural fields. The statistician should adapt itself to changes in both specific thematic and in the methodological skills.

We have shown that the profile of the modern agricultural statistician built with these technological and thematic changes and that the training and capacity building should be adapted accordingly.
New technological developments and topics as well economic, social than environmental are drivers for curricula and capacity bulding of researchers and practitioners.

The necessity to profile definition of modern agricultural statistician lies in the need to meet the needs of the professional world of agriculture. It should also consider cross-cutting issues such as gender, sustainable development, poverty reduction and other related agricultural thematic. However, it should consider the methodological issues raised by these dimensions and aspects for research and the production of agricultural statistics.

ABSTRACT

In the last few years the process of data statistical production in agricultural statistics in Poland was modernized. Data are collected exclusively with the use of electronic equipment - paper questionnaires are no longer in use, both for the obligatory reporting system, and for the sample surveys in private farms. The new techniques effected of diminishing the number of personal interviews (CAPI) and increasing the number of telephone interviews.

The new system of statistical production and data collection requires additional communication skills for the interviewers, such as:

- excellent knowledge of the subject matter i.e. the goal of the survey, basic information on agriculture in the surveyed area, basic information on a farm (if the farm was selected for other surveys)
- ability to establish contact with the farmer
- patience
- resistance to stress.

To improve the communication skills of the interviewers, several undertakings were initiated including professional trainings at the central and regional level, both for trainers and interviewers. E-learning has also been developed in order to enable improving the knowledge in the time preferred by employee.

As it was mentioned, the new techniques required both the professional knowledge and the use of modern technology. To increase quality and effectiveness of the interview, so called hints are commonly used in the IT application. In case of uncertainty the interviewer may click on the word and the definition appears. It helps the interviewer to go smoothly through the questionnaire.

There are also some other tools to help to communicate and collect the data:

- the announcing letter from the President of the Central Statistical Office sent to every holding, which was selected to the survey,
- the info line providing information and help for respondents,
- the organizational and methodological survey descriptions,
- promotion activities concerning statistics in general and statistical surveys in particular,
- improvement of IT tools.

Apparently, agricultural statisticians need to improve their communications skills in due to progressive specialization of employees, whose participate in - various trainings at the central and regional level. The trainings concern communication with media, finding the best way to sell the product, namely, agricultural statistics, and how to communicate with methodologists, IT specialists, survey coordinators and interviewers. The most important goal of these activities is to get the best result – high completeness and the best quality. To achieve this goal, except the skills the support of the technology is essential, hence the development of systems handling with metadata or new communication tools is essential. The other issue is presence of statistical institutions in social media, which requires engagement of statistician with entirely new competences.

Keywords: communication, data collection, modern methods

INTRODUCTION

Each country, each economic group or political party, implementing its program functions through its inherent structure of the authorities. and management must have the appropriate resource information that provides greater rationality and effectiveness of its policies.

Fundamental importance of statistics in democratic societies is to provide all categories of users appropriate range of information. Democratic processes may be implemented by the public in an appropriate manner only if there are the conditions for monitoring the development of the society on the basis of reliable and objective information that reflects the realities and consequences of political decisions.

These two statements are fundamental to the statistics and show in fact that in order to implement posed and ambitious goals, should seek to ensure good communication between the general public and the statistics realizing its statutory tasks.

Both the definition of statistics and the scope of surveys have evolved over the centuries. While in the XVIII century statistics have been defined as "a word recently introduced to express an image or a brief description of some of the kingdom, county or municipality" (Encyclopedia Britannica third edition of 1797), in XIX century statistics was considered as science and incorporated as a section of the British Association for the Advancement of Science. The Royal Statistical Society was founded in 1834. Statistics was defined then as follows: "the facts relevant to humans, possible to present in the form of numbers, multiplied in sufficient quantity indicating the general laws".

Statistical data usually are collected during statistical surveys – either full (comprehensive) or sample, where the primary source of information is the man.

In the last years the idea of acquiring the data from administrative sources is widely promoted, which on the one hand aims to reduce the respondents burden in the times of rapid growth of different surveys, inquiries, Gallup polls – conducted by telephone by institutions other than official statistics.

Official statistics is also updating the methods of data collection, using the CATI method more frequently in order to reduce the costs of statistical surveys. This enforces having adequate communication skills by statisticians to find a common language with various bodies, without which implementation of statistical surveys is impossible.

In the last years in Poland in agricultural statistics the breakthrough was noticed associated with the method of data collection. Due to the decision concerning resignation from the paper questionnaires the system of data collection on media information (internet, phone) was developed.
Paper questionnaires have been replaced by electronic application and hand-helds and tablets were introduced. This solutions forced the Polish statisticians other type of communication, primarily with IT people, but also with respondents who were accustomed to regular visits by interviewers.

COMMUNICATION

Speaking about communication one have to think what are so called target groups to which we want to reach with statistical information.

The main target groups, which Polish statistics communicates have been defined taking into consideration strategic goals of the European Union in the scope of dissemination and communication expressed in the Regulation of the European Parliament and the Council (EU) 99/2013 of 15 January 2013 on the European statistical program 2013-2017 with further amendments (Goal 4.1) directions of communication improvement of statistics with environment indicated in „The ESS VISION 2020" prepared in the framework of the ESSC as well as based on the strategic communication goals of the Polish official statistics.
According to the above, in the Polish statistics following communication target groups have been distinguish among the external environment:

Public sphere (public administration, self-government administration, National Bank of Poland and other banks, finance and insurance institutions, justice and law enforcement, associations, organizations, foundations),

Business sphere **(enterprises, analysts in companies, economic self-government)**
Scientific-educational sphere **(research institutions, universities, schools)**

Media (press, radio, television, internet media, journalists)

Foreign recipients (institutional recipients, international organizations, social organizations, statistical institutions, individual persons, students)

Individuals – persons looking for statistical information (neither connected with research activity nor with professional work)

Entities connected with statistical services (program partners of the CSO, engaged in the preparation and realization of the statistical program of official statistics, data providers from the information systems of public administration, respondents, candidates for the job)

From the point of view of agricultural statistics, especially having in mind the use of modern methods of data collection, specialization of farms, specific and ever-increasing needs of international organizations (FAO, OECD), the European Commission and national users of statistical data, the presented above breakdown of target groups is not entirely justified.

Modern agricultural statistician responsible for statistical surveys has to have broad skills depending the level (long list of diversified skills):

- inside the office – (interdisciplinary) with people from other departments and especially with the census people - if different from current statistical surveys and with the IT people, who play bigger and bigger role in statistical surveys,
- outside the office - with the field staff – interviewers, experts, employees from local governments supporting statisticians,
- respondents = farmers (thanks to them we are engaged in such fascinating area as agriculture) and farmers' organizations – to persuade them to provide the data because they are important also for them,
- stakeholders in the Ministry of Agriculture – to have an influence on the final shape of the legal acts significant for statistics (decreasing the respondents and statisticians' burden), here sociological skills are very important to avoid situation, they push us to do, what we do not want to do,
- owners of administrative data – to be allowed to get administrative data comparable and on time to be useful for statistics, with definitions compatible to those used in statistics and ensured good quality,
- media - how to interpret statistical data and phenomena, how to analyze them,
- among statisticians – exchange of experience in professional statistical journals,
- scientific environment – more and more frequently demanding anonymized individual data for in depth analyses.

What kind of activities from the statistical office should be undertaken to meet this objectives?

Effective communication is based on the principle of "I know who I'm talking to - I'm talking the language attractive and understandable to the recipient". Knowledge of the target groups is the basis of effective communication. Well-described group determine not only the type of message that should be addressed to them, the type of channel through which the message should reach them, the level of complexity of the language in which the message should be formulated, as well as the level of interest led to their message.

The overall message addressed to all recipients should contain the same idea, however the message addressed to each of the groups should be formulated taking into account its specific expectations, the level of interest and the possibilities of perception. At the same time for the addressees of communication relevant tools should be used to efficiently deliver the desired information. When planning communication activities for specific target groups, their expectations in terms of messages and proper, most effective tools of communication should be redefined.

In general we should know the background of the recipients of our information. Different communication skills are required to talk with scientific environment or with the stakeholders and different with farmers or farmers organizations as our respondents.

The skills inside the office.

Communication with the IT people is very important. More and more of statistical surveys is conducted using the electronic tools, like the internet (CAWI), tablets for interviewers (CAPI) or computer connected with the telephone (CATI). For this methods of data collection special applications must be developed, friendly both for respondents and interviewers. Ideal situation is if IT specialists know a little agriculture and agriculture statisticians know a little programming. This enables communication between both parties and ensure good results – good quality of the survey thanks to the simple and clear definitions and questions, rules of navigation through the application according to the specified paths, instructions how to handle errors. Apart from the questionnaire itself, the system of managing the survey is very important – among others tracking the progress of survey, completeness and quality of questions in the operational database.

All the needs of agriculture statisticians must be forwarded to the IT specialists in a concrete way, having in mind the expected results. When planning such statistical survey like farm structure survey, during the planning phase detailed analyses should be made concerning:

- EU legal acts from the point of view of characteristics required in the agricultural surveys,
- the needs of domestic users,
- EU and national definitions and their comparability,
- National and Eurostat validation rules,
- accessibility and quality of administrative sources,
- links between the questionnaire sections,
- experience from previous surveys (sequence of particular sections, sequence of questions, the form and the content of questions, mistakes that occurred most often),
- range values for quantitative characteristics,
- data collection methods.

This is only the example, that modern technology actually makes it easier to work, but requires additional knowledge.

A very important is communication with the people responsible for the census in case they are different units or organizations. All measures must be ensured to keep the comparability of results obtained in the census and other statistical surveys.

<u>Communication with the field staff – regional statistical offices</u>.

This is very important for agriculture statisticians, because the success – good quality with a high response rate survey results depend from the field services. Regular meetings with them builds the team, allows for exchange of experience in different regions, discuss problems, and to build good relationship, which help later in daily work. In the case of Poland regular trainings are organized for statisticians from regional statistical offices responsible for field work. They are trained both in the merit subject of the survey (refreshing existing rules and definitions, discussing in depth the new elements of the survey) and the technical elements – the electronic questionnaire – how to go through the application, how to treat the hard or discretionary errors, how to track and analyze the survey progress and results in a special module. In addition for communication among interviewers, supervisors, specialists from the headquarter and other involved in statistical survey a special tool was developed called JIRA, to put questions, announce problems and get the same answers at the same time.

Every year interviewers from the regional statistical offices in Poland are trained to extend and consolidate the knowledge of the legal basis of the functioning of public statistics, sampling methods and construction of the questionnaire. They also improve their interpersonal skills and how to cope with difficult situations. Statisticians can also use the e-learning program.

<u>Communication with the field staff – experts.</u>

Agriculture is a very broad area of statistics, depending on meteorological and economic conditions. It is good to have first-hand information. Having this in mind in Poland special contracts are signed with field experts recruiting from agriculture advisory extensions. They provide monthly information on different issues during the year and in the vegetation season – adequate information on the area and expected yields of individual crops.

The main objective of the communication activities is to convince potential experts about the nature of their participation in the project as well as that they constitute the important source of information on agriculture. They usually know the neighborhood, farmers and general condition of the area under their responsibility, so talking to farmers they also represent agricultural statistics – in a way.

Important part of activity of agriculture statisticians is participation in a different local conferences and fests organized for farmers, when statistical information are distributed. In some of such occasions farmers have had opportunity to provide data on a special computer for the currently conducted survey.

Respondents

Respondents are very important target group, from the communication point of view. Due to the need to maximize the percentage of completed reports and obtain the best quality data, official statistics should make every effort to ensure the proper way to communicate with respondents. The main objective of the communication is to convince the respondents about the importance of their participation in the survey and to convince them that they are the only source of information. It is also important to emphasize the fact that the information gathered by the survey will be used only to develop aggregate information and analysis, and individual data will not be available anywhere. Agriculture respondents in Poland can be divided into 2 specific groups, which are the subject of various communication activities: natural persons' farms as well as legal persons and organizational units without legal personality, which carry out the reporting obligation.

Towards physical persons – individual farmers, such activities like sending an invitation letter, explaining the goal of the survey, the ways and technics of data collection, information concerning statistical interviewers and possibilities of confirming their identity, statistical confidentiality and access to the survey results. If the e-mail address is known, respondent receives a message concerning participation in statistical survey.
On the website the questionnaires are placed informing on the frequency of data collection, allowing for earlier acquainted with the scope of the collected data, with the possibility of print. For all farmers there is also possibility for self-filling the questionnaire. In addition a special hotline (info) runs during the survey. All must be sure that statistical confidentiality will be kept.

In case of farm structure survey or agricultural census, posters are placed in the municipal offices, branch offices of the paying agencies and other visible places in the rural areas, as well as broadcast at local TV or radio are held to promote the survey and attract farmers to provide information.
They are a very important communication channels with farmers building the trust between both interested parties.

Towards legal persons and organizational units without legal personality, which carry out the reporting obligation similar activities are undertaken like placing on the CSO web site information concerning all surveys during the year as well as the questionnaires, to allow prior acquainted with the scope of the study. Electronic tool to provide the data, together with the information concerning login, account activation, contact person in case of unforeseen problems is also provided as well as discussion forum where comments can be submitted.

Stakeholders. Central administration and local government is a very important partner in the process of communication of Polish official statistics, including agriculture statistics. Communication actions that are taken to this group can be divided into activities addressed to the data users, data providers (including their role of owners of administrative registers) as well as the partners having an influence on the content and realization of the statistical survey program.

Policy makers' need reliable information to support decisions, so they have to be ensured, they can use statistics as reliable, evidence-based and an unbiased picture. This message must go from statistics, and in my opinion, the process of building of the statistical survey program, involvement in the consultation process of elaboration of European regulations concerning statistics allows for further understanding and cooperation. On the other hand statisticians, for good and effective communication, should have the knowledge on the Common Agriculture Policy (goals, priorities, mechanisms, implementation and evaluation) to collect and provide comparable data on agriculture and its structure in the country and at the European level.

In case of media and journalists statisticians should pay a special attention. This group of data users is crucial for the image of statistics, because they have the direct influence on other recipients of statistical information. Media are both the recipient of the message, as well as generate the same messages in the mass media – newspapers, radio, TV and in the internet (including social media). Message must be concrete, clear and on time. Quality of statement is very important – writing articles is perhaps less stressful, but personal participation in the radio or television broadcast reinforces the message. The form of communication is conducted in different ways – like press conferences, briefings, short messages in a paper form, interviews etc.
On the other hand statisticians should not only provide information to journalists, but also undertake an effort to improve the statistical literacy among them for better interpretation of statistical data and phenomena.

Scientific environment. Publications with in-depth analyses are elaborated together with and for researchers. In the process of bilateral consultation on the scope of statistical program, they have a contribution to the surveys conducted by official statistics. They also use the results generated by statistics. The new, modern forms of data presentation, vizualization and dissemination makes it possible that researchers can make their own calculations. Close contacts with researchers are important – we invite them to provide lectures at statistical conferences and statisticians are invited on scientific conferences to explain methodology, the process of data production, present the data and express professional skills. Among statisticians we usually share our experience in professional journals.

SUMMING-UP - CHALLENGES

To meet all requirements of contemporary statistics, statisticians are the subject to a constant process of training, improving their knowledge. In today's complex production process of statistics and their dissemination, agriculture statisticians need to improve ways to "reach out" to farmers (respondents) who are specific and increasingly demanding social group, as well as effectively communicate with owners of administrative registers, providers and recipients of statistical data.

Communication skills, as it was mentioned earlier are crucial for identification of information needs of data users and ability to respond flexibly to their needs in terms of survey topics, to attract the forms of data presentation with the use of modern communication channels as well as building partnership with data users.

Elaborated and published by Eurostat document “Digital Communication, User analytics and Innovative products” (ESS.VIP DIGICOM) provides information and show the new challenges. Underlines, that users’ needs are crucial and the European Statistical System should be flexible and responsive to them. The project will have a parallel approach – on one hand it will improve the methods for gaining insight into unmet needs of current and future users and on the other hand actually developing the innovative solutions meeting those needs.

Indicated priorities – tasks to perform in the near future will require new or improved communication skills from statisticians, including agriculture statisticians, who in many cases are pioneers in applying and implementing new solutions.

In the modern world, the comprehensive knowledge and interpersonal skills are as important as professional knowledge. In our work as agriculture statisticians, we communicate daily on different levels and in different ranges, using not only face to face talks but also phone calls, e-mails etc. We undertake decisions, we forward information and we perform commands. One should not forget, that some forms of communication arise from performed functions, therefore profiling contacts and improvement of communication skills is formed in a natural way.

SEVENTH INTERNATIONAL CONFERENCE ON AGRICULTURAL STATISTICS

FOOD AND AGRICULTURE ORGANIZATION OF THE UNITED NATIONS

Modernization of Agricultural Statistics in Support of the Sustainable Development Agenda
(Rome, Italy 26-28 October 2016)

Parallel Session – Cross Thematic set H:
Data dissemination & communication / Use of statistics for policy making & research
[48] The new professional profile of Agricultural Statisticians

Information Technology Skills in the Profile of Modern Agricultural Statisticians

Joseph L. Parsons

DOI: 10.1481/icasVII.2016.h48c

Abstract

Information technology skills are needed at each stage of official agricultural statistics production; including frame development, data collection, survey cleaning, analysis, summarization and disclosure, and publication. This topic will address the skills required tocomplete each phase of the statistical data collectionprocess and how statisticians can effectively partner with information technology specialists within the Ministries of Agriculture and National Statistical Organizations.

This paper will provide background on the evolution of information technology (IT) at NASS as it relates to the production of official agricultural statistics. It will also discuss the skills statisticians need and ways in which those skills can be developed.

Keywords: Skills, Information Technology, Data Collection, United States Department of Agriculture, USDA, National Agricultural Statistics Service, NASS

1. Introduction

The National Agricultural Statistics Service (NASS) is the principle agricultural statistics data collection organization within the United States Department of Agriculture. The agency conducts hundreds of surveys every year and prepares reports covering virtually every aspect of agriculture in the United States. NASS's mission is to provide timely, accurate, and useful statistics in service to U.S. agriculture.

Beginning in 2009, NASS started a journey to pursue three transformations, primarily to provide savings in staff resource costs and improve the quality of our statistical products by enabling the centralization or regionalization of survey operations. The transformational initiatives involved: (1) centralizing and consolidating network services from 48 locations (Parsons and Gleaton, 2011); (2) standardizing survey metadata and integrating survey data into easily accessible databases across all surveys; and (3) consolidating and generalizing survey applications for the agency's diverse survey program (Nealon, 2013). During this same time period, NASS reorganized its headquarters operations, opened a national operating center and consolidated the vast majority of its field staff into twelve regional offices. About one-half of agency statisticians and technology professionals are located in the field with the remainder located at a national operations center or a headquarter location. These changes all aspects of agency operations including the technology skills required of much of our workforce.

Most NASS hires are agricultural statisticians, mathematical statisticians or are in the information technology job series. The agricultural/survey statisticians tend to have a background in agriculture and economics with the requirement of having completed several math and statistics classes. Many of theagricultural/survey statisticians we hire today have a masters degree and a few have doctoral degrees. Our mathematical statisticians have at least a bachelors degree, typically in mathematics or statistics.Most have a masters degree and we hire several with doctoral degrees. Those with specialized degrees are concentrated in our research and methodology teams. Our information technology specialists are often hired mid-career and have varied backgrounds depending upon their specialization (e.g. database administrator, software developer).

In this paper we will discuss the need for technical skills and the development of those skills for statisticians collecting and disseminating official statistics on items related to agriculture. We will share the experiences at the National Agricultural Statistics Service and relate how those experiences might inform others with similar opportunities and challenges. We will focus on agricultural/survey statisticians in the first years of their professional career, but will offer some limited observations on the development of other key groups of employees.

2. Developing Technical Skills of Statisticians

NASS and other similar statistical organizations are 'data factories'. The 'tools' in our factories are for the most part, information technology applications and staff need theskills to leverage, develop and enhance those tools. The layout of the factory floor of those generating official statistics will be pretty familiar across different organizations. The Generic Statistical Business Process Model (GSBPM) components describe and define the set of business processes needed to produce official statistics (Appendix A). The major business processes include: specifying needs, design, build, collect, process, analyze, disseminate, archive and evaluate.

Each of these major business functions have information technology tools that underpin the statistical processing activity that must be completed to produce relevant official statistics. For example, NASS uses Blaise software for data collection in its call centers and for interactive editing of some of the surveys conducted. Statisticians located in regional field offices work in Blaise frequently editing data and reviewing records. A smaller group of statisticians, working with survey methodologists, design Blaise data collection and editing instruments. These statistician/designers interact with those information technology professionals that support the application, the infrastructure, centralized database and metadata on which the application depends. Those statisticians providing this backend support must interact and collaborate with others that support the other enterprise tools so that the entire 'factory' runs effectively.

Over time NASS has created protocols to develop and train newer agricultural statisticians. For the cohort of newer agricultural statisticians involved primarily in data collection and estimation working in our regional offices, the training efforts are relatively standardized. Additionally, every employee in NASS is required to have an individual development plan (IDP). An IDP is a tool to assist employees in career and personal development. Its primary purpose is to help employees reach short and long-term career goals, as well as improve current job performance (US Office of Personnel Management). For newer agricultural statisticians several training events and career experiences are included in their plan along with specialized items that address their particular career interests or job responsibilities. NASS has also developed career guides to assist employees in managing their career development (NASS, 2016).

Each year our training and career development group conducts a training needs assessment. Typically, the assessment is sent to first and second level supervisors to prioritize training needs that are widely recognized. Managers are informed by the gaps they observe in the staff they supervise and in the IDP consultations they conduct with their staff. In addition, statisticians receive a version of the assessment so they can take a personal assessment of their skills in these essential areas.

The assessment helps to prioritize the areas on which to train and further focus how the training is specifically delivered. The following is a snippet of a recent assessment to help drive the annual formal training agenda. As shown, many of the areas are a blend of concepts and use of the actual tools.

Figure 1: Skills Assessment Grid

	What percent of your unit's ag and math stats:				
	Do not regularly use this skill in their current position	Are NOT AT ALL Proficient and need significant additional training or experience	Are SOMEWHAT Proficient but need some additional training or experience	Are COMPLETELY Proficient and do not need any additional training or experience	Total
cSMS Functions--Set DCMS codes and identify survey modes (Paper, CAPI, CAWI, CATI)					100%
cSMS Functions--Use Events tool to set data collection flags based on DCMS codes					100%
Blaise Processes--Identify records of concern					100%
Blaise Processes--Conduct forms editing - identify and interpret warnings, and resolve data inconsistency					100%

Most of our newer statisticians work in team settings and are paired with one or more experienced statisticians. A great deal of informal on-the-job training takes place in this setting. Our newer statisticians generally bring good generalized technical skills such that they are very comfortable with typical information technology office tools. However, our 'factory' has many specialized business processes and information technology tools to support those processes. Our experienced team leads are a key resource in developing the skills of our newer staff and helping them understand the survey concepts and the specific applications and tools used within the agency.

We blend this on-the-job training with more formal training sessions developed from input received on the training assessment and constrained by budgetary resources. Formal training sessions are usually a business week in length and are typically held at our training facility located within our national operations center. These sessions typically include thirty to fifty participants. Most of our training is focused on a particular survey or survey program or task.We also have a series of courses that focus on survey and estimation concepts. In every training case, staff bring their laptops, connect wirelessly to our network and virtual desktop environment to work with applications and tools that are integral to the training.

Our distributed operating environment is enhanced by being able to conduct hybrid learning environments. For example, we frequently are able to include additional instructors and technical expertsvia video teleconference (VTC). This allows us to tap a larger set of skilled trainers for interactive training sessions. In addition to the week-long sessions, we conduct frequent VTC sessions of one or two hours. Some focus on survey management issues, but others – through screen sharing – help to educate a distributed workforce on new or updated information technology tools.

NASS has made strong effective efforts to move toward enterprise level applications for case management, editing, summarization, analysis and other key functions (Drennen and Parsons, 2014; Parsons and Duxbury, 2013). These enterprise tools can accommodate highly varied survey efforts. They rely on centralized relational databases and curated metadata (Nealon, 2013). NASS also moves data from the transactional databases that support these applications to analytical databases. We train newer statisticians to leverage standardized queries and predefined analytical tools to support the generation of accurate official statistics.

However, not all answers to relevant data issues will be found in these standardized queries and predefined analytical tools. We train more experienced agricultural statisticians to leverage business intelligence tools to explore and resolve data issues not easily addressed directly from within the tools. Our data services team that includes database administrators and metadata specialists often assist in hosting sessions on effective data exploration.

Some of the applications and technology that our agricultural statisticians use are not developed from within NASS. For example, statisticians in our regional offices frequently use applications from another USDA agency to mine farm program administrative data to verify operating status and estimate for nonresponse.

Most of our regional agricultural statisticians are generalists and work across the ‘factory floor’. However, we have some niche tasks in which our regional agricultural statisticians develop expertise. For example, our field data collection staff use Apple iPads for data collection, data transmission, and survey training. A corps of our regional statisticians help keep this fleet of several thousand devices operating and their users trained. We hold periodic training to support this corps of employees as tools and procedures are updated.

Many of our headquarters agricultural statisticians are former regional statisticians. Frequently, the headquarter roles have a specific focus such as frame development, gathering survey requirements, or estimation and dissemination. Their general background and experience is invaluable to be able to connect their specialization to the broader work of the organization.

Conversely, many of our mathematical statisticians are hired with skills in sampling or statistical programming and placed in specialized roles. We use temporary assignments and other experiences to expose these more specialized statisticians to other roles and tools used within the organization. Most recently our methodology team hired nearly twenty new mathematical statisticians into a variety of jobs. We have taken advantage of having an entire cohort of new specialized statisticians to hold a series of training sessions on the tools and concepts unique to the organization.

While tools and technology are imperative to the success of the modern agricultural statistician, the most important attribute is critical thinking. In fact, we must ensure that training on the “how” does not crowd out the “why”.

The profile of the modern agricultural statistician and the agricultural statistical agencycontinues to evolve. The tools we use and the focus on relational databases and the ability to manipulate data continues to grow. As we move forward, new skills will become more important. For example, we are using web scraping techniques to develop specialized lists of farm operations and explore the use of the technique to measure list sampling frame coverage. Specialized statisticians and geographers at NASS leverage big data to develop geospatial data products and inform other work of the organization. Almost certainly in the future, sensor, drone and other big data sources will inform our work and drive the technology skill set of our statisticians.

3. Conclusion

Another description of the nexus of the computer scientist, quantitative social scientist and statistician is the ‘data scientist’. Undoubtedly, NASS and other organizations that produce official government statistics will increasingly need employees that are comfortable in the space that blends computing and computer science skills and statistics. As has always been the case, it is challenging to produce accurate and relevant official statistics for agriculture, but there has never been a more demanding, exciting, or interesting time to work in the field of agricultural statistics.

The GSBPM describes and defines the set of business processes needed to produce official statistics. It provides a standard framework and harmonized terminology to help statistical organizations to modernize their statistical production processes, as well as to share methods and components.

PRE-CONFERENCE & CONFERENCE SIDE EVENTS

YOUNG STATISTICIANS

A two-day Training Seminar on Methodology for Agricultural Censuses and Surveys has been held on October 24 and 25, 2016. The seminar was intended for young statisticians working in the field of agricultural statistics, or statisticians new to the field of agricultural statistics to encourage an active interest.

GS TRAINING AND OUTREACH WORKSHOP ON AGRICULTURAL SURVEYS

A two-day workshop has been held at FAO headquarters in Rome, on 24-25 October 2016, back to back to the ICAS VII Conference. The Training and Outreach Workshop on Agricultural Surveys was opened for representatives of National Statistical Offices and Ministries of Agriculture and researchers, technicians and statisticians specialized in agricultural statistics methodology.

SEMINAR ON STRENGTHENING COLLABORATION BETWEEN AGRICULTURAL ECONOMISTS AND AGRICULTURAL STATISTICIANS

The seminar was held at FAO headquarters in Rome on 25 October 2016 and it was aimed at connecting producers and users of agricultural statistics with emphasis on the use of Agricultural Statistics in economic analysis.

COMMITTEES

ICAS VII SCIENTIFIC PROGRAMME COMMITTEE

The technical content of this Seventh International Conference on Agricultural Statistics was set by the ICAS VII Scientific Programme Committee, co-chaired by the Chair of ISI CAS and the President of the Italian National Institute of Statistics (Istat).

CO-CHAIRS

Giorgio Alleva | Istat President
Pietro Gennari | Chief Statistician | Food and Agriculture Organization of the United Nations (FAO) | Rome | Italy

MEMBERS

Rui M. S. Benfica | International Fund for Agricultural Development (IFAD)
Lisa Grace S. Bersales | Philippine Statistics Authority (PSA)
Mary Bohman | Economic Research Service, US Department of Agriculture (USDA-ERS) – USA
Flávio Bolliger | Instituto Brasileiro de Geografia e Estatística (IBGE)
Calogero Carletto | World Bank
Geoffrey Greenwell | Partnership in Statistics for Development in the 21st Century (PARIS21)
Neil Hubbard | Institute for Environment and Sustainability (JRC-IES) – European Commission
Arif Husain | UN World Food Programme (WFP)
Tassos Haniotis | Directorate-General for Agriculture and Rural Development (DG-AGRI) – European Commission
Marcel Jortay | Directorate-General Eurostat (DG-ESTAT) – European Commission
Shigeru Kawasaki | International Association for Official Statistics (IAOS)
Ada van Krimpen | The International Statistical Institute (ISI)
Angela Me | UN Office on Drugs and Crime (UNODC)
Pedro N. Silva | The International Statistical Institute (ISI)
Tolulope Olofinbiyi | International Food Policy Research Institute (IFPRI)
Susana Pérez Cadena | Instituto Nacional de Estadística y Geografía (INEGI) – Mexico
Alessandro Sorrentino | Università degli Studi della Tuscia – Italy
Franco Sotte | Università Politecnica delle Marche – Italy
Michael Steiner | National Agricultural Statistical Service, US Department of Agriculture (USDA-NASS) – USA

COMMITTEES

ICAS VII NATIONAL SCIENTIFIC COORDINATION COMMITTEE

The National Scientific Coordination Committee was set to promote the wide participation of Italy in the various fields of interest of the Conference. It also contributed to identifying the topics to be included in the different sessions; singling out the speakers; providing assistance to the evaluation activities of the national and international contributions deriving from the call for papers; offering a scientific support to Istat in carrying out the works.

CHAIR
