FOREWORD

The adoption of the Global Indicator Framework for assessing progress towards the 169 targets of the 2030 Agenda for Sustainable Development has been a watershed for the global statistical system. Monitoring the SDG indicators will be a very demanding task for all countries in the world. Not only they are about four times more numerous than the MDG indicators, but data will also have to be made available for various vulnerable population groups to reflect the guiding principle of "leaving no one behind".

Agriculture is at the heart of the 2030 Agenda. Modernizing agricultural statistics is thus crucial for enabling countries to rise to the challenge of monitoring the SDGs with timely, relevant and accurate data. In response to this need, the Italian National Institute of Statistics (Istat), in close collaboration with the Food and Agriculture Organization of the United Nations (FAO), organized the Seventh International Conference on Agricultural Statistics – ICAS VII, under the overarching theme "Modernization of Agriculture Statistics in Support of the Sustainable Development Agenda".

The Conference, held in Rome on 26-28 October 2016, convened 428 experts from around the world to discuss cutting-edge methodologies and best practices in the field of agricultural statistics for monitoring the 2030 Agenda. A significant part of the programme has been dedicated to the utilization of new data sources and innovative methods to support the production of cost-effective and high-quality agricultural statistics. At the same time, the interaction between analytical research and agricultural statistics has been one of the highlights of the Conference, together with a strong focus on the use of data for evidence-based decision making. The papers presented at the 48 parallel sessions and the four plenaries, as well as the posters, collected in this online editorial format, are meant to foster the methodological and analytical debate on the critical issues and opportunities that agricultural statistics face in the 21st century.

We are grateful to all session organisers and authors for the contribution they provided to the success of the Conference. Our sincere esteem also goes to all the members of the Scientific Programme Committee who have helped develop such a thought-provoking Conference agenda, and to all the sponsoring agencies who generously supported a large number of participants from developing countries.

The joint organization of ICAS VII has to be seen as yet another testimony of the long-standing and strong collaboration between FAO and Istat, which has allowed over the years a fruitful exchange of knowledge and expertise in support of the advancement of agricultural statistics at the international level.

P. Gennari | Chief Statistician | Food and Agriculture Organization of the United Nations (FAO) | Rome | Italy

MODERNIZATION OF AGRICULTURAL STATISTICS TO RESPOND TO NEW MULTIDIMENSIONAL DEMANDS

Session Organizer and Presenter
G. Alleva | President | Istat | Rome | Italy

DOI: 10.1481/icasVII.2016.pl1

ABSTRACT

Institutes of Statistics, National Institutions and International Organizations are committed to modernizing statistics worldwide. This commitment should include also agricultural statistics, which plays a key role in the analysis of human development, as widely acknowledged, for example in the Millennium Development Goals.

Modernization means changing, renewing, in order to better achievequality and relevance of statistical informationas well as efficiency in the production of such information. Modernizing implies lower costs, with a great opportunity, especially for developing countries.New technologies and statistical methods can enable to gain of efficiency, reducing time needed to improve and to fill the gaps.

Primarily, the exploitation of administrative sources provides a tremendous opportunity to reduce data collection costs, and therefore helping the modernization ofdeveloping countries and facilitating reducing differences between countries. The use of new technologies, new methods and the exploitation of existing databases can be favored by the action of international organizations.

Thus, the main areas of intervention of modernization processes are: joint exploitation and integration of data from different sources (e.g. administrative data vs survey data, master sampling frames, big data etc.), new data collection techniques, new technological improvements (e.g. GPS and remote sensing) and the production of new indicators in response to the growing demand by policy-makers and decision makers for statistics based oninformation that is interlinked in economic, social, and environmental aspects (e.g. indicatorsfor gender/youth-related data, rural statistics,agro-environment data, better integration of geographic information and statistics).

In addition to the above areas, organizational and human resource management issues are equally important. In particular , investing in the development of human capital will be crucial for the modernization of agricultural statistics as well as for the development in general .

To show the main and most challenging opportunities and advantages of the modernization of agricultural and rural statistics, discussing the key success factors of this process are the objectives of the session.

PAPER

Mr Gennari, distinguished guests, colleagues, good morning. It is indeed a great pleasure to welcome every one of you to the ICAS VII International Conference on Agricultural Statistics.

This seventh edition -- that we, as Istat, the Italian National Institute of Statistics, have had the honour to organise in collaboration with the Food and Agriculture Organization -- is intended to offer you the ideal forum to share views and ideas on the changing needs and new opportunities for agricultural statistics, both in terms of needs for information and methodological tools.

The next three days provide a very full agenda with a rich programme of sessions and side events. The conference has as its foundation 4 Plenary sessions, with 48 Parallel sessions focusing on: 5 sets of themes, 3 multi-disciplinary themes and one poster session. More than 200 presentations are scheduled, with over 600 contributors and almost 500 registered participants from some 80 countries around the world.

Today, I wish to discuss the modernisation of statistical systems, and of agricultural statistics in particular, which I believe is essential in order to be able to address the increasing complexities of the compelling need for information.

Of course, we are no longer at the starting gate of this race for information. A significant wealth of information at the global level has already been made available. Moving forward from this as a baseline, I would like to showcase just a few relevant and multidimensional milestones which also indicate directions for the future of world agriculture.

PL01

The need for information is still growing very quickly. World statistical capacity is growing too, and with the agreement that has been reached on the Sustainable Development Goals (SDGs), data producers are being asked to accelerate their production to new levels. The SDGs represent a challenging opportunity to strengthen the institutional statistical framework, to support governments' decisions, to enhance capacity, foster co-operation, share experiences and reduce inequalities. Actually, as we will see, agriculture statistics play a central role in the 2030 Agenda for Sustainable Development.

I will briefly review the coordinated efforts of agricultural statisticians in the building and achievement of a coherent global system of agriculture statistics based on high quality data.

Finally, starting from the existing toolbox that countries may use to produce high quality data, I will stress some key elements in the process of modernization of statistical systems as a strategy for the integration of sources, technologies, methodologies and competencies, a strategy which, I believe, is also highly relevant for agricultural statistics.

Agriculture lies at the very centre of a number of interconnections between humanity, its odds of survival, living conditions and the planet. It is no wonder, then, that the demand for statistical data related to the primary sector is increasing.

As it has been for thousands of years in the past, agriculture today is the basis of human food production. The perspectives for world population represent a huge challenge: the population of the world is expected to surpass 9 billion people by 2050, and feeding 2 more billion people represents the major goal for world agriculture. We need to address this challenge, which is all the more serious because the increase in population will occur entirely within urban areas.

Today, one person out of nine still experiences chronic hunger. The percentage of the undernourished population has gone from a level of 19 to 11 percent, nearly fulfilling the Millennium Development Goal target to "halve, between 1990 and 2015, the proportion of people who suffer from hunger". However, this situation is still far from satisfactory, particularly in those 30 countries where hunger affects over 20% of the population.

At the dawn of the third millennium, almost 2.6 billion people still base their subsistence on the pursuit of agriculture, forestry, fishery or hunting activities. The economic weight of the agricultural sector has experienced a long term decline, even if it recovered part of its original share of global GDP in the last decade, and today it represents about 4.3% of total GDP. One fifth of the employed population in the world is engaged in the agriculture sector.

Meanwhile, thanks mainly to a continuous rise in productivity, agricultural production has progressively increased, supplying more and more food to the world population (sessions B7 and B8 will be dedicated to agriculture productivity). At the same time, food deficit (a basic measure of access to food) has decreased considerably since the Nineties all over the world. Of course, food availability does not always guarantee high food security, which is also determined by income, food prices, infrastructures and social support. Many African countries still register a daily per capita food deficit index well over 100 kilocalories.

As for what concerns environmental issues, agriculture plays a positive role in capturing carbon, managing watersheds, preserving biodiversity and landscapes, and providing feed stock for biofuel production. At the same time, in most countries, agriculture is the largest user of water, a big producer of chemical pollution and soil degradation and a contributor to climate change. The Intergovernmental Panel on Climate Change estimated that agriculture accounted for one fourth of global greenhouse gas emissions in 2010, mostly with crop cultivation, the raising of livestock and deforestation. The trend is not encouraging. Agriculture greenhouse gas emissions have grown by 15% since 1990, even if they rose less than emissions from other human activities. In the same period, the production of livestock grew by 72% and 3% of forests disappeared. According to FAO's 2016 SOFIA Report, the status of fish stock is also of great concern, despite certain improvements in the recent past.

Well, some of these key facts and figures in agriculture I just presented are probably well-known to most of you, and this is only a minor portion of the data you can find on FAOStat and in other international data-warehouses. However, let me say that if we are able to draw accurate pictures of world agriculture, it is thanks to producers of agricultural statistics, to FAO, to National Statistical Offices, researchers, it is thanks to you.

Nevertheless we cannot consider ourselves satisfied, ever: very basic information. such as, for example, the exact number of farmers, is still unknown. A long road is still ahead of us and important challenges need to be met.

First of all, a huge new need for information is represented by the Sustainable Development Goals and the set of indicators associated with them. Agriculture is by nature a crucial determinant of any sustainable development strategy. Each one of the 17 Sustainable Development Goals somehow relates to agriculture, and agriculture can be considered as a common thread that binds all of the 17 SDGs together.

For some of the goals, the relationship is direct and self-evident, such as for the 'zero hunger goal (2)', 'life on land (15)' and 'fishery (14)'. We have to consider that the rural population represents the largest majority of the world's poor (1) and agriculture is a massive (substantial) source of employment and a fundamental economic sector (8). Infrastructures (9) will definitely alleviate poverty, facilitate access to food and water, but also generate employment and reduce poverty in rural areas, thus reducing overall inequalities (10) and limiting the creation of slum dwelling (11). The enhancement of a sustainable consumption and production model (12) forecasts a sharp decrease in food wasted.

Food systems consume about a third of the world's available energy and agriculture contributes to the production of energy crops (7), effects healthy environments and produces emissions (13). Crops and livestock account for about 70 percent of all water withdrawal, and agriculture is also a significant water polluter, therefore playing a central role in the clean water goal (6).

In some cases, the relationship between agriculture and SDGs is less immediate, but still strong and persistent. Since the demand of water and wetlands is at the heart of many conflicts, an increase of efficiency and sustainability in agriculture might be considered as a tool to promote peaceful and inclusive societies (16). Over half of the food in the world is produced by women, but difficulties in access to resources makes them less productive than their male counterparts, feeding gender inequality (5). Moreover, child agriculture workers represent nearly 60 percent of child labour that has limited access to a quality education (4). Finally, all these processes need a strengthening of international aid and technical cooperation for agriculture (17).

On overall, statistics has been given a prominent role in the implementation of the 2030 Agenda for Sustainable Development and, in particular, in the monitoring of the 169 targets associated with the 17 goals.

This new common framework could bring about important results in terms of statistical capacity. Indeed, data availability has significantly improved thanks to the adoption of the Millennium Development Goals framework. Yet, with 304 proposed indicators, some of which are difficult to monitor or have very little data coverage and availability, monitoring the SDGs will be even more challenging as time goes on, and it will entail significant costs. The latest Statistical Capacity Indicator dashboards show that during the past 10 years nearly 30% of the 146 selected countries never conducted an agriculture census, the fundamental source of information for this field.

Substantial work is still needed to strengthen statistical systems at the national level and improve methodologies. According to the Sustainable Development Solutions Network (SDSN, a global UN initiative), about 1 billion dollars a year may be needed in 77 low income countries to strengthen statistical systems in order to support and track the SDGs. (*The issue of financing the modernization and resource mobilization will be addressed on Friday in Plenary PL 4*).

The increase in statistical capacity must be confronted with a view to building a consistent and homogenous global system of agricultural statistics, which will necessarily be based on the interdependence of national and international statistical activity.

This comprehensive and detailed framework is represented by the Global Strategy to Improve Agricultural and Rural Statistics, which was approved by the UN Statistical Commission in 2010 and aimed at improving the availability and use of reliable agricultural and rural data.

These goals are to be achieved with the production of a minimum set of core economic, social, environmental and geographical data, which each country in the world should collect; through a more complete integration of agricultural statistics into national statistical systems and by achieving substantial advances in governance and statistical capacity building.

The challenge represented by the new emerging demands for information and processes has to be tackled keeping in mind the ultimate goal of statistics: producing high quality data.

Data quality basically refers to compliance with agreed upon international standards: the professional independence of statistical authorities, the adoption of sound methodologies, the accuracy and precision of estimates, their timeliness and punctuality, their coherence, comparability, accessibility and clarity.

In addition to what has been said, official statistics is encountering human and budget constraints all over the world. Thus, efficiency also becomes a necessary condition for meeting our responsibilities.

However burdensome, quality standards should be applied to each step in the data chain, from the statement of objectives to data collection and processing to dissemination.

Indeed, there are many challenges National Statistical Offices need to face:

- The measurement of new complex cross-cutting issues (such as, for example, globalization, sustainable development, climate change)

- Sampling surveys are expensive, response rates are decreasing, and it is necessary to limit response burden. Nonetheless, the conduct of surveys will remain essential in order to satisfy the multidimensional demand for good quality statistics
- Agriculture, forestry and fisheries statistics normally draw on several different sources and are often collected by statistical offices, ministries and other research authorities, therefore consistency checks are important
- Data collection should not be redundant. Close cooperation should be established between all institutions involved for the purpose of increasing efficiency
- New technologies, administrative data and big data may reduce the number and the sample size of statistical surveys; we shall see several examples of this during the conference. Re-thinking data capturing systems represents a milestone in re-engineering the work of statistical offices
- Finally, human capital skills must be improved and adapted to changing roles and responsibilities

All these factors contribute towards the enlargement of the methodological toolbox and a re-thinking of the organization traditionally implemented by statistical offices. New methodological and technological instruments and international best practices should drive change; new possibilities for collecting, processing, integrating and disseminating high quality statistical data in a more efficient way should be explored.

We refer to all these different improvements using the term "modernisation".

The modernisation of agriculture statistics needs to be addressed through the analysis of the strengths and weaknesses of available techniques.

Traditional statistical surveys tend to respond to local or national conditions, cultures and goals, even if, over the past few years, increased efforts have been made to establish methods to allow comparison and evaluation across national and cultural boundaries.

Aside from their solid methodological background, dependence on traditional surveys is associated with a difficulty in identifying other coherent and timely data sources.

Administrative data are more and more important in the framework of official statistics (*sessions F32 and F33 are specifically dedicated to this issue*). The acquisition of administrative data may have lower costs for the statistical offices, and timeliness is normally not an issue but may vary widely among sources. A lot of capacity is required for setting up the infrastructures for storing and computing this type of data and the methodologies for exploiting them in official statistics production. The measurement of accuracy is also a complex issue to be managed; stability and efficiency of national statistical systems are key requirements to ensure the usefulness of these data for statistical purposes.

Experts' estimations are very often used for hard-to-measure phenomena, such as rare or illicit cultivations, even though the quality of expert's estimates may be poor (*Session B9 tackles this issue*). These estimates should be periodically benchmarked with more robust measurement tools.

Statistical models (which will be discussed during sessions G43 and G45) and Small Area Estimations are also needed when very detailed or rare phenomena are to be measured (for example, to estimate crop production for particular small areas or the degree of humidity of some cereals). They enhance overall quality, leveraging spatial and time correlations of data.

Finally, the use of Big Data in the agriculture statistics framework is still developing, but some best practices are rapidly growing, and examples of application are going to be discussed during various sessions of this conference.

Among Big Data techniques, the ones deriving from the use of remote sensing are very often used in agriculture; they may achieve high quality standards, especially in estimating coverage and detail. This is one of the latest measurement tools, however it usually requires additional field surveys to validate the preliminary estimations from satellite images (*Session F30 is specifically dedicated to these techniques*). Recently, the availability of free of charge maps has reduced the costs of implementation, although a relevant capability of the statistical office is still needed.

Other Big Data sources are used in agriculture to a lesser extent. Potentially, the implementation of more robust methodologies and best practices will improve quality and timeliness of agriculture statistics.

Nevertheless, the use of Big Data introduces new areas of concern related to data access and privacy issues, real costs, a shift in IT requirements, the impact on consolidated methods and data processing.

All these techniques may be combined with each other, as often happens in many statistical offices. As stressed by Constance Citro "we can and must move from a paradigm of producing the best estimates possible from a survey to that of producing the best possible estimates to meet user needs from multiple data sources". In order to achieve this goal, we need to build capacity in different directions, by integrating knowledge and methods and experimenting and co-operating with many national and international partners.

Increased effort must be dedicated to the full integration of administrative data with existing surveys. Statistical institutes in Northern European countries have shown that a "register-based statistical system" can be a powerful approach for fully exploiting all statistical information in an integrated manner. Data sources integration in agricultural statistics along with observation of the associated populations allow for measurement and evaluation of various issues related to the agricultural sector: for example, the educational level of a farm holder and the size of the farm can affect the productivity of land parcels and the risk of malnutrition of rural households (*Plenary session 2 and sessions F33, F34, F35 are dedicated to these topics*).

Techniques should be "sustainable" for statistical offices. Sustainability depends on human skills, technical development, financial support and specific strategies.

The answer to these strategic, thematic and methodological challenges lies in the modernisation of statistical systems.

Key elements of the modernisation process could be summarised as follows:

- Assessing user needs as the first stage for tailoring products and services

- Giving incentives for the development and exploitation of methodological, technological and organizational innovation

- Integrating and linking sources to boost coherence

- Guaranteeing a sound legal framework to manage the existing trade-offs among confidentiality, open access to microdata and IT security

- Enhancing and reorienting staff skills (*session H48 addresses this issue*)

- Moving away from the traditional 'silo' approach of statistical agencies towards the setup of horizontal services (for management, methodology and IT services that would serve to impel the integration process)

- Reducing the response burden with the reuse of available data and information

- Increasing the use of technology, resulting in significant efficiencies and reducing time lags

The adoption of a "register-based statistical system" represents a milestone in a modernization strategy for official statistics. It is a structure based on the integration of administrative and survey data which are organized into a system of statistical registers linked together on the basis of defined keys. Such a system may succeed in terms of reducing costs and response burden while continuing to maintain data quality.

A register-based system represents a long-term goal to be progressively implemented in accordance with country-specific characteristics, whereas its adoption should be based on best practices and institutional support from statistical offices already involved in such a process.

I would also like to stress the crucial role that the Census of agriculture plays for agricultural statistics. As we have seen before, a significant number of countries are still not carrying it out. Since the 1980s, the FAO World Program for the Census of Agriculture has been setting definitions, concepts, standards and guidelines, in order to ensure data comparability and address emerging information needs.

The 2020 edition of WCA calls attention to emerging themes in the digital era, giving emphasis to the use of information technology in data collection, processing and dissemination. Technology also serves to support data dissemination with the use of interactive maps, charts and graphs; aggregate data and microdata can be disseminated on-line to empower wide public access. The use of these accessible technologies inevitably represents the immediate future for agriculture censuses all over the world.

It is clear that modernization initiatives need to be shaped in accordance with the maturity of the particular national statistical system and with awareness of the institutional setting. Countries are at different stages in terms of their use of administrative records and innovation methodologies, and, in addition, statistics production in diverse thematic areas may be at different stages within the same country.

To summarize, five key drivers may characterize a successful process of modernisation: trust, quality, competencies, research and innovation, partnership.

These drivers are strongly related and they feed on each other. Quality, transparency and the independence of the statistical authorities are crucial to engender trust in an NSI's work; quality is based on the competencies of the researchers and analysts who are responsible for the day to day data production. Research in the development of new techniques and methodologies is crucial in fostering improvements, defining new processes and procedures, creating new products. Finally, modernization calls for strong partnerships among the public and private sectors and the scientific community in order to enrich the information and improve data quality.

I would like to close with an invitation to all the stakeholders in the agriculture statistics system: the national statistical systems, national and international agencies, the scientific community, private data producers and data owners, governments. There is an increasing need for stimulating a coordinated effort to fulfil international goals set at the global level, be those relative to the production of new information, or relative to the adoption of methodological standards.

Of course, everyone needs to take part in this process, according to his or her own abilities and responsibilities.

Donor countries have recovered only in 2013 the absolute value of Official Development Assistance, yet without raising its share of GDP. Even if agriculture is increasing its share of total ODA, thanks to a steep increase in bilateral and multilateral aid flows to agriculture, there is a need for additional resources. Sharing experiences among NSIs and taking advantage of globalisation can disseminate innovative solutions for every country.

Let me conclude by stating that modernisation is a priority on the statistical agenda today and in the future. Efforts to modernise agricultural statistics are crucial for providing those tools that are essential in order to be able to address particular issues and monitor advancements in the sustainable development agenda.

Keeping this in mind, we should all be engaged and forward looking. I wish for all of you a very fruitful work throughout the next three days. Thank you.

PLENARY SESSION

02

INTEGRATION OF DATA SOURCES IN AGRICULTURAL STATISTICS

Session Organizer
P. Lavallée | Statistics Canada | Ottawa | Canada

ABSTRACT

Agricultural surveys are often targeting specific topics: crops, livestock, finance, etc. To get a global picture of the agriculture behaviour of a country, it is often necessary to measure such information in an integrated way. The addition of social and household data to information agricultural can also help in refining such studies. For example, studies such as agricultural practices and productivity, poverty reduction and social well-being, are generally benefiting from such integration. Now, simply adding the results of independent surveys or data sources together is generally not enough to get data that will lead the required studies, and thus, a planned integration of surveys and data sources needs to be done. This session will present different methodological approaches to integrate data sources and surveys, with the emphasis on agricultural and social topics. These approaches will be presented in relation with integration projects performed by statistical agencies

ABSTRACT

As in many statistical organizations, Statistics Canada is examining ways to reduce the amount of survey response burden placed on its respondents while maintaining a high level of quality for its statistics. Statistics Canada's Agriculture Statistics Program has placed a high importance in recent years on exploring the expanded and improved use of farming revenue and expense data reported by farm operators to Canada's tax agency when filing their tax returns.

The Canadian Census of Agriculture is no exception to this initiative. In addition to questions on agricultural characteristics such as livestock inventories, crop acreages and agricultural practices, the Canadian Census of Agriculture has traditionally collected information from farm operators related to revenue and detailed expenses. The possibility of removing these detailed, high response- burden financial questions from the Census and replacing them with income tax data was explored following the 2011 census occasion as part of a feasibility study. The study concluded that such a replacement would work well for the vast majority of farms, but there were certain sub-populations in which it would not perform well.

Agricultural tax data can also be used in the processing of other variables collected by the Census of Agriculture. Tax data will be used in the data validation stage of the 2016 Census of Agriculture, to corroborate the responses provided to census questions such as agricultural commodities. They will also be used to improve the nearest neighbour donor imputation of total non-response.

A further use of tax data has been to help define the frame of farm operations to be used for the mail out of the Census. Detailed agricultural tax data are used to add and remove units from the agricultural population.

The paper will describe the studies undertaken after the 2011 Census of Agriculture to assess the feasibility of using tax data for the replacement of respondent-provided information and frame generation. It will also describe the new agricultural tax data environment developed at Statistics Canada which can be used by both the Census of Agriculture and other agricultural programs, including the Agriculture Taxation Data Program. Finally it will discuss the manner in which tax data will be used for the Census of Agriculture in 2016.

Keywords: Data replacement, agricultural frame, data validation, feasibility study

PAPER

1. Introduction

Statistics Canada's Agriculture Statistics Program has a long history of using administrative data. These data are obtained from other federal and provincial government departments as well as non-government organizations, and are incorporated into the Agriculture Taxation Data Program (ATDP), the quinquennial Canadian Census of Agriculture (CEAG), the Remote Sensing and Geospatial Analysis project and ongoing and special agricultural surveys. This paper will discuss recent initiatives undertaken by Statistics Canada to increase the use of agricultural tax data obtained from Canada's tax agency, the Canada Revenue Agency, in the construction of the agricultural survey frame, the redesign of the agricultural tax data environment, the processing of the 2016 Census of Agriculture and the potential replacement of existing variables in a future Census of Agriculture. Adding to the challenge of achieving these goals is the fact that multiple agricultural projects have been historically using tax data in different ways, and the new standardized processing and frame methodology must now meet their various needs at the same time.

2. Building the Agricultural Survey Frame

Prior to 2012, Statistics Canada maintained a list of agricultural operations solely for the purposes of the Agriculture Statistics Program called the Farm Register (FR). The CEAG and agricultural surveys derived their survey frames from the FR, which included baseline information necessary for survey design. The FR in turn was largely updated in terms of additions and deletions of operations and contact information primarily by conducting the CEAG once every five years, and to a lesser extent throughout each year based on feedback from agricultural surveys.

That changed in 2012 when Statistics Canada made the decision to use the Business Register (BR) to maintain its frame of agricultural operations for its Agriculture Statistics Program, similar to most other business survey programs at the Agency, in an effort to reduce redundancy. The BR is a complete list of Canadian businesses primarily maintained by reported tax data and other associated administrative signals, such as indications of cessation of business activity, structural changes, and shifts in primary business activity type. A key field on the BR is the Business Number, a nine-digit code that facilitates interaction with some government departments and that has been incorporated into the CEAG. The post-2011 CEAG reconciliation of the FR with the BR involved major challenges; for more information see Dongmo Jiongo et al (2013). Tax data are typically received for existing farm businesses every year and in some cases every month. The direct connection between the BR and tax data allows the BR, and hence the agriculture survey frame, to be updated more fully and more frequently.

A key annual use of tax data is in the selection of which businesses should be added into (birthed), or removed from (deathed), the agricultural survey frame. Initially, the BR identifies a unit as a birth or a death based on the appearance or long-term disappearance of tax data. The agricultural survey frame, as a subset of units on the BR, will then reflect these additions or removals. New units added to the BR are included in the agricultural survey frame based on tax indications of agricultural activity. However, it is not prudent to include all new businesses that have reported agricultural activity. Filtering has proved necessary for a variety of reasons. For example, some BR units that file agricultural tax information are out of scope to the Agriculture Statistics Program. Out of scope agricultural tax units may include landlords who rent out farmland to others, but do not actively operate a farm themselves, yet still identify themselves when filing taxes as being an operator of a business of an agricultural nature and with agriculture-related revenue. Conversely, there are other businesses that report agricultural tax activity that are suspected, but not yet confirmed, to be in a partnership of some sort with an existing unit on the agricultural survey frame. Their automatic addition would generate duplication. A filter is therefore applied to only incorporate tax births that exhibit significant, unique, detailed and commodity-specific agricultural revenue and/or expenses to the agricultural survey frame.

Finally, tax information, in the form of commodity-specific agricultural revenue and expense information supplied by the tax filer, is used to derive measures of commodity-specific agricultural production that allow agricultural surveys to better identify their survey populations and develop efficient survey designs. Currently these production measures are generated for previously unknown (birthed) frame units on an annual basis, and so overall the agricultural survey frame now has a better, more recent picture of the agricultural activities of Canadian farm operations during the inter-censual period.

3. The Redesigned Agricultural Tax Data Environment

For over 25 years the ATDP has tabulated statistics based on agricultural revenue and expense information reported on farm operators' Canada Revenue Agency tax returns. Prior to 2016, the ATDP received a sample of tax records from the Canada Revenue Agency that contained some indication of agricultural revenue. The ATDP processed the tax fields obtained from this sample using custom rules and methodology. Starting in 2016, the ATDP will be defining their population of interest using the BR in a similar manner to that used by the CEAG and agricultural survey programs. Tax data will be obtained for all units resulting in a census of in-scope agricultural tax filers rather than a sample. This transition faces some challenges. Statistics Canada has a system in place for the processing of tax data for businesses in all industries including those outside of the agriculture sector, but this system does not include some specialized rules and variables necessary for both the ATDP and other uses within the agriculture program. It was therefore necessary to build a new hybrid system, consisting of the general Statistics Canada tax processing rules plus some extra agriculture-specific requirements. Furthermore, the standardized tax data processing does not uniformly produce the highly specific commodity-level revenue and expense details required by ATDP, and so a new imputation system for agricultural tax data was implemented.

This updating of the agricultural tax data processing environment was undertaken collaboratively, with ATDP contributing their tax data processing techniques and CEAG their agricultural frame expertise. The ultimate goal of these efforts is to produce one high-quality Agricultural Tax (Ag-Tax) database that will be capable of supplying all agricultural statistics programs in Statistics Canada with highly detailed, processed financial information on a sub-annual basis. The Ag-Tax database resulting from this initiative will be made available to a variety of agricultural statistics programs, including the CEAG, for the first time in 2016 for the 2015 tax year.

With both the ATDP and the CEAG now defining their populations based on the BR and using the same set of processed agricultural tax data, the potential benefits are great. ATDP can now produce financial statistics based on a census of agricultural operations rather than a sample. The resulting Ag-Tax database from the redesigned tax system reduces the need for the CEAG to collect this data from respondents directly, and makes it feasible to directly replace detailed expenses in a future Census or other agricultural surveys which require financial information. In addition to the reduction in survey response burden, it results in more coherence between the financial statistics from different products within the Agriculture Statistics Program.

4. Use of Agricultural Tax data in the 2016 Census of Agriculture

Drawing directly from the newly created Ag-Tax database described above, the 2016 CEAG will for the first time have a high-quality comparative dataset of agricultural tax revenues and expenses available at a commodity-specific level of detail. The most extensive use of this database will be made by CEAG data validation, although it will also be applied to total non-response imputation.

Ag-Tax data, as well as other sources of administrative data, will play an important role in the validation of CEAG data. They will be used to confront and validate both the data provided by respondents, as well as data which has been imputed. For tax data in particular, CEAG will use total farm revenue and total operating expenses tax fields to validate the gross farm receipts and total operating expenses questions on the CEAG questionnaire (Statistics Canada, 2015). CEAG will also make use of other tax variables in the Ag-Tax database to improve the data quality in other sections of the CEAG questionnaire. For example, the detailed revenue Ag-Tax variables will be used to validate the presence of corresponding commodities as reported by the respondent on the Census questionnaire. CEAG validators will also use tax data to validate the value of land and buildings and machinery values provided by respondents on their census form. Another important use of tax data in validation will be to ensure that the values reported by the respondent do not include components that are considered to be out of scope for the Census such as capital sales and goods purchased only for resale. Goods purchased for resale can be a difficult concept to identify in the gross farm receipts value provided by the CEAG respondent, so CEAG validators employ ratios using detailed expense items and other relevant questions on the questionnaire. For example, seed purchases in relation to greenhouse area under glass to remove resales in greenhouse operations; and livestock purchases in relation to feed purchases to eliminate sales from livestock dealing activities. Finally, using detailed revenues from tax data will also allow analysts to identify non- agricultural receipts, such as revenue from trucking, rental income or oil leases.

Another application of the Ag-Tax database in the 2016 CEAG will be to use variables from this database as matching variables to assist in the identification of nearest neighbours in the CEAG total non-response imputation stage. Ag-Tax variables used in this manner are total revenue, total expenses and a field describing the main agricultural activity of the farm. As has traditionally been the case, the CEAG uses a nearest-neighbour hot-deck imputation system, imputing missing information from a valid CEAG donor record using Statistics Canada's BANFF generalized imputation system (Statistics Canada, 2014). It is expected that the application of tax data here will lead to improved total non-response imputation results, with recent Ag-Tax data now being used instead of five-year old CEAG data.

Finally, tax data will be used to maximize coverage of CEAG farms. While the initial 2016 CEAG frame is derived from the agricultural survey frame, and hence the Business Register, as close to Census day as possible, there is still at that time a volume of new tax units that will not be added to the BR until later in the year. Since the goal of the CEAG is to achieve 100% coverage of all Canadian farms as of Census day, an attempt is made to match this set of new tax units to the Canadian Census of Population, which is carried out concurrently with the CEAG and contains a question asking if anyone in the household is a farm operator. At defined points throughout census collection, a list of Census of Population households with an agricultural operator is generated.

Households from the list that link successfully to a tax unit on the waiting list that has reported agricultural tax data are eligible to be sent a CEAG questionnaire.

5. Potential for Detailed Financial Data Replacement in a Future Census of Agriculture

The 2011 CEAG questionnaire (Statistics Canada, 2010) featured two questions on financial totals (Total Sales and Total Expenses) and seventeen questions on detailed financial expenses, such as fertilizer expenses, livestock purchases, wage expenses and machinery rental. In many (but not all) cases these census questionnaire variables sought the same information as that which was already available on the agricultural tax forms submitted to the Canada Revenue Agency. With the goal of assessing whether a direct replacement of CEAG questionnaire variables with tax data from the proposed Ag-Tax program would be feasible in the future, a comparative analysis was undertaken in conjunction with the 2011 CEAG collection period.

The 2011 CEAG Tax Data Replacement Initiative was a strategic investment of Statistics Canada and was part of the 2011 CEAG program. The tax data replacement feasibility study (TAX) (Statistics Canada, 2013) replaced 2011 CEAG financial data with corresponding tax data from the Canada Revenue Agency.

The purpose of the study was to evaluate the robustness of tax data as a replacement for detailed operating expenses provided by respondents. It has been estimated that the use of administrative data to replace all of the detailed CEAG financial questions would reduce the response burden for CEAG respondents by as much as 13.5% in terms of time spent completing the questionnaire. In addition, their removal would address requests to do so by respondents in previous censuses. Tax data were processed through the existing 2011 CEAG production edit and imputation system to produce a set of financial data for all of the approximately 200,000 Census in- scope records. In this manner CEAG-TAX financial data were fully edited, imputed and consequently validated using the same processing methodology as in 2011 CEAG production, allowing for a fair comparison between 2011 CEAG and CEAG-TAX replacement data.

The results of this comparison, showing the percent relative difference between TAX and CEAG financial data, are shown below in Table 1. Results are grouped into "Standard" and "Non- Standard" farm types. "Non-Standard" here defines the less than 1% of Canadian farms that are either extremely large and/or complex in terms of production and therefore have a critically high impact on the Agricultural sector in Canada, or that are highly unique in terms of their reporting arrangements.

Table 1: Percent Relative Difference between TAX and CEAG: Gross Farm Receipts and Total Operating Expenses, by Farm Type

CANADA	FARM TYPE	% RELATIVE DIFFERENCE (TAX vs. CEAG)
Gross Farm Receipts	**All**	**-2.00%**
Gross Farm Receipts	Standard	-0.70%
Gross Farm Receipts	Non-Standard	-8.65%
CANADA	**FARM TYPE**	
Total Expenses	**All**	**0.60%**
Total Expenses	Standard	2.60%
Total Expenses	Non-Standard	-8.63%

Overall, the comparison for all farms between TAX and CEAG for gross farm receipts and total operating expenses at the Canada level was good. However, there were significant differences in the comparability between TAX and CEAG for "Non-standard" CEAG farms. This analysis was also extended to detailed expense items, and a similar pattern of results was found, with most detailed expense categories comparing well for "Standard" farms and the largest differences occurring for "Non-standard" CEAG farms.

The study arrived at several key conclusions. For "Standard" farms, which make up 99% of the farm population in Canada, the total replacement of CEAG detailed expense items was deemed feasible by the study; however, it was considered essential to keep gross farm receipts, value of forest products sold and total operating expenses fields on future CEAG questionnaires. Gross farm receipts and total operating expenses are considered critical fields for reconciliation between CEAG questionnaires and tax data, and also for imputation for the small number of CEAG units for which linkage to tax data is not possible. Value of forest products sold is not obtainable from tax data with any degree of quality and so it should continue to be asked on the questionnaire.

While it was deemed feasible to use tax data for total wages and salary expenses, it was recommended not to provide the split between family and non-family wages directly through tax replacement. It was recommended that future CEAG questionnaires collect the proportion of family or non-family wages and salaries.

The study concluded that due to their complex structures and importance to the agriculture sector, extremely large agricultural operations should continue to provide their detailed finances via the CEAG questionnaire rather than through tax data. Similarly, due to their unique nature and the poor reconciliation between CEAG questionnaires and tax forms, it was recommended to continue to require direct collection of detailed finances for community pastures, institutional farms and northern farms. To allow for the replacement of financial data with tax data for collective farm operations, it was recommended that research be undertaken to better understand their organization and reporting tendencies. It is worth noting, however, that the more recently developed harmonized Ag-Tax processing environment may provide significant and necessary methodological improvements regarding the processing of raw tax data for the above-mentioned "Non-standard" farms. If this proves to be the case, this recommendation would need to be revisited.

In general, the feasibility study showed shifts in financial variables, with some shifts more unique and impactful than others. Having used the same processing methodology to treat tax data and CEAG financial data alike, the feasibility study recognized that some of these shifts may be due to systematic differences in the way that certain financial information is reported to the Canada Revenue Agency as compared to CEAG. Consequently it was recommended that CEAG should consult with agricultural accountants and other knowledgeable parties to understand reporting tendencies relating to tax filing and to help provide explanations for these data shifts.

Overall, the results of the feasibility study were encouraging. They align well with Statistics Canada's commitment to increase the use of administrative data to reduce the burden on survey respondents (Statistics Canada, 2016) and the recognition that harmonization of the processing of raw agricultural tax data within the agricultural statistics program would reduce duplication of efforts and also improve the overall quality of financial data. However, while the Ag-Tax database was successfully developed as described above in Section 3, fiscal constraints resulted in the 2016 CEAG cycle being unable to implement the replacement of detailed expenses with tax data. Plans are ongoing to consider having the 2021 CEAG ask only total agricultural sales, total expenses and value of forestry product information as in the 2016 CEAG questionnaire, and use the Ag-Tax database of processed micro-level tax data to fully replace the detailed financial expense questions. At this time, a final decision has not been made. If the decision is made to proceed with tax data replacement in 2021, these financial expense fields would be processed and validated alongside other 2021 CEAG questionnaire fields such as questions on commodity, machinery and land management practices to ensure consistency, and released as part of 2021 CEAG dissemination.

CONCLUSION

Statistics Canada has successfully undertaken the major recent initiative to adopt the Business Register as its agricultural survey frame, which directly enabled linkage to administrative data including tax data. The CEAG and the ATDP are therefore now both running off a similar frame, and the ATDP will for the first time produce a census file of tax records, as opposed to a sample.

The resulting availability of up-to-date, processed tax and administrative data will support the ongoing maintenance of the agricultural survey frame. It will also make it easier to use tax data for the validation and imputation of the 2016 CEAG. Building on the results of a feasibility study, continuing investigations are being made to consider using tax data to replace detailed financial questions on future censuses and agricultural surveys. The resulting efficiencies gained in population coverage and contact success rates as well as the reduction in response burden on Canadian farm operators with regard to the reduced direct collection of financial information should be significant.

Optimal Sampling for the Integrated Observation of Different Populations

P. D. Falorsi Istat | Rome | Italy
P. Righi Istat | Rome | Italy

DOI: 10.1481/icasVII.2016.pl2b

ABSTRACT

This work deepens the problem of defining an optimal sampling in the multivariate case where the variables of interest are related to different target populations. In order to get insight to the underlying phenomena, the observation has to be carried out in an integrated way, implying that units of a given population have to be observed jointly with the related units of the other population. Indirect sampling provides a natural framework for this setting since the units belonging to a population that is the object of a given survey can become carriers of information on another statistical population. This problem is studied with respect to the different contexts which characterize the available information in the sampling design phase, ranging from very well organized situations in which the links among the different units are known in the design phase to a situation in which the available information is very poor. Empirical studies on agricultural data of two developing countries are developed. These show that controlling in the design phaseis effective since by not doing so, the errors of the indirectly observed population can become very high. Furthermore, the need of having good models for predicting the unknown variables or the links is stressed.

Keywords: integrated surveys, sample allocation, indirect sampling

PAPER

1. Introduction

The need of observing in an integrated way different statistical populations related to each other is often encountered in survey sampling. The underlying relationships among the populations are regulated by formal rules, contingent dependencies or relationships created for the pursuit of common purposes. For instance, agricultural surveys often refer to statistical units such as rural households, farms and land parcels that are related to each other. The integrated observation of such populations allows to measure global phenomena of the agricultural sector: for example, the education level of a farm holder and the farm size can affect the productivity of land parcels and thus the risk of malnutrition of rural households. The observation of such units in an integrated way can be recommended to get insights into the agricultural system of a country.

Indirect sampling (Lavallée, 2007) provides a natural framework for the estimation of the parameters of two target populations that are related to each other since the units belonging to a population that is the object of a given survey can become carriers of information on another statistical population, through the type of relationship between the entities. Furthermore, indirect sampling is suitable for producing statistics of populations for which there is no sampling frame. In such context, the sampling procedure assumes a population U^A related with the population of interest U^B, and for whichthe sampling frame of U^A is available. Then, a sample is selected from U^A, and using the existing links between the two populations the units of U^B are observed.

This work deepens the problem of sampling allocation when an indirect sampling design is implemented. The allocation problem for the direct sampling setting has been dealt with in several papers. When one target parameter is to be estimated for the overall population, the optimal allocation in stratified sampling can be performed (Cochran, 1977). When more than one target parameter is to be estimated the problem aleads to a compromise allocation method (Khan et al., 2010), with a loss of precision compared to the individual optimal allocations. Several authors have discussed various criteria for obtaining a feasible compromise allocation: see, for example, Kokan and Khan (1967), Chromy (1987), Bethel (1989) and Choudhry et al. (2012).

Falorsi and Righi (2015) provide a general framework for multivariate and multi-domain surveys. This paper offers a further generalization of the framework proposed by Falorsi and Righi (2015) to the case of integrated observation of two or more populations. Different scenarios related to the level of knowledge of the existing links are examined. Section 2 introduces the background and symbols. Sections 3 and 4 illustrate the basic allocation problem and how it is declined in the different informative scenarios.

PL02

2. Background

Let s^A, M^A, m^A be a selected sample from U^A without replacement and with fixed sample size, thenumber of units in U^A and the number of units in s^A, respectively. We use π_j^A to represent the inclusion probability of the *j*th unit in U^A with $\pi_j^A > 0$ and $\sum_{j\in U^A} \pi_j^A = m^A$. We denote with $y_{j,v}$ the value of the *v*th (*v*=1,…,*V*) characteristic on unit *j* and the total of all $y_{j,v}$'sby Y_v^A.We estimate the total Y_v^A according to the Horvitz-Thompson (HT) estimator, $\hat{Y}_v^A = \sum_{j\in s^A} w_j^A \, y_{j,v}$, where $w_j^A = (1/\pi_j^A)$.Many practical sampling designs define planned domains that are sub-populations in which the sample sizes are fixed before selecting the sample. Denote by U_h^A (*h*=1,…,*H*) the planned domain of size $M_h^A = \sum_{j\in U_h^A} d_{j(h)}$ where $d_{j(h)} = 1$ if $j \in U_h^A$ and $d_{j(h)} = 0$ otherwise. Let us suppose that the $d_{j(h)}$ values are known, and available in the sampling frame, for all population units. Fixed sizes sampling designs are those satisfying $\sum_{j\in s^A} \mathbf{d}_j = \mathbf{m}^A$,where $\mathbf{d}_j = (d_{j(1)},\ldots,d_{j(h)},\ldots,d_{j(H)})'$ and $\mathbf{m}^A = (m_1^A,\ldots,m_h^A,\ldots,m_H^A)'$ isthe vector of integer numbers defining the sample sizes fixed at the design stage, with $\sum_{j\in U^A} d_{j(h)}\,\pi_j^A = m_h^A$. In our setting, the planned domains can overlap; therefore, the unit *j* may have more than one value $d_{j(h)} = 1$ (for $h = 1,\ldots, H$).Several customary fixed size sampling designs may be considered as special cases. A well-known example is the stratified sampling design where strata are the planned domains and the $\mathbf{d}_j$ vector has *H*-1 elements equal to zero, and one element equal to 1.We suppose that the $M^A \times H$ matrix $\mathbf{D} = (\mathbf{d}_1,..,\mathbf{d}_j,\ldots,\mathbf{d}_{M^A})'$ is non-singular. According to this general sampling design framework, Deville and Tillé (2005) proposed an approximated expression of the variancebased on the Poisson sampling theory for $\hat{Y}_v^A$ given by $V(\hat{Y}_v^A \mid \mathbf{m}^A) \cong \sum_{j\in U^A} [(1/\pi_j^A) - 1]\eta_{j,v}^2$,where

$$\eta_{j,v} = y_{j,v} - \pi_j^A \, \mathbf{d}'_j \, \boldsymbol{\beta}_v \text{ and } \boldsymbol{\beta}_v = \boldsymbol{\Delta}^{-1} \sum_{l\in U^A} \pi_l^A \,(1/\pi_l^A - 1)\,\mathbf{d}_l \, y_{l,v} \text{ ,with}$$

$$\boldsymbol{\Delta} = \sum_{j\in U^A} \mathbf{d}_j \, \mathbf{d}'_j \, \pi_j^A (1 - \pi_j^A).$$

We also make use of the notation: M^B, N^B, U_i^B and M_i^B to be the number of units in U^B, thenumber of clusters in U^B, the *i*th cluster of U^B with $\bigcup_{i=1}^{N} U_i^B = U^B$ and the number of units in the*i*th cluster U_i^B. We indicate by $y_{ik,r}$ the value of the *r*th (*r* =1,…,*R*) characteristic for the *k*th unit of the *i*th cluster of U^B and the total of all $y_{ik,r}$'s by $Y_r^B = \sum_{i=1}^{N^B} \sum_{k=1}^{M_i^B} y_{ik,r}$.

We define $l_{j,ik}$ as an indicator variable of link existence: $l_{j,ik} = 1$ indicates that there is a link between *j*th unit in U^A and *k*th unit in U_i^B, while $l_{j,ik} = 0$ indicates otherwise.

Let us suppose that we carry out an indirect sampling process in which if the unit $j \in U^A$ is included in $j \in s^A$, then all the clusters U_i^B, for which $L_{j,i}^B = \sum_{k=1}^{M_i^B} l_{j,ik} > 0$, are observed in the indirect sample of population U^B. Let n^B be the cluster sample size of population U^B obtained after the indirect sampling process. We estimate Y_r^B according to the Horvitz-Thompson estimator based onthe theory of the Generalized Weight Share Method (GWSM):

$$\hat{Y}_r^B = \sum_{i=1}^{n^B} w_i^B \, y_{i,r} \qquad (2.1)$$

where $y_{i,r} = \sum_{k=1}^{M_i^B} y_{ik,r}$ and $w_i^B = \sum_{j\in s^A} w_j^A \, \tilde{L}_{j,i}^B$, with $\tilde{L}_{j,i}^B = L_{j,i}^B / L_i^B$ and $L_i^B = \sum_{j=1}^{M^A} L_{j,i}^B$.

Theorem in Section 3 of Lavallée (2007) states that (2.1) offers an unbiased estimator for Y_r^B provided all links $l_{j,ik}$ can be correctly identified and $L_i^B > 0$ for all $i \in U^B$.By defining $z_{j,r} = \sum_{i=1}^{N^B} \tilde{L}_{j,i}^B \, y_{i,r}$, the estimator (2.1) can be expressed as an usual Horvitz-Thompson (HT) estimator on the z values referring to the U^A population, $\hat{Y}_r^B = \sum_{j \in s^A} w_j^A z_{j,r}$ .Therefore, the variance, $V(\hat{Y}_r^B)$, of $\hat{Y}_r^B$ maybe expressed as the variance of the HT estimator on the U^A population.The approximate variance of $\hat{Y}_r^B$ implementing fixed sizes sampling designs isgiven by $V(\hat{Y}_r^B \mid \mathbf{m}^A) \cong \sum_{j \in U^A} [(1/\pi_j^A) - 1] \eta_{j,r}^2$, where $\eta_{j,r} = z_{j,r} - \pi_j^A \mathbf{d}'_j \boldsymbol{\beta}_r$ with $\boldsymbol{\beta}_r = \Delta^{-1} \sum_{l \in U^A} \pi_l^A (1/\pi_l^A - 1) \mathbf{d}_j z_{l,r}$.

3. Problem

Given the above framework, we are interested in finding the vector $\boldsymbol{\pi}^A = (\pi_1^A, \ldots, \pi_j^A, \ldots, \pi_{M^A}^A)$ of inclusion probabilities that minimizes the expected survey cost bounding the sampling variances, $V(\hat{Y}_v^A)$ (v=1, ... ,V) and $V(\hat{Y}_r^B)$ (r=1,... ,R) under given variance thresholds:

$$\begin{cases} \min \sum_{j \in U^A} c_j \pi_j^A \\ V(\hat{Y}_v^A \mid \mathbf{m}^A) \le V_v^* \quad \forall v = 1, \ldots, V \\ V(\hat{Y}_r^B \mid \mathbf{m}^A) \le V_r^* \quad \forall r = 1, \ldots, R \\ 0 < \pi_j^A \le 1 \end{cases}, \tag{3.1}$$

where V_v^* ($v = 1, \ldots, V$) and V_r^* ($r = 1, \ldots, R$) are the variance thresholds fixed by the sampling designer and c_j is the variable cost for observing the unit j in the population U^A and the linked $L_j^A = \sum_{i=1}^{N^B} L_{j,i}^B$ units in the population U^B. A reasonable expression of c_j is $c_j = f_c(L_j^A; C^B)$,where f_c is a known monotone non-decreasing function and C^B is the per unit cost for observing a cluster in the population U^B .Brewer and Gregoire (2009) propose an extensive analysis of different forms of costs functions. The minimization problem (3.1) is a generalization of the univariate precision constrained optimization approach (Cochran, 1977).The problem (3.1) assumes that all the values $y_{j,v}, y_{i,r}, y_{ik,r}, L_j^A$, $L_{j,i}^B$ and L_i^B are known as alsothe vectors $\boldsymbol{\beta}_v$ and $\boldsymbol{\beta}_r$, although they depend on the vector $\boldsymbol{\pi}^A$. In this case, problem (3.1) becomes a classical Linear Convex Separate Problem (LCSP; Boyd and Vanderberg, 2004) and can be solved by the algorithm proposed in Falorsi and Righi (2015). The algorithm represents a slight modification of the algorithm of Chromy (1987), originally developed for multivariate optimal allocation in Stratified Simple Random Sampling Without Replacement (SSRSWOR) designs and implemented in standard software tools[1]. Alternatively, the LCSP can be dealt with by the SAS procedure NLP as suggested by Choudhry *et al.*(2012).

4. Informative contexts and optimization problem

Optimization problem as presented in (3.1) is quite theoretical since one needs to know the values of the variables of interest in both populations and the values of actual links among the unitsof the two populations. From now on, we introduce three more concrete informative contexts in successive steps. We start from two contexts in which the information is very rich, whereas the third context considers a casein which the information is very poor. Thelatter context is the most common, altough the incresing availability of administrative registers and statistical software tools for data integration increase the plausibility of the first two contexts.

Context 1. The sampling frames for U^A and U^B are available. All the values L_j^A $L_{j,i}^B$ and L_i^B are known and the values of $y_{j,v}, y_{i,r}$ are unknownbut can be predicted by suitable superpopulation models.

This context may be realistic in countries, like the Nordic ones, having well established register based systems (Wallgren and Wallgren, 2014) in which the units ofagiven statistical register have unique identifiers of good quality, which allow to identify the same unit in the whole systems of registers.The*working*models that we studycan be expressed under the following forms:

[1] See for example the Mauss-Rsoftware available at: http://www3.istat.it/strumenti/metodi/software/campione/mauss_r/.

$$\begin{cases} y_{j,v} = \tilde{y}_{j,v} + u_{j,v} = f_v(\mathbf{x}_j;\boldsymbol{\varphi}_v) + u_{j,v} \\ E_{M_v}(u_{j,v}) = 0 \quad \forall j \\ E_{M_v}(u_{j,v}^2) = \sigma_{j,v}^2 \\ E_{M_v}(u_{j,v}, u_{l,v}) = 0 \ \forall j \neq l \end{cases}, \begin{cases} y_{i,r} = \tilde{y}_{i,r} + u_{i,r} = f_r(\mathbf{x}_i;\boldsymbol{\varphi}_r) + u_{i,r} \\ E_{M_r}(u_{i,r}) = 0, \\ E_{M_r}(u_{i,r}^2) = \sigma_{i,r}^2 \\ E_{M_r}(u_{i,r}, u_{i',r}) = 0 \ \forall i \neq i' \end{cases} \tag{4.1}$$

where, omitting the subscripts for the sake of brevity, $\mathbf{x}$are vectors of predictors (available in the two sampling frames), $\boldsymbol{\varphi}$ are the vectors of regression coefficients and $f(\mathbf{x};\boldsymbol{\varphi})$are known functions, u are the error terms, $\tilde{y}$ are the predicted values and $E_M(\cdot)$ denote the expectations under the models. We assume that the parameters of the models to be known, although in practice they are usually estimated. The right-hand side superpopulation model of (4.1) can be defined starting from an elementary unit level model. We do not dealt with this second modelin this paper. The model expectations at cluster level on the right hand side of (4.1) can be easily derived as:

$E_{M_r}(y_{i,r}) = \tilde{y}_{i,r} = \sum_{k=1}^{M_i^B} \tilde{y}_{ik,r}$; $V_{M_r}(y_{i,r}) = \sigma_{i,r}^2 = M_i^B \sigma_r^2 [1 + (M_i^B - 1)\rho_r]$; $Cov_{M_r}(y_{i,r}, y_{i',r}) = 0$ for $i \neq i'$,

where V_{M_r} and Cov_{M_r} denote respectively the model variance and covariance.

Note that the *working* models (4.1) are variable specific. They are introduced as useful tools for defining the sampling design but they are not necessarily representing exactly the real models generating the data.

According to (4.1),the model predictions and the variancesof the z variables are given by

$E_{M_r}(z_{j,r}) = \tilde{z}_{j,r} = \sum_{i=1}^{N^B} \tilde{L}_{j,i}^B \tilde{y}_{i,r}$ and $V_{M_r}(z_{j,r}) = \sigma_{j,zr}^2 = \sum_{i=1}^{N^B} (\tilde{L}_{j,i}^B)^2 \sigma_{i,r}^2$.

Thus, in the optimization problem,the variance terms $V(\hat{Y}_v^A \mid \mathbf{m}^A)$ and $V(\hat{Y}_r^B \mid \mathbf{m}^A)$ are replaced by the Anticipated Variances. Denoting with E the expectation under the sampling design, the anticipated variance of the HT estimator $\hat{Y}_v^A$ is $E_{M_v}E(\hat{Y}_v^A - Y_v^A)^2 = E_{M_v}V(\hat{Y}_v^A - Y_v^A)$., with $V(\hat{Y}_v^A - Y_v^A) = V(\hat{Y}_v^A \mid \mathbf{m}^A) \cong \sum_{j \in U^A}[(1/\pi_j^A) - 1]\, \eta_{j,v}^2$ The same result may be derived for the estimate $\hat{Y}_r^B$. Thus,we obtain the following expressions: $E_{M_v}[V(\hat{Y}_v^A \mid \mathbf{m}^A)] = \sum_{j \in U^A}[(1/\pi_j^A) - 1]\, E_{M_v}(\eta_{j,v}^2)$,

$E_{M_r}[V(\hat{Y}_r^B \mid \mathbf{m}^A)] = \sum_{j \in U^A}[(1/\pi_j^A) - 1]\, E_{M_r}(\eta_{j,r}^2)$,where $E_{M_v}(\eta_{j,v}^2)$ and $E_{M_v}(\eta_{j,r}^2)$ arenot given here for the sake of brevity.The problem (3.1) is then reformulatedusing $E_{M_v}V(\hat{Y}_v^A \mid \mathbf{m}^A)$and $E_{M_r}V(\hat{Y}_r^B \mid \mathbf{m}^A)$.

Remark 4.1: Falorsi and Righi (2015) propose an upward approximation of the anticipated variances that simplified the optimization problem. This conservative approximationis a safe choice in this setting, since they prevent from the risk of defining an insufficient sample size for the expected accuracies.

Remark 4.2: Lavallée and Labelle-Blanchet (2013) deal with the problem of indirect sampling applied to skewed populations by suggesting eight alternative methods for modifying the links, $l_{j,ik}$, to reduce the variance of the estimates.

Context 2.Suppose that in the sample design phase, the links $l_{j,ik}$ are not known with certainty but the probabilities of existing links, $Pr(l_{j,ik} = 1) = \lambda_{j,ik}$, are available.

To include the linkage uncertainty in the optimal allocation, we assume the links follow a Bernoulli model $M_l, l_{j,ik} \sim \mathrm{B}(\lambda_{j,ik})$, where $E_{M_l}(l_{j,ik}) = \lambda_{j,ik}$ and $V_{M_l}(l_{j,ik}) = \lambda_{j,ik}(1 - \lambda_{j,ik})$.We assume the parameters $\lambda_{j,ik}$ to be known, although in practice they are usually estimated with probabilistic record linkage procedures(Lavallée and Caron, 2001).

In this framework, the anticipated variance has to take into account both the models M_l and M_r .Since $E_{M_l}E_{M_r}E(\hat{Y}_r^A - Y_r^A)^2 = E_{M_l}E_{M_r}V(\hat{Y}_r^A - Y_r^A) + E_{M_l}V_{M_r}E(\hat{Y}_r^A - Y_r^A) + V_{M_l}V_{M_r}E(\hat{Y}_r^A - Y_r^A)$ and $E(\hat{Y}_v^A - Y_v^A) = 0$, the problem (3.1) can be reformulated replacing the function to be minimized by $\min \sum_{j \in U^A} E_{M_l}(c_j)\pi_j^A$ and the two set of variances respectively with $E_{M_v}V(\hat{Y}_v^A \mid \mathbf{m}^A)$ and $E_{M_l}E_{M_r}V(\hat{Y}_r^B \mid \mathbf{m}^A)$ where $E_{M_l}E_{M_r}[V(\hat{Y}_r^B \mid \mathbf{m}^A)] = \sum_{j \in U^A}[(1/\pi_j^A) - 1]\, E_{M_l}E_{M_r}(\eta_{j,r}^2)$. The main results for the derivation of the expression of $E_{M_l}E_{M_r}V(\hat{Y}_r^B \mid \mathbf{m}^A)$are not given in the paper. They are based on the Taylor' series approximation and making some reasonable assumption on the links. The predicted $\tilde{z}_{j,r}$ values are obtained as $\tilde{z}_{j,r} = \sum_{i=1}^{N^{\smile}} \tilde{\Lambda}_{j,i}^{B} \tilde{y}_{i,r}$,where $\tilde{\Lambda}_{j,i}^{B} = (\Lambda_{j,i}^{B} / \Lambda_{i}^{B})$,with $\Lambda_{j,i}^{B} = \sum_{k=1}^{M_i^B} \lambda_{j,ik}$ and $\Lambda_{i}^{B} = \sum_{j=1}^{M^A} \Lambda_{j,i}^{B}$.

Remark4.3:the uncertainty on total survey costs, which depends both on the selected sample and the model uncertainty on costs, obliges to consider in the optimization problem the *expected costs* $E_{M_1}(c_j) = f_c(\Lambda_j^A; C^B)$ where $\Lambda_j^A = \sum_{i=1}^{M^B} \sum_{k=1}^{M_i^B} \lambda_{j,ik}$.

Context 3.Data integration is not possible because the record linkage process does not provide good linkages, or simply because the frame of population U^B does not exist.

This is the most usualcontext in developing countries. However, it may also characterize specific survey contexts in developed countries, for instance in case of hard-to-reach populations.

In this case, the optimizazion problem can be dealt byusing all the available information, even if of poor quality. For instance, if a size variables x related to the variable y_r is known from the frame for the unitsof population U^A, and totals or estimated totals $\tilde{Y}_{r(q)}^{B}$ of U^B are available at certain domain level q (q=1,…,Q),then the predicted z variables can be determined as:

$$\tilde{z}_{j,r} = \frac{x_j}{\sum_{l \in U_q^A} x_l} \tilde{Y}_{r(q)}^{B} \quad \text{for } j \in U_q^A . \tag{4.2}$$

Examples of building the z values are illustrated in Section 5.3.2 of *Guidelines on Integrated Survey Framework* (FAO, 2015). Here, an example is reported. Population U^A is given by the farm register of a country. From the register, we known the region q where agiven farm belongs. The population U^B is defined by the rural households. Suppose furthermore that we know (from the Census data or from a previous survey) the total $\tilde{Y}_{r(q)}^{B}$ for a given variable of interest, e.g., "revenue", for the domain q. In particular, consider the farm j of region q with 50 workers living in the region q. In this region, the total number of workers of the farms (estimated or known) is 330,000, and we havethe total $\tilde{Y}_{r(q)}^{B} = 100,000$. The predicted revenue $\tilde{z}_{j,r}$ for the farm is given by $\tilde{z}_{j,r} = (50/330,000)100,000 = 15.15$.Note that this kind of prediction corresponds to the hypothesisof uniformity of the links in the qth domain. In absence of unit level information for U^B , this hypothesisseems tobe reasonable.In this context, it is necessary to try to model directly the z-value with a model of the type:

$$\begin{cases} z_{j,r} = \tilde{z}_{j,r} + u_{j,zr} = f_{zr}(\mathbf{x}_j; \varphi_{zr}) + u_{j,zr} \\ E_{M_{zr}}(u_{j,zr}) = 0 \quad \forall j; \\ E_{M_{zr}}(u_{j,zr}^2) = \sigma_{j,zr}^2 ; \\ E_{M_{zr}}(u_{j,zr}, u_{l,zr}) = 0 \quad \forall j \neq l \end{cases} \tag{4.3}$$

where $\mathbf{x}_j$ is a vector of variables related to the size of unit j. For building plausible predictions on the variance $\sigma_{j,zr}^2$,it may be necessary to carry out a pilot survey. However, in some cases, it may be very difficult to implement such an effort. Making reasonable assumption on the relationship of the squared predictions $\tilde{z}_{j,r}^2$ with the variances $\sigma_{j,zr}^2$,the optimization problem could be carried out with considering the variances of the predictions.

It is also necessary to build a model for assessing the survey costs on the total links L_j^A :

$$\begin{cases} L_j^A = \Lambda_j^A + u_{j,\Lambda} = f_{\Lambda}(\mathbf{x}_j; \boldsymbol{\varphi}_{\Lambda}) + u_{j,\Lambda} \\ E_{M_\Lambda}(u_{j,\Lambda}) = 0 \quad \forall u_{j,\Lambda}; \\ E_{M_\Lambda}(u_{j,\Lambda}^2) = \sigma_{j,\Lambda}^2 ; \\ E_{M_\Lambda}(u_{j,\Lambda}, u_{l,\Lambda}) = 0 \quad \forall j \neq l \end{cases} \tag{4.4}$$

The predictions Λ_j^A needto be positive. A useful model is the logaritmic one: $\log(\Lambda_j^A) = \mathbf{x}'_j \boldsymbol{\varphi}_{\Lambda}$. The model (4.4) allowsthe prediction of the total number of links Λ_j^A of the unit j, thus defining the expected cost survey cost attached to it.

Accordingly to the models (4.3) and (4.4), the problem (3.1) can be reformulated as follows:

$$\begin{cases} \min \sum_{j \in U^A} E_{M_A}(c_j)\pi_j^A \\ E_{M_v} V(\hat{Y}_v^A \mid \mathbf{m}^A) \le V_v^* \quad \forall v = 1,\dots,V \\ E_{M_{zr}} V(\hat{Y}_r^B \mid \mathbf{m}^A) \le V_r^* \quad \forall r = 1,\dots,R \\ 0 < \pi_j^A \le 1 \end{cases} ,0 \qquad (4.5)$$

where $E_{M_A}(c_j) = f(\Lambda_j^A; C^B)$. The solution algorithm is identical to the one that solves the problem defined in context 2 except that the models for predicting the z-values and the expected costs are less specific, which results in a higher model uncertainty.

Remark 4.4:In some situations, the model variances $\sigma_{j,zr}^2$ are not known, and it is not feasible (for organizational or cost constraints) to carry out a pilot study for assessing them, while the predictions $\tilde{z}_{j,r}$ can be assessed with a super-simplified model as in (4.2). In order to find a realistic sampling solution, it may be reasonable to assume that the following relations hold: $\tilde{z}_{j,r}^2 + \sigma_{j,zr}^2 \cong \kappa \tilde{z}_{j,r}^2$,where $\kappa > 1$.The sample designer may find a *quasi-optimal* sampling solution by running the problem with alternative reasonable choices of the κ value (e.g., κ =2, 3 or 4), and studying the sensitivity of the different solutions.

Remark 4.5: a good strategy which allows to be robust against model failure is to select a balanced sample with respect to the auxiliary variables $\mathbf{x}_j$. In this case, the auxiliary variables $\mathbf{d}_j$ of the balancing equations are replaced by the augmented variables $\mathbf{d}_j^* = (\mathbf{d}'_j, \mathbf{x}'_j / \pi_j^A)'$. For the calculation of the variances, the residuals $\eta_{j,v}$ are substituted by the modified residuals $\eta_{j,v}^* = y_{j,v} - \pi_j^A (\mathbf{d}_j^*)' \boldsymbol{\beta}_v^*$, where $\boldsymbol{\beta}_v^* = (\boldsymbol{\Delta}^*)^{-1} \sum_{l \in U^A} \pi_l^A (1/\pi_l^A - 1)\, \mathbf{d}_j^* y_{l,v}$ with $\boldsymbol{\Delta}^* = \sum_{j \in U^A} \mathbf{d}_j^* (\mathbf{d}_j^*)' \pi_j^A (1 - \pi_j^A)$. For the modified residuals $\eta_{j,r}^*$, similar expressions are used.

MEASURING THE STRUCTURAL TRANSFORMATION OF THE AGRICULTURAL SECTOR

ABSTRACT

Background: Global agriculture is undergoing important structural transformations, which are creating challenges for national statistical agencies.

In many countries, large commercial enterprises, sometimes encompassing multiple farms and complex organizational designs, account for growing shares of agricultural production. Even where production is shifting to larger farms, there remain many small farming operations, such that production is highly skewed, with a relatively small number of larger farms accounting for high shares of production. In a related development, large organizations are investing in farmland — sometimes to farm themselves, and sometimes as an investment vehicle while leasing the land to farm operators. The nature of farm tasks is also being transformed. Farm may specialize in a single stage of production of a production process: for example, farms may specialize in livestock production, while other farms produce feed; they may specialize in a single stage of livestock production, such as breeding or feeding. They may contract with another farmer to manage feed crop production on their farm, while focusing their energies on livestock. Structural transformations carry challenge for statistical agencies. They may have to organize and apply surveys in different ways to capture the key elements of transformations. Even if existing surveys are adequate to the task, agencies may need to rethink the measures and reporting that they use to summarize survey results. Papers should address the methodological challenges posed for statistical systems by structural transformation in agriculture. What statistics need to be collected, and with what frequency? Does structural transformation change the universe of entities that ought to be surveyed, and how should statisticians respond to that challenge? How should samples be designed? How can we best measure the key elements of structural transformation? How have those measures changed over time?

ABSTRACT

Structural change has been a constant factor in agriculture, the Netherlands included. For decades the number of farms has decreased and the size of farms has increased. Agricultural statistics help to analyse and understand structural change, but at the same time structural change affects and to some extend complicates the compilation and use of agricultural statistics. Developments in the size of farms and the number of farms, although often used as indicators of structural change, have a limited impact on agricultural statistics. Other factors such as the increase in complexity of agricultural holdings have a potential large impact.

Keywords: structural change, farm level statistics, complexity

PAPER

1. Introduction

In this paper the structural change in agriculture in the Netherlands will be described. Section 2 describes the driving forces of agricultural change as described in literature. Subsequently section 3 describes how structural change has had an impact on agricultural statistics and what kind of strategies are implemented to solve these problems (section 4). In this paper we focus on the impact on farm level statistics such as the Farm structure survey (FSS) and the Farm accountancy data network (FADN).

2. Driving forces of structural change

Structural change has been of large interest to policy makers and agricultural researchers. Several studies on structural change have provided a list of factors that determine structural change. Zimmermann et al. (2009) derive 8 factors from these studies. The factors identified are technology, off farm employment, policy, human capital, demographics, market structure, social setting and economic environment.

We will highlight some of these factors. With respect to technology Zimmerman et al. refer to Cochrane's treadmill. Technological innovation reduces the per unit costs. When adoption spreads, competition increases and prices will go down. This forces the others to adopt this technology or leave the business which leads to structural change. Another effect of technology not described by them is the increase in labor productivity. In the Netherlands still many farms are run as family farms. Investment in new labor saving technologies allows the farmer or the farming family to run a larger farm with the available family labour or allows for off farm employment.

In this way, off farm employment can sustain small farms or even subsidize the farm from other income sources. Off farm employment can also be considered as the first step out of agriculture. If wages outside the agricultural sector increase it becomes more attractive to allocate more labour to off farm activities. Increase in wages can also lead to a pressure to increase the scale of the farm to achieve similar income levels as outside of agriculture.

Policies affect structural change. Measures from agricultural policies such as subsidy payments, price support, and production quota have an impact on the structural development of the sector. Peerlings et al. (2010) and Zimmerman and Heckelei (2012) for example describe the impact of the EU dairy policy on the structural change in the dairy sector in different regions in Europe. Besides agricultural policies, also other policies on taxes, social security, inheritance, credit programs can affect the structural development. In the Netherlands also environmental policies influence the development of farms by setting restrictions on the environmental pressure of farms (for example the policy that the growth of dairy farms depends on its mineral surplus and the possibilities to process these surplus minerals (de Koeier et al. 2014).

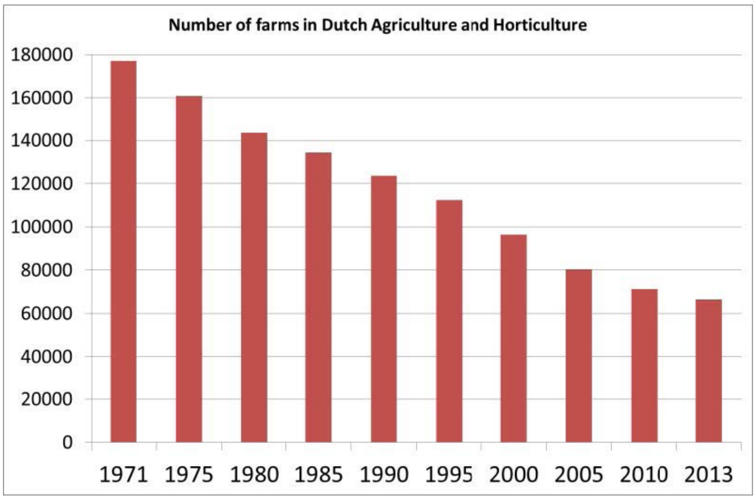
Human capital refers to schooling and management skills. Demographics refer to the age structure of farming and the availability of successors. Market structure determines the market power and therefore the setting of prices, but also the local opportunities for short supply chains (like on-farm sales). Besides market structure, also organisational structure should be mentioned. Vertical and horizontal integration has had a major impact on the agricultural sector, although the impact on structural change of agriculture is less clear. Social setting is mainly linked to the societal and individual motivations of family farming. The economic environment as a driving force for structural change refers to macro-economic developments such as price developments (especially also of labour income outside farming), exchange rates and interest rates.

This is a wide set of factors affecting structural change. Most of these factors are not directly captured by agricultural statistics. Some information is available on off-farm labour and income. Analysing these factors therefore asks to include information from other sources, apply a more case based approach or to infer proxi variables (productivity as a proxi for technology). In the next section we will describe the structural change in Dutch agriculture.

3. Structural change in Dutch Agriculture

Dutch agriculture has shown a continuous decrease in number of farms (see figure 1) and a continuous increase in the scale of production. Since the seventies the number of farms has decreased 2 to 3 percent every year. After 2000, this decrease has even accelerated. The explanation of this decrease is a combination of economic, technological and policy related factors as described in the previous section. Increased labour costs in combination with technical innovations enabled the reduction of labour input and the increase of the size of the farm that could be managed by one farmer. The increased labour costs also reflect attractive incomes in the booming economy outside agriculture. New juridical and financial structures further increased the scale of production.

Figure 1 - Decrease in number of farms



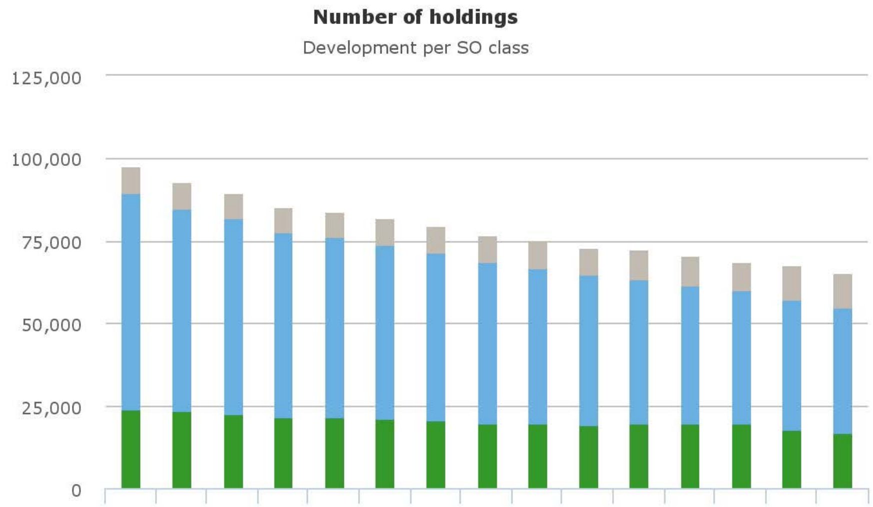
The continues increase in the average size of farms does not mean that all farms follow a similar growth path. The farming population is and always has been a heterogeneous group. Besides farm characteristics and the environment in which a farm is operating, it is also strongly influenced by different farm strategies. Some farms have chosen for a strategy of growth to grasp the benefits of economies of scale. Others have chosen a strategy of diversification of income sources by developing other off and on farm income activities. For still others the farming activity is just a hobby activity, which is not run (or only partially) to provide a source of income.

This is illustrated with figure 2. This figure shows that especially the mid-size group has declined over time (period 2000-2014). The group of small farms has remained stable at a percentage of around 25 percentage of the total farm population. The largest size group has shown a substantial increase (in number of farms and especially in the share of the production value). The mid-size group is declining because it is too small to remain competitive and too big to be run as a part-time or hobby farm.

Given these different farm strategies and differences in the developments of farms, the average size of the farm is more and more difficult to interpret. Therefor Lund (2004), later adopted by the OECD, have introduced the mid acreage or mid livestock indicator, meaning that 50% of the acres or 50% of the livestock can be found at farms larger than this mid-point and 50% on farms smaller than this mid-point. We will illustrate this indicator based on the developments in the dairy sector over a long time period.

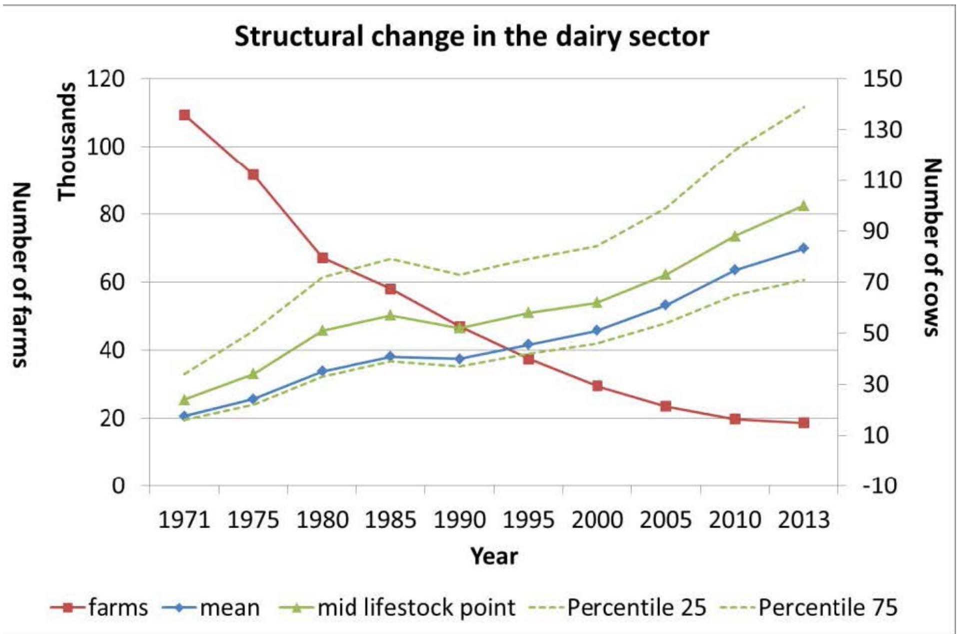
The dairy sector has always been an important sector in Dutch agriculture and structural change is clearly reflected in the developments of the dairy sector. In 1970 there were still more than 110 thousand farms with dairy cows in the Netherlands (see figure 3). The average number of dairy cows

Figure 2 - Development in the size distribution of farms



was about 25. In 2014 the number of dairy farms decreased till about 18 thousand and the average herd size increased till 84. Although still limited compared to the development in some other countries, also the Netherlands shows rapidly increasing herd sizes. The mid livestock point in 2013 was above 100 dairy cows (50% of the cows are in herd sizes of more than 100 cows) and the 75 percentile of this indicator increased till above 140 cows (25% of the cows are in herd sizes above 140). Despite this strong growth in size of dairy farms, the dairy sector still consists to a large extent of family farms.

Figure 3 - Structural change in the dairy sector



Compared to the dairy sector, the development of the landless sectors (intensive livestock and glasshouses) have even shown a much more rapid development. The average vegetables glasshouse increased from 1 hectare in 2000 till more than 3 hectares in 2013.The mid acreage point increased during that same period from 2 till more than 7 and the 75th percentile increased from 3,5 till 14 hectares.

This increase in farm size has been accompanied by large changes in the organisational and financial structure of farms e.g. to handle business risks (and separate family savings or spouse's income from the business, or to manage production in different locations. The traditional family farm (although still dominant in some of the sectors) has been replaced by limited companies and other juridical structures involving the cooperation of several farm holders.

PL03

4. Impact on agricultural statistics

Structural change has often been studied based on the developments in number of farms and size of farms in different sectors (Goddard et al, 1993; EU, 2011; Offerman and Margarian, 2014). These factors are relatively easy analysed and well described by agricultural statistics. Also in the Netherlands the agricultural census provides meaningful data to describe these developments (as reported in section 3 above). Size and number of farms have however a limited impact on agricultural statistics. Other factors reflecting structural change (Jaklic et al., 2009; Goddard et al, 1993) have a much bigger impact on agricultural statistics. Table 1 gives an overview of the factors of structural change and its impact on the compilation and use of agricultural statistics. These impacts will be further elaborated in this section.

Table 1 Characteristics of structural change and impact on agricultural statistics

Factors of structural change	Impact on agricultural statistics
Increase in size of farms	Limited, small farms often cause the largest problems;
	Increase in record keeping facilitates data collection
	Impact on sampling plans
Larger dispersion in size	Need for other indicators (average has limited value)
	Increased risk of disclosure
	Choice of allocation mechanism in sampling becomes more relevant: e.g optimal vs proportional
Decrease in number of farms	Cheaper census, less elements
	More difficult to include sample elements of small strata;
	Impact on sampling plan
Increased specialisation	Easier data collection, less relevant data items Could improve or complicate benchmarking
Increased complexity (vertical and horizontal integration)	Definition of a farm becomes more unclear
	Increased risk of different definitions in different administrative / statistical / commercial systems
	More difficult data collection (in case different intertwined activities in bookkeeping)
	More difficult recruitment in voluntary sample
	Difficult separation of agricultural and nonagricultural activities and agricultural outputs can be hard to observe and value if they are input to another product (e.g. maize for energy production)
	Complicates use of data for benchmarking
Financial structure	Other indicators needed
Increase in Multi household farms	
	Decreased feasibility of collecting off-farm income
	Increased complexity of collecting farm demography
	Multi dm's increase complexity of farm recruitment in voluntary samples
Age structure	Young farmers better educated, more used to recording
Farm entry / exit	Difficult to capture with current statistics, especially in voluntary systems

Increase in size of farms

An increase in size does not necessary complicate agricultural statistics, in practise often the small farms cause problems (Pedersen, 2013). If the increase in size continues it could lead to changes in the structure and management of the farm that do have a strong impact. The increasing organizational complexity of farming establishments can affect data collection, accuracy of estimates, and the use of data, e.g., in multivariate and policy analysis, disclosure, and dissemination of estimates (Ahearn, 2013).

Increase in dispersion in size

Structural change affects the sample design procedures applied in agricultural statistics. Most countries apply a disproportional stratified sample in their Farm Accountancy Data Network (FADN) or other business-related statistics with a type of Neymann-allocation to allocate the sample capacity to the different size classes. The calculation of the heterogeneity is often based on the variance of the economic size in a stratum. Due to structural change and the increasing farm size the heterogeneity in the largest stratum increases rapidly. Applying the Neymann allocation could therefore results in a large shift of the sample capacity to the largest strata in each of the types of farming. Taking into account the non-response rate, extra work on bigger (more complex) farms and the decreasing number of farms this results in infeasible sampling plans. An increased dispersion of farm sizes could make indicators such as averages more difficult to interpret and creates a need for alternative indicators (Lund and Price, 1999).

Decrease in number of farms

A decrease in number of farms reduces the costs of a census as data on less farms needs to be collected. However, such a decrease could complicate sample statistics because the choice of farms in a certain strata is more limited, which could increase the recruitment costs. Furthermore changes

in the distribution of farms over different farm types might require an adjustment of the sampling rates in different strata. In the use of the data, a decrease in population numbers could make it more difficult to publish results of subgroups because of a lack of data.

Increased specialisation

Given the trend to specialize production, the number of mixed farms is decreasing in almost all countries at a stronger rate than the farming population in total. Data on specialised farms are often more easy to collect (less relevant data items) and more easy to use (no arbitrary allocation of overhead costs and inputs to different agricultural activities). One exception is specialisation in niche markets (for example in horticulture producing a specific flower or plant). Such specialisation could reduce the willingness of farmers to participate due to a lack of relevant benchmarking information and the perception that data is competitive sensitive information.

Increased complexity

Changes in the legal structure of enterprises, multiple households related to one agricultural holding, agricultural activities intertwined with other commercial activities or other on and off farm income sources raise serious conceptual and practical questions.

A large share of farms supplement their farm income with income from other sources (off farm and on farm). Besides the traditional other gainful activities such as cheese production, nature management and farm tourism, also other activities such as care farming, investments in renewable energy (digesters, wind mills) become more and more important. Sometimes these activities are conducted in the same business holding, sometimes separate legal entities are started for these activities.

All these issues affect the definition of a farm and the farming sector. The definition as applied in agricultural statistics 'a single unit, both technically and economically, which has a single management and which undertakes agricultural activities' (REGULATION (EC) No 1166/2008) becomes more difficult to apply in practise.

There is an increasing difference how a farm is managed in practise and how the farm is recorded in the agricultural census. In the Netherlands more than 5% of the farms as recorded in the Farm accountancy data network have multiple recordings in the agricultural census. The reason of these multiple recordings can differ from manure application laws, entitlements for subsidy payments, financial and organisational structures (like having bought a farm at a second location that is then integrated in the mother farm but legally still registered as a separate farm).

This complexity also affects the participation rates in FADN. To some extent it is a challenge to fit in these complex structures in the normal FADN data collection, therefore data collectors might be tempted to exclude these type of enterprises from the sample which might result in a biased sample. Furthermore also the respondents might refuse to participate because they feel less connected to the agricultural sector and might not consider themselves as a 'representative' unit to be included in agricultural statistics (Vrolijk, 2005).

Financial structure

The idea of a family farm which is operated with a lot of own assets and some bank loans to finance new investments is becoming less common. Farming is a capital intensive activity, and therefore often requires large long-term loans. These developments have an impact on data collection and especially on the use of the data. In the use of the data this means that also an indicator like family farm income is a less suitable indicator to compare the profitability and distribution of income of farms. Johnson et al.(2007) propose to use net value added (NVA) at the micro level to reflect the participation of a wide variety of stakeholders (e.g. banks, land owners, paid labour) in the organization and output of farms.

Multi household farm business

PL03

The increasing complexity of farm structures is also shown in the increasing complexity of collecting off farm income statistics and an a decreasing trend of the willingness among farmers to provide these data (increase in item non response). This not only asks for a re-evaluation of the relevance of off farm income for the operation of the farm, but also a revision of instructions which data items to collect for which persons in which households. (data for only the spouse of the farmer in family farms, or also for a broader set of household members of the farm holders of multi household farm holdings). Multi household farm businesses could also complicate recruitment processes in voluntary data collection because the commitment of several persons is needed.

Age structure

Old farmers are often less willing to participate. An ageing farm population could therefore make recruitment of farmers for a system like FADN more difficult. Willingness of participation is lower due to the idea that the farming business will end or be transferred in a few years' time. Furthermore there is a link between age structure and level of (agricultural) education. A higher level of education leads to a higher interest in useful management information and the willingness to benchmark farm performances and therefore increase the willingness of participation.

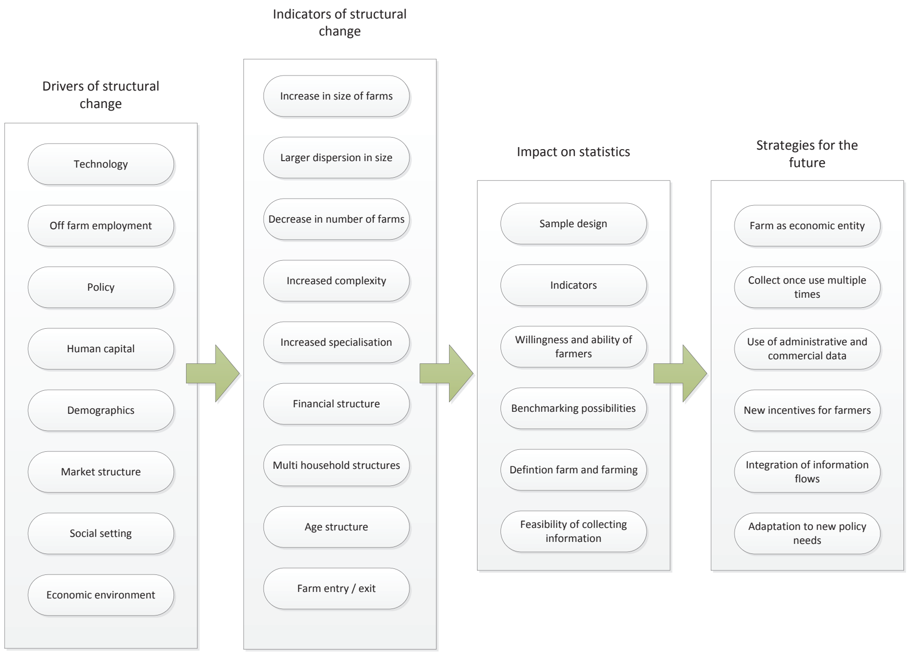
Farm entry exit

Farm entry and exit is an important indicator of structural change but is difficult to fully grasp by agricultural statistics. The farm accountancy data network (FADN), which provides extensive information on the economic performance of farms, is organised as a rotating panel, and the current statistics do often not allow determining whether a farm exits the survey due to the closing down of the farm or other reasons (Offerman and Margarian, 2014). The farm structural survey on the other hand provides information on farm entry and exits but also there it requires further analysis to understand the development of farms (merging of farms, change in juridical structure etc.).

5. Solutions and Future steps

Given the structural change of Dutch agriculture as described in section 3 and the potential impact of structural change on the compilation and use of agricultural statistics as described in section 4 there are some important challenges in the system of agricultural statistics. This section describes some principles and initiatives in the Netherlands to handle these challenges. Figure 4 provides the framework with drivers of structural change, the indicators of structural change, the impact on statistics and the strategies for the future. These strategies focus on the definition of the farm, the way of collecting data, the way of involving farmers and the need to reconsider the whole system of agricultural information.

Figure 4 - Structural change and the impact on future strategies in agricultural statistics



Definition of the farm and farming sector

In the past farmers who were in the farm register received an invitation to submit the agricultural census. Due to the focus on active farmers in the current CAP, the population of the agricultural census

PL03

has been redefined as those enterprises registered at the chamber of commerce as an agricultural producer (according to the NACE coding system). This registration as an agricultural producer is also a requirement to receive agricultural subsidies. Besides adapting to changes in the CAP, this change also reflects the trend in the Netherlands that agricultural enterprises are treated as any other economic sector.

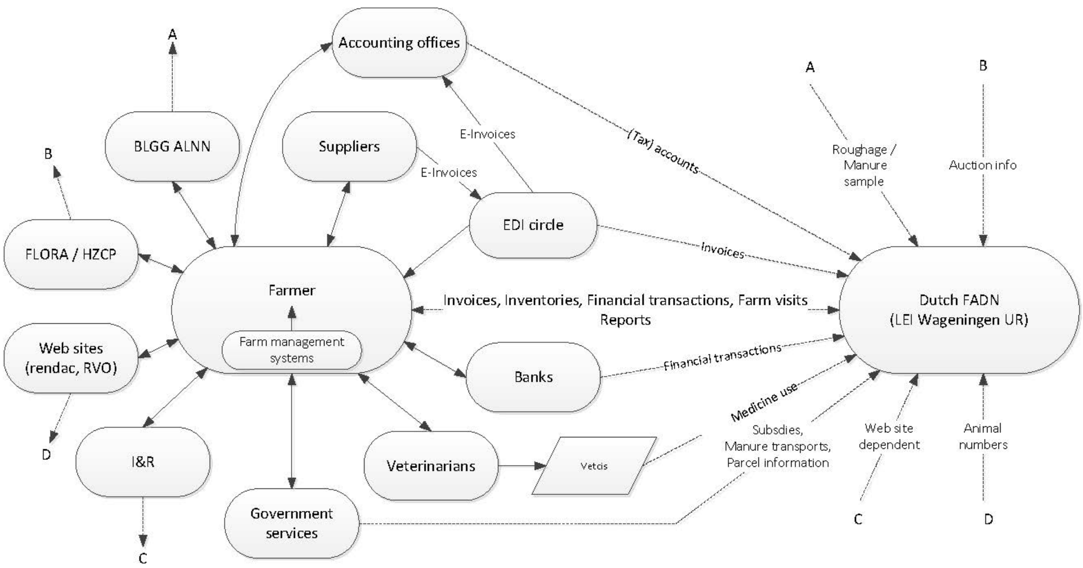
Collect once use multiple times

In Dutch agriculture there is an increasing group of farmers who only want to share information if it does not take too much of their time. For those farmers, the traditional data collection methods of a data collector and the farmer filling in forms at the kitchen table does not work anymore. This is not only true for farmers, but for all entrepreneurs. An important policy objective of the Dutch government is the reduction of the administrative burden. One of the core elements of this policy is the 'collect once use multiple times' principle. The government can only ask a specific data item once. If this item is needed for other administrative or statistical purposes the already collected data should be reused or the data collection should be integrated. This has resulted in an integration of data collection for administrative and statistical purposes.

Increased use of administrative and commercial data

As a next step, large benefits can be gained by re-using not only administrative data but also commercial data. In the Dutch FADN system there is a strong focus on the re-use of existing data to lower the administrative burden, to increase the efficiency of data collection, to increase the quality of the data and to enable a wider set of analysis. In Dutch FADN a wide set of data sources is used to compile the farm (bookkeeping) data. Figure 5 illustrates the data sources used. This varies from bank transactions to use of animal medicines, and from electronic invoices to information on the manure flows. All these data sources are used to compile the recordings for individual farms. At the end of the year, the system generates a list of missing data items which should still be asked from the farmer (for example labour hours or allocation of inputs to different crops). In this way the administrative burden for farmers is minimized by only asking the farmer, if there is no other information source available.

Figure 5 - Data sources in Dutch FADN



Incentives for farmers

In these systems it is also increasingly important to consider the benefits to farmers and the farming sector to share this information. New concepts need to be developed where all stakeholders benefit. Other incentives for farmers to participate are needed.

6. Discussion

This paper described structural change and the impact on agricultural statistics. Responding to these developments requires the adaptation of the content and working procedures on agricultural statistics. It is important to realise that this is not the only need for agricultural statistics to adapt.

Also the requirements for agricultural statistics change. New policy and research topics emerge that need to be analysed and for which relevant information is necessary. This requires the adaptation of the system of agricultural statistics to the new policy needs. At the EU level this is a slow process. In the Netherlands the ability to adapt to these changes has been a core design principle in the national FADN.

In this paper we have focused on farm level statistics. Structural change also has an impact on other types of agricultural statistics, such as price statistics. In certain sectors price statistics become more difficult to compile because of an increased heterogeneity in production (due to a strategy of product specialisation and niche markets) and due to a concentration in production and in chain actors. As a consequence, price information is more and more treated as competitive sensitive information. Also changes in the marketing of products from auctions to direct contracts reduces the availability of price information. Although some of trends make the access to information more difficult, at a broader scale the availability of information only increases.

With the trends of big data, internet of things and precision agricultural the availability of information will only further increase. Also the need for information in the agro food sector increases continuously. Traceability, certification, labelling, production planning require detailed data on production and production processes. This makes it even more necessary to consider the whole system of information flows in the agricultural sector to achieve a synergy between the different needs and applications.

All these developments make it necessary to not only look at the needs for agricultural statistics. Agricultural statistics should be an integral part of the whole system of information needs and information flows in and about the agricultural sector

Structural transformation in North America: what does it mean for agricultural statistics?

J. MacDonald | USDA Economic Research Service | Washington, DC | USA

DOI: 10.1481/icasVII.2016.pl3b

ABSTRACT

Farming in North America is undergoing a series of structural transformations: production is shifting to larger farms; farms are adopting more complex organizational arrangements; and consumer demand is changing, with a greater emphasis on more highly differentiated agricultural products. Analysis of these changes is complicated by another feature of farm structure—the farm size distribution is highly skewed, with many very small farms and a heavy concentration of production by a relatively small number of large farms.

Structural transformation creates a series of challenges for statistical agencies; the challenges are not completely novel, as statistical agencies have been dealing with each of these issues for many years. However, agencies may have to organize and design surveys in different ways to capture the key elements of transformation, and to continue to provide reliable measures of standard variables of interest. Even where existing surveys are adequate to the task, agencies may need to rethink the measures and reporting that they use to summarize survey results.

Keywords: Farm structure, farm size, farm organization, census of agriculture

PAPER

1. Introduction

Farming in North America is undergoing a series of structural transformations: production is shifting to larger farms; farms are adopting more complex organizational arrangements; and consumer demand is changing, with a greater emphasis on more highly differentiated agricultural products. Analysis of these changes is complicated by another feature of farm structure—the farm size distribution is highly skewed, with many very small farms and a heavy concentration of production by a relatively small number of large farms.

Structural transformation creates a series of challenges for statistical agencies; the challenges are not completely novel, as statistical agencies have been dealing with each of these issues for many years. However, agencies may have to organize and design surveys in different ways to capture the key elements of transformation, and to continue to provide reliable measures of standard variables of interest. Even where existing surveys are adequate to the task, agencies may need to rethink the measures and reporting that they use to summarize survey results.

We describe these elements of farm structure and structural change below, and then show how each affects statistical surveys and reporting. We use U.S. data from censuses of agriculture, including a 2014 followon to the 2012 census called to Tenure, Ownership and Transition of Agricultural Land (TOTAL) survey, which replaced USDA's large annual farm survey--the Agricultural Resource Management Survey (ARMS)--in that year.

PL03

2. Structural Change

We focus on three key elements of structural change: shifts of production to larger operations, increasing organizational complexity in the farm sector, and increasing commodity differentiation. Analysis of each is complicated by an ongoing feature of the farm sector: the extreme skewness of the farm size distribution.

What do we mean when we say that the U.S. has a skewed distribution of farm sizes, and why does it matter? We use U.S. crop farms as an example, using data from the 2014 TOTAL survey (figure 1). Most crop farms are quite small: nearly half had less than 50 acres of cropland in 2014. However, those small farms collectively accounted for only 3.5 percent of cropland and less than 7 percent of the value of crop production. The distribution also features a long tail: over 50,000 farms had 1,000-2,000 acres of cropland, and the range extends to nearly 100,000 acres. Farms with at least 1,000 acres of cropland—6.2 percent of all crop farms--accounted for well over half of cropland and crop production.

The skewness is apparent in summary statistics. The mean farm size (261 acres of cropland) far exceeds the median of 50 acres. However, most cropland and crop production is on farms that are far larger than the mean: the midpoint, where half of all cropland is on larger farms and half is on smaller, was at 1,296 acres in 2014. The U.S. farm size distribution has grown more skewed in recent years, as the middle has hollowed out while farms and acreage have moved to the extremes (MacDonald, Korb, and Hoppe, 2013).

We have used cropland acreage as an example, but similar patterns appear for livestock (herd and flock sizes) and for distributions using farm sales or value of production. Most farms are very small, while most animals, acreage, or sales are on a relatively small number of large farms.

The skewness of farm sizes is particularly pronounced in the U.S. because of the way we define farms, using a commodity sales threshold that is relatively low ($1,000 worth of commodity sales, or land or animal assets capable of generating $1,000 in sales) and not adjusted for inflation. We have seen sharp increases in the reported number of very small farms since 2002; with increasing numbers of very small and very large farms set against declining numbers of midsize farms, and stable total cropland acreage, we see little change in mean size even as land shifts to larger operations. However, while skewness is extreme is the U.S., it is a feature of agriculture sectors in other OECD countries as well (OECD, 2015)

2.1 Production is shifting to larger farms

Why does a skewed distribution matter? It affects sample design choices, as we see below, but it also complicates reporting on structural changes. For example, the mean crop farm size in 2014—261 acres—was only slightly above the 1992 mean of 257 acres. If one looks only at the mean, easily calculated and widely reported in our official publications, one would not think that there was much consolidation in the U.S. farm sector (figure 2, using census data only). However, that conclusion is shaken by the trends in midpoint sizes. For cropland, the 2014 midpoint of 1,296 acres was noticeably larger than the 2012 midpoint of 1,201 acres, and much greater than the 1992 midpoint of 749 acres, which in turn represented a large increase from 589 acres in 1982 (figure 2). The U.S. has undergone a substantial shift of cropland and production to larger farms, but our simple measures don't capture it.

The shift of acreage and animals to larger operations is large, and an important element of structural change. It has been occurring in almost all U.S. states and almost all crop and livestock commodities, and has been persistent over time (MacDonald, Korb, and Hoppe, 2013). The census of agriculture provides enough commodity detail to track midpoints for harvested acreage in specific crops, as well as animal inventories and removals, from 1987 through 2012. We report estimates for selected crop and livestock commodities in table 1. Dramatic changes occurred in hog and in dairy sectors, but we can also see quite striking changes in fruits and vegetables and in field crops.

The pattern is not unique to the United States. A recent OECD study documented a general pattern of shifts of acreage and animals to larger operations, although the shift was most pronounced in the U.S. and in Canada (OECD, 2015).

2.2 Farm businesses are becoming more complex

Structural change also encompasses increasing organizational complexity, covering how agricultural tasks are allocated among firms, and how farms and other agricultural businesses are organized.

Consider how farms are organized. Some farms are now part of multi-farm businesses: for example, some family businesses own several large dairy farms, or large grain operations in several states, or multiple cattle feedlots. Farms may also operate non-agricultural "value added" businesses that complement the farm business. For example, a farm family may also operate a bed and breakfast agri-tourism business, or a cheese-making business linked to a dairy farm, or a trucking business growing out of the farm's livestock or grain movements. We think that each of these are growing phenomena, but we don't have comprehensive data on the topic.

In other instances, businesses that look as if they are based on a single farm operation may organize themselves into several ownership entities for purposes of minimizing taxes, maximizing government payments, or managing family conflicts (or example, a farm may organize a land-owning entity, held by various farming and non-farming family members, and an equipment owning entity also owned by family members; each entity may then rents land and/or equipment to one or more farming entities, also owned by various family members).

The above examples concern how farm businesses are organized. The other issue of complexity concerns the performance of agricultural tasks by non-farm businesses. For example, contract agriculture links independent farms and farm input providers through a network of contracts. For example, about 95 percent of U.S. broiler production is coordinated by 20 large integrators, which own hatcheries, feed mills, and processing plants (MacDonald, 2014). The integrators contract with farms to provide eggs for hatcheries, and they contract with about 15,000 independent growers to raise chicks to market weight. Contract growers, who invest in housing and equipment, are provided with feed, chicks, and support services by integrators, and their compensation reflects pay for growers' services rather than payment for the value of the birds. Similar arrangements, where farm production costs are shared by several different firms, can be found in egg, turkey, and hog production, and in some areas of vegetable production and horticulture. In these cases, farms provide only some of the inputs in agricultural production, while integrator, who are necessarily defined as farms provide the rest.

Similarly, some farm tasks may be performed by specialized service providers that are not farms. Crop tasks—like field preparation, planting, spraying, or harvesting—are frequently performed by custom service providers for a fee. Some custom providers are also farm operations aiming to use their equipment and labor more intensively, but others do not operate their own farms and are not captured in surveys. Other specialized service providers include labor contractors, farm management firms, and equipment lessors.

2.4 More differentiated agricultural products

There is growing interest in agricultural products with differentiated physical attributes, like taste, color, or size. Examples can be found in many fruit and vegetable products, such as eggplants, peppers, potatoes, tomatoes, cantaloupes or tangerines, but they can also be found in some meat products, such as pork from "heirloom" varieties of hogs.

However, there is also growing consumer interest in the processes associated with farm production, and therefore with products that are differentiated not by their physical attributes but by their production processes. Examples include livestock raised without antibiotics, pork from farms that don't use gestation crates, grass-fed beef, cage-free eggs, or food products that have no ingredients from genetically modified plants, to name a few. The common feature of these products is that the relevant attributes are features of farm-level production processes; consumers care about the processes, but cannot observe them. In these cases, consumers rely upon some sort of certification of processes, whether provided by farmer advertising, retailer assurance, third party certifiers, or government agencies.

There's also a growing interest in locally produced agricultural commodities, which bear some resemblance to products differentiated by production processes, in that consumers can't observe whether a product was actually produced locally.

There is every reason to believe that interest in these and other alternative agricultural products will continue to grow, and that statistical agencies will have to consider how to track and report on the products, and how to account for their influence in existing reporting.

3 Structural Transformations and Statistical Surveys

Statistical agencies have been dealing with each of these challenges for many years. They use stratified sample designs, with greater sampling probabilities attached to larger operations, to handle skewed size distributions, especially when the reporting of production or sales aggregates is the goal. They sort data into farm size classes—measured by acres, animals, value of production or sales—when reporting on the farm size distribution itself. They put extra—sometimes special—effort into handling complex farms and operations that are large enough to appear in many survey samples. In a sense, our story is about the accentuation of issues that statistical agencies have been dealing with for some time

3.1 Structural change, reporting, and survey design

USDA puts considerable effort into reporting on farm structure. For example, census of agriculture publications report the number of farms, harvested acreage, and production, sorted by harvested acreage class, for 31 different field crops (USDA/NASS, 2014). The classes are well thought out and their range updated for structural change, so that the largest class listed rarely accounts for more than one-quarter of acreage and production. For most of those crops, one could estimate the midpoints reported in table 1 with considerable accuracy, based only on publically available data and not the confidential data that underlie the table. One could also generate means and good estimates of medians from the data at hand, and could use the reported distributions to provide comprehensive information on changing structure.

However, the effort is not quite as successful in other vegetable and livestock commodities, where the largest size class reported frequently accounts for well over half of harvested acreage or animal inventories. In that case, one can't really generate a good estimate of a midpoint, and one can't use the full distribution table to track changes in structure. The critique also extends to several of the all-farm size distributions based on value of production or acreage (the summary tables), where the largest size class again includes most production or acreage.

Structural change affects survey design as well as reporting. With production consolidating in a smaller number of large farms, some farms now have a high probability of appearing in many surveys. Since many of these same farms are also approached by private data collectors, and since many of them also have regulatory reporting requirements, statistical agencies face a growing problem of respondent burden. Declines in large farm response rates, should they occur, would threaten the viability of many estimates.

One approach to dealing with the particular respondent burden faced by larger operations would be to take a more tailored approach to them. Statistical agencies could seek to acquire information in ways that reduce burden, by adjusting to the reporting systems used by large operations; by altering survey forms to ask for updates, rather than newly filed information in each visit; or by seeking to allocate common information acquired in one survey to other surveys as well. Each of these could be extended from statistical surveys to regulatory and administrative filings, in order to further reduce respondent burden, with one major caveat. Data collected in statistical surveys retain confidentiality protection, such that individual records cannot be disclosed to the public or to regulators; administrative and regulatory filings are not subject to the same protections.

3.2 Farm complexity: who and what to survey

Complexity creates several interrelated statistical challenges. USDA surveys generally use farm respondents to generate data on production, acreage, input use, financial outcomes, and other features of the agricultural economy. With a focus on farms as respondents, samples for agricultural surveys and censuses are drawn from sampling frames that are lists of farms, and considerable effort is put into building and maintaining lists.

With organizational complexity, farms are not always the best source of information. In contract production arrangements, where some inputs are provided by farms and some are provided by contractors, the contractor may be better informed (for example, about feed or chick expenses in contract poultry production). Similarly, for multi-farm firms, a central office may be better placed to provide information on certain expenses. Farms can provide information on expenses and tasks associated with custom services, but may not be informed about other specific features. Statistical agencies often maintain contacts with contractors and central offices to obtain these data in their normal course of business, but the relationships are often informal and non-systematic.

Because sampling frames are built from farms, USDA can also provide extensive reporting on farm structure. For the same reason, however, USDA surveys are not organized to support reporting on multi-farm firms, providers of farm sector services, or non-farm contractors. Efforts to track and report on multi-farm firms, agricultural service providers, or contractors would require a new effort to build business lists into sample frame. That exercise could use some non-comprehensive sets of linkages built by statistical agencies as part of their normal business. However, they would most likely need to use tax and other administrative records to build up to a more comprehensive file. In short, reporting on multi-farm firms and farm service providers would require an investment in building sampling frames.

The notion of complexity also includes "value-added" activities associated with farm businesses—such as further processing of agricultural commodities, or the joint production of farm and tourist services with farm inputs. Value-added activities matter for the agricultural sector farm income and productivity accounts produced by USDA: to the extent that they are joint products that depend upon at least some of the same inputs used for farm production, each account needs to take account of the returns to such farm-related activities. USDA surveys aim to elicit enough information on them to fulfill the needs of those accounts, but agencies do not aim to report separately on them.

3.3 Product differentiation: tracking and interpretation challenges

Because they are more costly to produce, differentiated products typically generate higher prices than conventional products. This can create challenges for reporting on farm productive and financial performance. If differentiated products are not reported separately from conventional products, then average measures of costs of production, gross returns, and net returns may be reflective of neither the conventional nor differentiated product, but an amalgam of them. Moreover, if differentiated products account for a growing share of production, or if their cost and price trends do not track conventional cost and price trends, then aggregate reported trends may not be reliable indicators or trends for either differentiated or conventional products.

For this reason, but primarily because of interest by industry participants, differentiated products create new demands for reporting on specific differentiated commodities—for timely information on production, inventories, and sales as well as reporting on prices. These demands may sometimes be met through low-cost adjustments to ongoing surveys, but they also may require new surveys. These are standard tasks for statistical agencies, but doing new surveys can put resource pressures on agencies.

4. Conclusion

Structural change in agriculture results partly from changes in technology that allow farmers to manage more cropland or more animals, and to utilize more complex organizational forms. Some technological change results from innovations derived from biological sciences and some results from mechanical innovations; however, some also results from improvements in information technology (IT), bit directly and as applied in biological and mechanical innovations.

IT innovations also affect statistical agencies, by facilitating improvements in survey design, administration, and editing as well as facilitating more rapid and more widely disseminated reporting. Thus while structural change in agriculture create new challenges for statistical agencies, the accompanying changes in information technology create some opportunities for different ways of gathering and reporting on data.

Structural change in Brazilian agriculture

F. Bolliger FAO | Rome | Italy

DOI: 10.1481/icasVII.2016.pl3c

ABSTRACT

The paper presents prominent aspects of the changes in the structure of Brazilian agriculture. The purpose was to address the main structural changes found in Brazilian agriculture, based on census data. Data from the 1960 census and 2006 are compared. The general outline of the changes reflects the industrialization process of agriculture, where old functions are absorbed by upstream and downstream activities. It was argued that a complete view of the agriculture structure should refer to the overall agriculture value chain. The lack of data was then discussed, as well as the growing demand for statistics relating to the value chain, particularly those revealing the phenomena of integration and quasi-integration in agriculture.

Keywords: agricultural statistics, agricultural structure, Brazil

PAPER

1. Structural changes in Brazilian agriculture

Many changes in Brazilian agriculture are self-evident. They can be clearly associated with the modernisation and industrialisation processes of Brazilian agriculture that has seen a major boost since the 1960s.

In this context the differences in scale are considerable: just considering the growth and size achieved in the activities developed there, in the course of the last fifty years. Since 1960, there was an increase in cattle herds threefold, daily production sixfold, poultry ninefold, grain production sevenfold and sugarcane production tenfold. This implied an increase of 33% in farming land, 2.7% in the cropping area, and 1.3% in pastureland, with almost another two million farms, the total number of which rose from 3.3 to 5.2 million. On the other hand, the contingent of people occupied in farming has dropped around one million from 16.6 to 15.6 million.

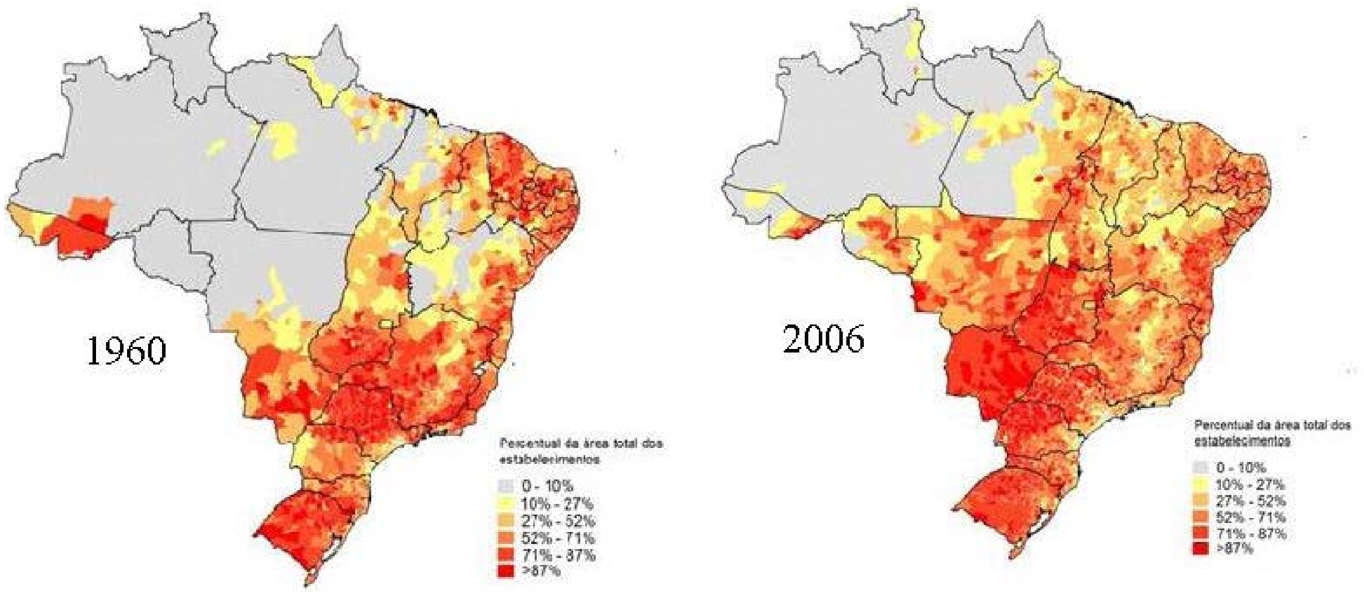
Expansion meant the addition of new areas and more intensified farm production. The following cartograms show changes observed in the density of agricultural exploration in national territory, noting the occupation of land by farming enterprises, intensity of cropping and cattle farming, as well as the degree of mechanisation, expressed by the availability of tractors in relation to the total surface of each municipality. The same stratifications (legends) were used for 1960 and 2006, in order to demonstrate the changes. In 1960 large areas of land in Pará, Maranhão, Mato Grosso, Rondônia and even Bahia had a very low occupation per farming enterprise 1960, (less than 10%), and today they are considerably more apropriated and explored (Figure 1).

Figure 1 - Intensity of farming occupation - Brazil, 1960/2006



Source: IBGE – Censo Agropecuario
Note: Total area of farms over the land surface of the municipality (%).

The change in the pattern of Brazilian agriculture results in major changes to the production composition. For example, it is worth noting in the case of soybean today as one of the principal crops with 17 million hectares harvested in 2006, while in 1960 its area was not even considered worthy of census calculations. Also iconic is the fact that coffee plantations currently cover less than half the area covered in 1959.

The farming activity is still considerably concentrated in terms of space, conforming to the most suitable edaphoclimate conditions. It is strongly intensified in São Paulo and South Brazil, especially in Paraná, with its agriculture even more concentrated in the northern part of the State and its amazing displacement towards the savannah regions, with important enclaves in Mato Grosso, Goiás and Bahia.

Intensification, displacement and spreading are much more noticeable in livestock farming. Its expansion over the last fifty years evidenced a major increase in its intensity over vast regions in Pará, Mato Grosso, Rondônia, Acre, Mato Grosso do Sul and Paraná, and the abandonment of certain regions with more profitable farming alternatives, as occurred in São Paulo. As figure 2 demonstrates, between 1985 and 2006 cattle farming was replaced by cropping in the regions more favorable to agriculture, and the intensity of both activities increases in the western and northern regions

In 2006, around 30% of farms used mechanical power for farmwork while in 1959 this percentage was scarcely more than 1% . Tractors were counted in tens of thousands and today are hundreds of thousands. In the 1960 Census, the investigated maximum power limit of tractors was 50 CV and in the 2006 Census the minimum limit was 100 CV. The types of equipment researched have diversified and almost doubled in number, considering that the current models have more power and in general are mechanically driven.

Figure 3 shows the generalisation of the tractor's presence in the Brazilian countryside today, compared to the shortage prevailing in the mid-20th century. It also illustrates that the use of mechanized farming, which had been confined basically to São Paulo, spread throughout the country, although it is still highly concentrated in that State and in southern Brazil.

The use of so-called modern inputs has definitely expanded. In 1960, 157,000 farms stated that they used chemical fertilisers while in 2006 no less than 1.3 million said that they used the input. So little was used that the 1960 Census did not even inform the number of farmers using insecticides and fungicides, while in 2006 the farmers using agrochemicals totalled 1.4 million.

The increase in the quantities of farm instruments and agricultural inputs, whose use and availability, together with genetic improvement and the advance of agronomic techniques, explain the gains in productivity. The significant spread of some of them, due mostly to credit incentives and other farming policy instruments, has changed the aspects how Brazilian agriculture is perceived, today on a par with the world's sstate-of-the-art.

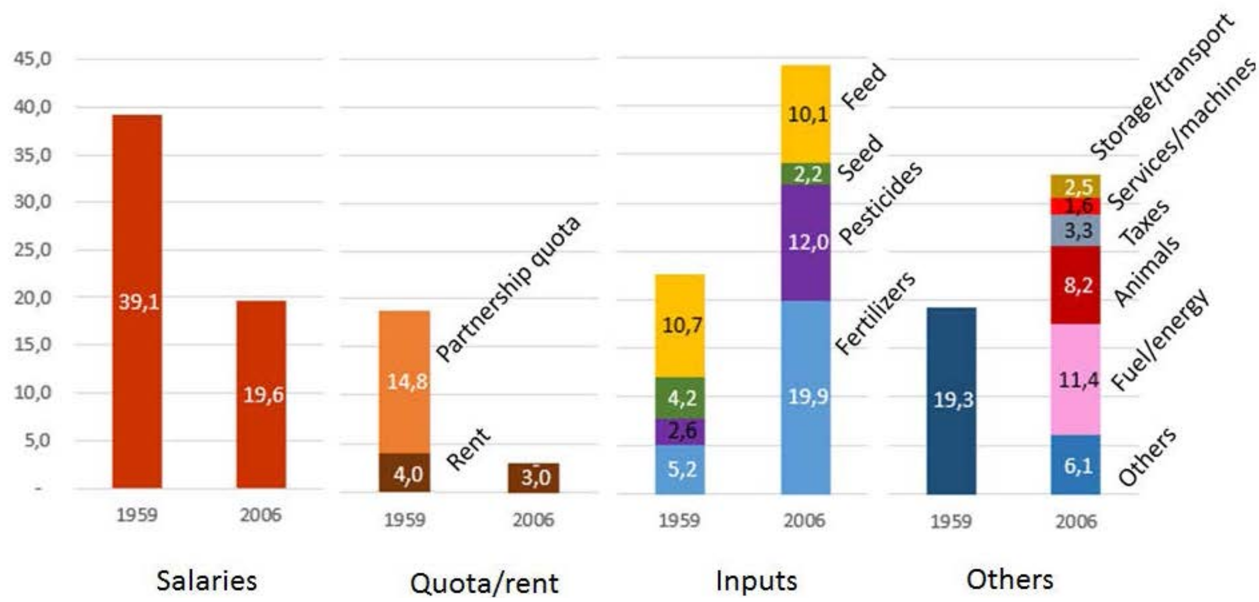
The changes found in the spending pattern of farms illustrate the drastic alterations resulting from the modernisation process due to industrialisation of the production process (Graph 3). Wage expenditure, which had been the main item in expenses in 1959, representing almost 40% of the total, was now reduced to half that figure. The participation in the payment of share partners, which in 1959 was 14% of expenses, was reduced to a minimum. On the other hand, the share in inputs rose 20 percentage points, with emphasis on spending on fertilisers, correctives and agrochemicals, which were 12% of the expenses in the mid-20th century and today they total 34% of expenditure of agricultural businesses. Moreover, other expenses such as, for example, electricity and fuel, animal procurement, storage and transport, taxation and financnial costs have soared.

Graph 3 – Profiile of farm expenditure – Brazil, 1959/2006



Source: IBGE – Censo Agropecuario

Major changes have also been observed in labour relations. Table 1 shows that fifty years later the contingent of occupied personnel in the a partnership relationship and another condition (residents and households), which was almost half the permanent personnel with no family ties to the farmer, has plummeted. This group, which in the past numbered the same as the permanent employees, is less than 10% today.

Table 1: Non-family permanent occupied personnel, Brazil 1960-2006

Categories	1960		2006	
	Abs.	%	Abs.	%
Non-family permanent personnel	**2,801,534**	**100.0**	**1,494,957**	**100.0**
Permanent employees	1,428,950	51.0	1,369,074	91.6
Partner / Partner employee	All	32.7	83,060	5.6
Other	916,039	16.3	42,823	2.9

Source: IBGE - Census of Agriculture

It is worth mentioning that wage-earning became more prevalent due to the drop in other forms of hiring labour, since the number of wage-earners in farming, both permanent and temporary, is lower today than half a century ago. The number of permanent employees calculated in the Census of Agriculture 2006 corresponds to 96% of those in the Census of Agriculture 1960, and only 76% of temporary employees.

Table 2: Number of farms by status of the person in charge, Brazil 1960-2006

Status of person in charge	1960	2006	Difference
Total	**3,337,769**	**5,175,636**	**1,837,867**
Owner	2,234,960	3,745,528	1,510,568
Settler farmer without definitive title deed	...	182,671	...
Leaseholder	327,136	221,587	-105,549
Partner	252,833	138,125	-114,708
Occupant	356,502	405,219	48,717
Administrator	166,236	227,487	61,251
Landless farmer	102	255,019	254,917

Source: IBGE - Census of Agriculture

The total number of farms in the same period increased 55%. And also in the other direction, the number of farms run by leaseholders and partner farmers has dropped, the latter diminishing to almost half of those in 1960 (table 2). The drop in the partnership and in households and residents and the increase in the use of modern technical resources occurred to a greater or lesser degree all over Brazil.

Brazilian agriculture has undergone major structural changes over recent decades, although with little change to the basic features of its constitution. Particularly with regard to the case of land distribution, a more basic structural characteristic of agriculture. In fact, despite the industrialisation of Brazilian agriculture, the pattern of inequality in land distribution has stayed very much the same. Since the 1960s the proportion of the very small and largest farms increases while the proportion of other categories decreases (see table 3), while the high value of the Gini index for land distribution was more or less stable over time, at around 0.85.

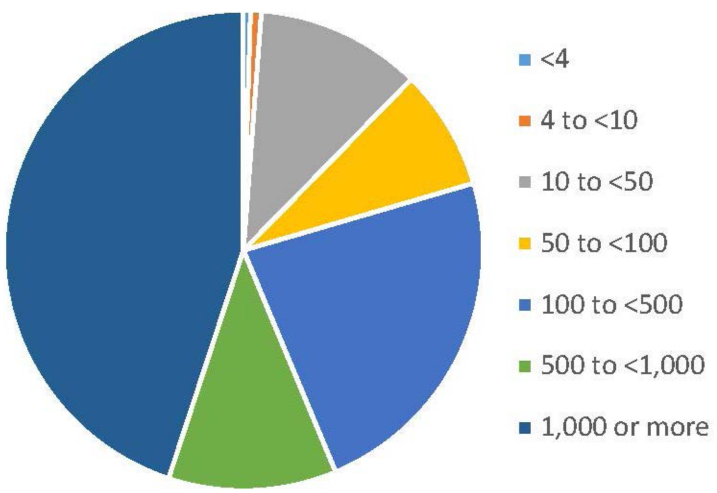
Table 3: Farms by size - Brazil, 1960-2006

Farms	1960	2006	Variation %
Number	3,333,746	4,920,617	47.6
Size (ha)	Distribution (%)		
<2	12.3	21.3	73.3
2 to<5	18.6	16.1	-13.4
5 to <10	14.0	12.9	-7.4
10 to <50	36.6	32.1	-12.1
50 to <100	8.2	7.9	-2.9
100 to <500	8.2	7.5	-8.5
500 to <1,000	1.2	1.1	-10.0
1,000 to <5,000	0.9	0.8	-1.5
5,000 or more	0.1	0.1	4.9
Total	100.0	100.0	…

Source: IBGE - Census of Agriculture
Note: Landless farm holding is not included

Nowadays half the land in Brazil is managed in large farms over 1000 ha in size, and more than three quarters of the land belongs to farms over a 100 ha. The millions of small farms, as say, in the case of Brazil, with less than 10 ha, control a very **marginal proportion** of farm land (Graph 4tra). Moreover, three quarters of the land is managed by non-family farms and over 30% by hired managers.

Graph 4 – Farm land distribution, by size – Brazil, 2006



Source: IBGE – Censo Agropecuario

Alberto Passos Guimarães (1963) in the middle of last century foresaw the occurrence of the following processes: landownership concentration, small-scale landownership fragmentation, substitution of landholding crops for extensive cattle farming and the (slow) introduction of advanced techniques (chemical and mechanical) and of capitalist wage-earning. A situation reflecting the crises of the first half of the 20th century and the capitalist development of the country and Brazilian agriculture, which mean the downfall of the old landownership system and the coming on stage (formation) of the "capitalist property" . Some iconic references in his work are the substitution of the bangüê (traditional sugarmills) by the central industrial plant and the emergence of the new "coffee barons", converting landowners in millowners or "manufacturers", concentrating land and offering better commercial, farming and industrial organisation. The majority that fail to pursue this path become suppliers, sell their land or take refuge in extensive cattefarming. If we assume the proxy suggested by Guimarães according to which the extreme classes of "less than five hectares" and "more than 1000 ha" represent the small-scale farms and large estates respectively, the process he indicated has followed its course.

Guimarães compared "two agricultures: export agriculture based on the large freehold estates, and subsistance farming based on capitalist ownership and on peasant ownership", the former being a retrograde obstacle that must be overcome and the latter holding the keys to development (Guimarães, 1981, p. 208).

The movement of "capitalist transformations" as it was called at that time recalls a parallel with contemporary work that foresaw a "new phase" of Brazilian farming, according to which large-scale productive and technological efficiency is a requirement for the survival of farms: on one hand "a very small group of extremely able farmers" capable of accounting for the entire farm production, including exports and expanding their activities, and on the other "the vast majority of low-income farmers, ... small and medium in size", whose development process will become "redundant" and, therefore, destitute and dependent on a public policy to survive (BUAINAIN et al, 2013, p.114).

It is worth mentioning that in the mid-20th century the partnership-based latifundio was predominant. The absentee landlord farmer would keep the countryside lagging behind and curb development. Although still incipient or restricted to certain regions, it was foresseable that the freehold farmer and director of the modernising enterprise with capitalist relations would change the face of the Brazilian countryside.

Today, the modern freehold farmer predominates. New competitive demands appear to demand absolute liaison with markets and financial and technological capacity. Although embryonic, there are signs of corporate farmer protagonism or agricultural entrepreneur free from land ownership. The share owner is now the minority partner and, in addition to being absentee, is merely a rentier. The landowner, ditto, operates under contract regulations and standards in new partnerships (Bolliger, 2014)

The structural changes in Brazilian agriculture reflect the known industrialising process of agriculture. A phenomenon marked by so-called modernisation of agriculture with emphasis on mechanisation, agrochemicals, genetic improvement and, more recently, microinformation technology, telecommunications, genetic modification and biotechnology. New technologies are now seen to reach remote regions, different farming activities and large and small farms. In this process, primitive farming, characterised by fully integrated systems, has also undergone gradual disintegration of its functions, making way for an intricate supply chain of inputs and services (Rehber, 2000)

Added to this is the striking transformation process of the agrifood sector at a global level at which open markets have been replaced by strongly structured agrifood chains.

It is acknowledged that the combination of these kinds of changes is associated with a trend toward greater professionalism in conducting the different productive segments of agriculture in Brazil. On one hand, the displacement of the former large landowner, holder of large explored areas with low productivity and, on the other, larger numbers of small farmers integrated in market, or through agroindustrial businesses or public policies.

Therefore, today the farming structure can no longer be addressed without reference to agribusiness or, more specifically, the agricultural value chain. This is clearly true for Brazil: some of the biggest agroindustrial enterprises are Brazilian and a large part of the top global corporations operating in the agroindustial chain are present in Brazil. However, as we will see below, it seems to be the same in most countries.

These facts were once linked to the well-known phenomenon of a change in the profile of demand and marketing process of agricultural production verified over the past century when direct selling to the consumer and middlemen and commercial networks lost ground to the agroindustries, cooperatives and more recently to supermarket chains.

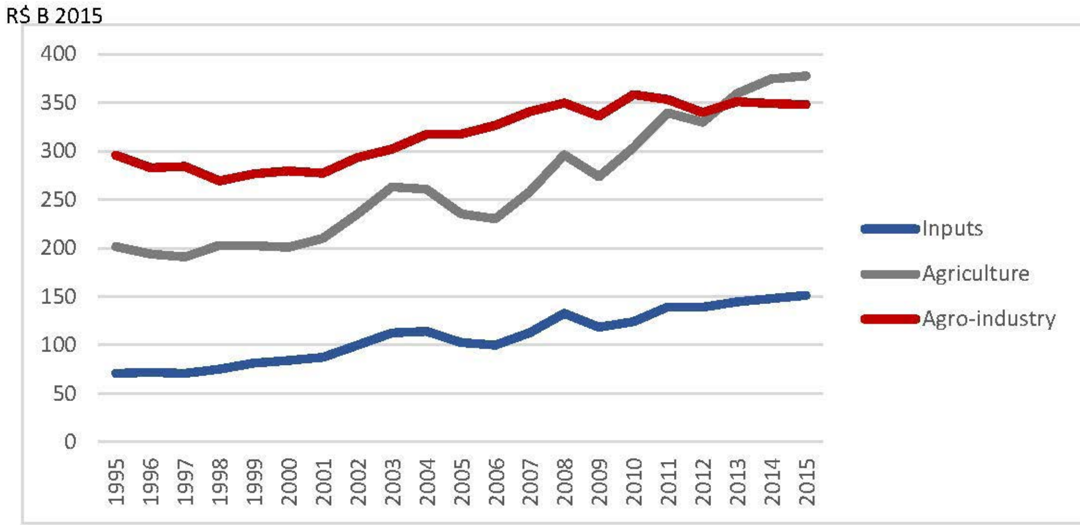
2. Brazilian agricultural value chain data

National Accounts present a set of concepts and data fully in favour of preparing analyses relating to the value chain. There are many studies therefore on the topic based on the national accounts relating to dimensioning and dynamics of the agricultural chains and complexes and on the economic relationships between sectors and sub-sectors of the activity, particularly analysing the effects of backward and forward linkages in the matrix of inter-industrial relationships.

The most commented data by analysts and policy drivers merely concern the relevance of the overall agrifood chain whole. The aim is to highlight the importance of the set of related activities, very often with political motivation and not uncommonly with some exaggeration .

The IBGE, the institute responsible for Brazilian official statistics, has never adopted the task of creating satellite accounts related to the agroindustrial complex. The Advanced Studies Centre in Applied Economics (CEPEA, ESALQ/USP) demonstrates a series of data for the Agribusiness GDP, which goes back to 1995 and is regularly updated, based on national accounts data. Countless studies are being carried out in the country to analyse the relationships and dynamics of the Brazilian agroindustrial complex based on the same data. Their main restriction concerns the level of aggregation provided by the accounts data. Given the nature of the national accounts data, the information is simply too clustered. Efforts have been made to obtain estimates with pieces of interest, such as, for example, the book on the Family Farming GDP (2007), published by the Ministry of Land Development, but which inevitably depend, however, on many assumptions.

Graph 5 – Value added - Agribusiness – Brazil, 1995-2015



Source: USP-CEPEA

On the other hand, a multiplicity of studies on particular agroindustrial chains and/or regional segments of specific chains are undertaken by university centres and economic research institutes. Many of them analyse in detail the relationships and functioning of the links in the chain, collecting their own data. In general, with firm basis on qualitative research, many are quite restricted case studies. Important ones can be found in an Agribusiness Studies Centre named PENSA at the University of São Paulo and others in the Contract Framing Resource Centre maintained by FAO .

Therefore, a complete view of the farming structure now requires the broader perspective of the production chain in which it is incorporated: in actual fact, both services and flows downstream and upstream from agriculture. In the literature on agricultural economy, this view is provided by analysing the agricultural value chain. However, official statistics have yet to follow the same path.

FINANCING THE MODERNIZATION OF AGRICULTURAL STATISTICS: STATISTICAL CAPACITY DEVELOPMENT INITIATIVES AND RESOURCE MOBILIZATION

Session Organizer
C. Duhamel | FAO | Rome | Italy
F. Lawson | African Development Bank | Abidjan | Ivory Coast

ABSTRACT

For many countries it remains a challenge to obtain the funding required for statistical development, particularly for developing countries which face a lack of financial resources for producing the data needed to develop appropriate policies, to target scarce resources, to measure progress, to make effective use of aid and to monitor and evaluate outcomes. The international community has emphasized again the necessity of these improvements and this has been recognized in the Busan Action Plan of Statistics in 2011 where "an increase of resources for statistical systems would entail continued investment to break the vicious cycle of neglect and disuse of statistics". Countries will have to be prepared for greater challenges such as the post 2015 development agenda and address the underlying question of financing the modernization of statistics, particularly in the agricultural sector. As element of the national statistical system, the agricultural statistics sector has been facing a dramatic situation from the beginning of the 1980's with a decline in the quantity and quality of statistical data. In order to respond to this specific issue, the international community has set up a concerted effort to strengthen agricultural statistics which has resulted in particular in the launching of the Global Strategy to improve Agricultural and Rural Statistics, to support countries in strengthening their capacities and helping them to prepare sustainable and long-term plans for the development of the agricultural statistical sector. Additional advocacy efforts and calls for stakeholders will be necessary for ensuring that funding will be made available in a sustainable way, in particular for collecting data, and to collectively identify new funding modalities. The aim of the session is to: i) Highlight success stories of concerted approaches at international level aiming at providing support in the field of statistical capacity building: which value for money? ii) Review the existing mechanisms of integration of agricultural staistics within the overall National Statistical Systems, particularly under the financing point of view : should agricultural statistics be funded independently ? iii) Explore innovative approaches, tools and financial instruments used by the countries, e.g. pooling through basket funds, budgetary aid, mechanisms of dialogue between the government and the donors, SWAP approaches grounded to national development policies: what are the good practices? iv) Address the challenges for countries in terms of financing data collection and meeting international requirements from a financing perspective: who will pay for it and how? The session will welcome thematic papers focusing mainly on these areas.

DOI: 10.1481/icasVII.2016.pl4

ABSTRACT

Today's fast changing landscape of emerging new data sources and digital technologies poses significant challenges to the capacity of national statistical offices and international organisations to modernise agricultural statistics. If we want to develop strategies for producing high quality agricultural and rural statistics that meet users' needs and the increasing demand for evidence-based policy making, we need tomobilise resources, develop new skills and introduce innovative ways to provide training and capacity building. With the more active use of administrative data and new information sources such as big data, building up partnerships outside the statistical community is becoming an increasingly important way to mobilise resources for the successful transformation of agricultural statistics.

The presentation looks at how the European Statistical System is developing its capacity to moderniseagricultural statistics in the supranational context of the EU. The presentationshares results achieved and lessons learned that might be useful for other institutions undergoing similar modernisation programmes

Keywords: agricultural statistics; capacity building; modernisation; European Statistical System

PAPER

1. Introduction

Over the last decade, the shift towards evidence-based policy making in general and output-oriented development policies in particular hasgenerated an ever increasing demand for high quality official statistics across the globe. As a result, national statistical offices (NSOs), other national authorities and regional and international organisations now more than ever need the capacity to provide data. A range of technical assistance and capacity-building initiatives have been launched in various statistical domains, including the agriculture and food sector. A major part of thisworkhas focused on enhancing NSOs' human resources capacity and on developing their technical skills. In agriculture,this related to sampling techniques, planning and conducting agriculturalcensuses and building food supply balance sheets. In addition, the Paris 21 consortium of international development institutions has been assisting countries to develop national statistical development strategies and makeagriculture an integral part of them.

Over the years, the European Commission has supported agricultural statistics byco-financing actions as part ofthe FAO's'Global Strategy to Improve Agricultural and Rural Statistics' (GSARS, 2016) and through the Paris 21 partnership. To mention one example, the EU is supporting capacity building for agricultural statistics through the 'Information for Nutrition Food Security and Resilience for Decision-Making Programme' (INFORMED) (FAO, 2016).The EU is contributing EUR 20 million, or 59 %, for the project duration until June 2019. INFORMED supports decision-making by improving the availability of regular, timely and early warning information. It also produces evidence-based analysis on food security, nutrition and resilience. Three outcomes are expected:

- better and more integrated data systems for long- and short-term trend analysis of food crisis situations;
- strengthening of the Integrated Food Security Phase Classification (IPC) process largely applied at country level;
- improved resilience programming byapplying a common methodology to measure resilience.

Eurostat has a multi-faceted role in international cooperation over statistics. Firstly, it represents the Commission in the United Nations Statistical Commission (UNSC), in bilateral relationships with international financial institutions such as the IMF, the World Bank and regional development bank and on the OECD Statistics Committee (CSTAT). Secondly, Eurostat cooperates with these international statistical agencies to:

- set up international standards for statistics;
- improve the comparability of statistical information;
- improve the coordination of international statistics-related activities;
- support financially and technically national statistical systems in building capacity to deliver data on agriculture and food.

This work involves on-the job and formal training in country-level field projects, study tours, international, regional and national training seminars and workshops, and preparing and disseminating methodological and technical guidelines.

Despite the efforts and investment in statistical capacity building, we are having to cope withnew data demands. These are triggered by the latest trends in agriculture and rural developmentand the increasingly important role of sustainable management of natural resources in response torising concerns about climate change, biodiversity loss and water and soil quality. The analysis of the available data for monitoring and evaluating the recently adopted UN Sustainable Development Goals (SDG) identified a number of data gaps linked to the availability of geo-referenced and regional data and challenged statistical capacities across countries. The increasing global interconnectedness of agricultural production structures, prices, yields and supply chains callsfor detailed data in this area. This will make it possible to carry outrapid crisis responses and have more effective policyin general. At the same time, the astonishing developments in information and communication technologies and the instantaneous availability of information are openingup new opportunities to produce statistics faster and cheaper and to improve theirquality. Accessing the emerging new data sources requires new capacities. Statisticians'classical role in designing and carrying outsurveys and turning the results into statistics isno longer sufficient. Capacitiesto adapt to rapid change, acquire knowledge and innovate are becoming the most valuable assets for any statistical office, whether in developing ordeveloped countries. As stated in the Report *A World that counts: mobilizing the data revolution for sustainabledevelopment* prepared by the Independent Advisory Expert Group (IAEG, 2014) established by the UN Secretary General on data revolution, '*...improving data is a development agenda in its own right, and can improve the targeting of existing resources and spur new economic opportunities. Existing gaps can only be overcome through new investments and the strengthening of capacities.*'.In other words, modernising statistical production now depends on one'scapacity todo so, making this latter issuea universal problem.So far, discussions about statistical capacity building at various international fora have focused largely on less developed countries. However,nowadays the challenges and opportunities triggered by the data revolution are faced byall NSOs and systems, including the most developed ones, as well as by international organisations. In the age of data deluge and digital transformation, capacity building has expandedto include thecapacity to modernisestatistical production. Changing user needs mean that statisticians need to have an open and broadapproach in order to respond to the requestsmade to them. Continuing the traditional approach by creating additional surveys or by adapting existing surveys is not a feasible option in times of resource constraints at all levels. Instead, smart ways of producing statistics are needed. This paper looks specifically at agricultural statistics and how the European Statistical System is developing its capacity to modernisestatistics in this field in the supranational context of the EU. It shares results achieved and lessons learned that might be useful for others undergoing similar modernisation programmes.

2. New capacity for high quality agricultural and rural statistics in the EU:results achieved and lessons learned

Thispaper is based on the idea that building capacity to provide high quality statistics goes beyond technical skills. Building capacity involves establishing a robust and sustainable institutional set-up and a legal framework that requires interaction with many other national authorities. Building sustainable statistical capacity is a long process that requires more than just money. Even in the area of mobilising financial resources, new business models of partnership and financial instruments could be explored. The current context of digital transformation and data deluge even demands this.To build and provide the technical assistance needed to boost skills, we needto beinnovative and to embracethe opportunities offered by information technology. Finally,we also need leadership and high-level political support and national ownership ofthe capacity-building processif we want to modernise agricultural statistics and strengthen our capacity to stay relevant to evolving user needs.

The EU context: a common agricultural policy

Since the early 1950s statistics on agriculture in the European Union has developed with the aim of supporting the policy design, implementation, monitoring and evaluation of the common agricultural policy (CAP) and ofenvironmental and rural development policies. In response to the evolving policy needs and increasing role of evidence-based policy making in the EU, agriculture statistics has developed in a rather consistent manner among the EU Member States over the past 60 years. Over 77 % of the EU's territory is classified as rural (47 % is farm land and 30 % forest) and is home to around half its population (farming communities and other residents). Agriculture accounts for almost 40 % of the EU budget and is supported almost exclusively at the European level, unlike most other sectors, which are governed by national policies. With an annual budget of around EUR 59 billion,the CAP aims to providea stable, sustainably produced supply of safe food at affordable prices for consumers, while also ensuring a decent standard of living for 22 million farmers and agricultural workers in the EU. Agriculture also plays an increasingly important role in the sustainable management of natural resources against the backdrop ofrising concerns about climate change, biodiversity loss andwater and soil quality.

The CAP's focus has moved away from structural measures to modernise farmsand guaranteed prices to encouragefood production towards environmental protection, the development of rural areas and responding to consumers' concerns. This has led to new data needs and new phenomena that need to be measured and described. For example, cereals have started to be used for energy production and not for food and feed only. Greenhouse gas emissions from agriculture also are a telling example of the clear link between agriculture and climate-related policies.

The value proposition of agricultural statistics — Link betweenstatistics andthe systems for monitoring and evaluation of policies

The active use of official statistics in the design, monitoring and evaluation of the CAP and rural development policy over the years has been a strong driving force inthe evolution of statistics and the strengtheningof the capacity of both Eurostat and NSOs. Here comes the first useful lesson from EU experience. A stronger link between country capacity-building programmes and systems for monitoring and evaluating agricultural and rural development policies could help to break the vicious circle betweenunder-resourced NSOs, low-quality statisticsofno use and demand for official statistics that exists in a number of developing countries. This could also facilitate the involvementof potential resource partners interested in investing in agricultural statistics.

Communicating the value proposition of agricultural statistics to users, in particular to national governments and international donors, has played an essential role in mobilising resources for building sustainable statistical capacity. The starting point in theprocess is the mechanism for permanent review of data needs and user engagement in settingpriorities. In the EU context, a crucial role has been played by the European Statistical Advisory Committee and regular hearings with the European Commission departmentsthat implement agricultural, environmental and rural development policies. On many occasions, these stakeholders have served as promoters and supporters ofthe need for investment toextend capacity building for measuring new phenomena and modernising statistical production.

A holistic approach and integrated framework for agricultural statistics

Starting from user needs, it has been crucial to follow a holistic approach and plan an integrated framework for agricultural statistics that canserve multiple policy purposes.In 2014, Eurostat initiated a review of the current state of the European agricultural statistical system and a discussion with Member States on the system's future.

In line with the Global Strategy to improve agricultural and rural statistics, the plannedEuropean2020 integrated framework of agricultural statistics involves a combination of the Agricultural Census and intercenialcore, module and adhoc sample data collections (surveys).Following the approach recommended by the FAO's World Programme for the Census of Agriculture 2010 (FAO 2005), the Agricultural Census will continue to be a core data collection instrument that provides statistics on farms at the lowest geographical level. An essential novelty in the framework are the flexible adhoc surveys that will focus on special topics not traditionally part of the EASS, i.e. surveys which aim to cover variables that fulfil new and emerging data needs. Their exact content will be determined later, prior to their implementation.They are not planned to be carried out at fixed intervals, but may be repeated when needed[1].

The integrated framework of agricultural statistics has made it easier to present them to users and to wintheir support, including financial support.It has also helpedwithbetter planning of diminishing budget resources available to carry outthe planneddata collections. Similar approaches could be useful for developing countries because they help to ensureinterest by national and international resource partners in investing in statistical capacity building. A targeted integrated framework that at the same time includes opportunities to add some ad hoc data modules could attract and guide potential donors and investors who would like to receive statistical outputs and services after initial investment in building statistical infrastructure and capacity.

Embrace opportunities provided by new technologies and multiple data sources

[1] A seguito della istituzione del nuovo comune di Valsamoggia (legge regionale 7 febbraio 2013, n. 1, in vigore dal 1° gennaio 2014), in provincia di Bologna, avvenuta mediante fusione di cinque comuni, appartenenti a zone altimetriche diverse, per il criterio della prevalenza della superficie, la percentuale di territorio collinare complessivo passa dal 41,64 al 41,65 per cento, mentre il territorio di pianura dal 23,17 al 23,16 per cento.

While agricultural statistics in the EU havebeen evolving, a set of administrative registers have been set up in individual countries and at EU level with the primary objective of enablingimplementation and monitoring of the CAP. Technological advances lead to ever more data: aerial images are nowadays available without cost, whilesmart farming creates another data source. These new sources have created a treasure trove of information that is worth exploiting for the benefit of official statistics, topotentiallyreduce the burden on respondents andto reducethe costs of statistical production.In order to cope with the challenges, a number of steps have been taken in the European Statistical System (ESS).Some useful lessons could be derived from that experience as well. In 2014, the headsofthe national statistical institutes and Eurostat adopted the ESS Vision 2020 (ESS, 2014). The ESS Vision 2020 aims to increase efficiency, reduce response burden, cut the cost of compiling statistics and respond better to user needs byexploiting new and emerging data sources, innovative data collection methods and digital technologies. The basic elements of the ESS Vision 2020 were implemented in concrete modernisation programmes in the core statistical domains.

Wider use of administrative sources has occupied a central place in the modernising of agricultural and rural statistics in the EU. In the past, administrative data weremostlyused for sampling frame construction or as auxiliary information in estimation processes and in analysing and validating the data from surveys. However, recently administrative data have been more and more used as a direct data source. The motivation is two-fold: to reduce costs and to decrease theresponse burden. The results indicate that integrating administrative registers with censuses and sample surveys is a cost-effective way of producing statistics while reducing the burden on respondents. The quality dimension 'accuracy' is a key issue for further development to improve quality when integrating registers and surveys in farm structure statistics.

Sharing and promoting best practices

Pilot projects to setup and improve the use of administrative data in producing agricultural statistics were launched in 14 countries between 2013 and 2015, with financial support fromEurostat.Results were presented at a thematic seminar with directors of agricultural statistics in 2016 in Belgrade. Poland shared itsexperience on creating an agricultural holdings register using administrative data sources, whileGreece shared its experience on upgrading the quality and timeliness of agricultural statistical survey with the farm register. Serbia explained the integration of administrative data for crop production data collection and Slovenia focused on using administrative data in the context of the preparation/provision of annual crop statistics. Sweden showed how information from control bodies is incorporated in statistics on organic farming. During the animal statistics working group meeting in February 2016, Hungary shared itsexperience of using administrative data in animal production statistics and Poland presented the first insights fromits investigation ofdata validation in animal production statistics.

Strong legal basis that ensures the use of administrative data sources

While exchange of best practices and methodological solutions in using administrative data for statistical purposes has proven to be a driving force for innovation and strengthening statistical capacity in the EU, it is equally important to have a strong legal basis that ensures access to these sources by NSOs. At EU level, the access to administrative data for statistical purposes in general is provided for by the Statistical Law[2].

Article 17a of the Statistical Law lays down the right of the national statistical institutes and Eurostat to access and use, promptly and free of charge, all administrative records and to integrate them with statistics, to the extent necessary for the development, production and dissemination of European statistics. More specifically, the current EU Regulation for the Farm Structure Surveys[3] in the EU Member States includes an article explicitly ensuring access to three administrative data sources available in EU Member States: the Integrated Administration and Control System (IACS), the System for the Identification and Registration of Bovine Animals and the Organic Farming Register.

Partnership with owners of the administrative registers

While the legal base foraccessing administrative data is laid down by law, the practical implementation is not immediately given. In order to be useful for statistics production, data from other sources need to be available in a usable form and in a timely manner. Experience in several EU Member States has shown that building a trusting and process-oriented relationship with the owner of the administrative register is essential to success. Even if the holder of the register is legally obliged to give statisticians access to the information, the statisticians need to invest in explaining the 'user needs of the statistics' and to influence the content of the register so that it isas useful as possible for statistics production. This cooperation needs well-defined governance and can by no means be left to the technical level or individualgoodwill.

Increasing use of administrative data sources

[2] Article 17a of Regulation (EC) No 223/2009 as amended by Regulation (EU) 2015/759.

[3] Regulation (EC) No 1166/2008 of the European Parliament and of the Council of 19 November 2008.

The EU Member States are more and more consideringthe use of administrative sources to reduce expenditure ondata collection and significantly decrease the response burden. Several lessons could be derived from the experience so far that might be useful in building statistical capacity in the rest of the world:

- The first step in the process should be the mapping of the existing information (data sources) followed by the elimination of sources which could not provide the level of information requested.
- Statistical data (unit of observation, coverage, definition of characteristics, classifications, periodicity for data collection, reference period etc.) are mainly regulated by statistical legislation or clearly defined in methodologies for data collection. Therefore, the difference for any variable will imply a reduction in data quality.
- The use of administrative data for statistical purposes depends very much on cooperation and communication between the statistical office (or the responsible body for the agricultural data collection and dissemination) and the owner of the administrative data. It is important that the authorities responsible for agricultural statistical data collection are formally and regularly involved in preparingadministrative data.
- All the available options should be taken into consideration, including the possibility to adapt statistical collection methods or slightly adapt administrative data collection channels.
- The use of a common identifier that would make it possible tolink observed units in the various statistical data collections with the administrative register(s) is one of the key points of the whole process, together with the management of metadata (storage, maintenance, transmission procedures, etc.).
- Generally, the transition from statistical survey data collection to the use of administrative data takes time, needs resources and usually cannot be completelyimplemented from one year to another.

Institutional and financial capacity to deal with new data sources

Private data sources need to be identified, while their suitability and potential for sustainability need to be evaluated. It would also be worthwhileto analyse whether any obligation exists to report such data to an administrative body in the Member State, as this could provide for access without additional cost to the statistical office.

In view of the scarce resources available, EU Member States and Eurostat combine resources through cooperation in modernisation programmes via networks and ESSnet projects[4] to exploit the potential of new data sources. Building partnerships,firstly with other countries inside the ESS and secondly with actors outside the statistical community, with private data owners and with the owners of administrative data, is becoming an increasingly important way tomobilise resources for thesuccessful transformation of agricultural statistics. Statisticians will no longer be self-sufficient in designing and carrying out data collection and in producing statistics. The traditional role of statisticians will need to be supplemented by the capacity to work with others in a partnership.

New quality framework for the use of new data sources and for the combination of data sources

Although the advantages of administrative data use are quite evident, it is also necessary to consider the possible disadvantages and shortcomings of such a practice. Although it is often believed that administrative data are free of errors, this is not always the reality. Administrative authorities also use some kind of collection processes, which inevitably produce different kinds of errors in the collected data. Besides these measurement errors, which are due to the 'hidden' collection processes, some other quality issues mayalso exist. Theseare specific to the administrative data and should be studied in as a detailed manner as possible before deciding to includesuchdata in the production process of official statistics. Data matching and data linking is usually easily feasible if unique identifies are used for the observation units. In the agricultural sector, this might for example be farms, people or land parcels. Using a unique identifier in different data sources will generally lead to higher quality data than if no such identifier is available. This is just one example that illustrates the need for a new quality framework.

3. Conclusion and way forward

Capacity building goes beyond the traditional approach of training and resource allocation. The lessons drawn from the experiences gathered in the EU and summarised in this paper couldbe of relevance for any statistical institute that is modernising agricultural statistics in today's fast changing landscape of emerging new data sources and digital technologies. While we have long known a lot about the pros and cons of some of these technologies in agricultural statistics, promoting the better use and improving the quality of administrative data for statistical purposes appears to be the most significant innovation for improving the existing statistical systems.

[4] 'ESSnet project'means'A network of several ESS organisations, aimed at providing results that will be beneficial to the whole ESS'.

PL04

Building partnerships together in the ESS with actors outside the statistical community, including with private data owners, is becoming an increasingly important way to mobilise resources for the successful transformation of agricultural statistics. In the age of data deluge and digital transformation, capacity building is expandingto include the capacity tomodernise statistical production. If we want to develop strategies for producing high quality agricultural and rural statistics that meet users' needs and the increasing demand for evidence-based policy making, we need tomobilise resources, develop new skills and introduce innovative ways to provide training and capacity building.

Agricultural statistics in the era of Sustainable Development Goals (SDG'S) [1]

M. V. Belkindas Open Data Watch | Washington, DC | USA

DOI: 10.1481/icasVII.2016.pl4b

ABSTRACT

This paper deals with measurement of SGD's related to agriculture. It shows the variety of SGD indicators which are or can be related to agriculture and rural development. It briefly looks at a set of National Strategies for Development of Statistics (NSDS) to see how well improvement in agricultural statistics are covered in the documents. It also analyses how open are data on agriculture as measured by the Open Data Inventory (ODIN) conducted by Open Data Watch (ODW). Lastly it looks at the issues of financing statistics in the era of SDG's and the ongoing data revolution.

Keywords: Data OpennessFinancing Statistics

PAPER

1. Indicators to Measure SDG's

The era of Millennium Development Goals ended in 2015 and the World embraced new targets which will guide policy makers over the next 15 years. With the creation of the SDG's and the accompanying data revolution statistics havebecome even more important. While the achievement of the SDG's will make the world a better place to live, measureable indicators are imperative to know whether or not such goals are achieved. In this paper we look at the SDG's and indicators which relate to agriculture, rural development and food security. Among the 17 SDGs, there are 11 goals, 45 targets, and 58 indicators relating to agriculture. Goal 2 to End Hunger, Achieve Food Security, Improved Food Nutrition, and Promote Sustainable Agriculture appears to be the main goal covering agriculture. It contains targets for increasing agricultural productivity, diversity, and investment. However, there are additional goals that include targets and indicators that measure agriculture or other elements that impact agriculture. Goal 12 on Responsible Consumption and Production, Goal 14 on Life Below Water, and Goal 15 on Life on Land include targets directly related to agriculture, focusing on food waste, fisheries, and use of genetic resources. These goals also include targets with an indirect relationship to agriculture, measuring nutrition, pollution, consumption of natural resources, marine conservation, and protecting terrestrial ecosystems. Goal 6 on Clean Water and Sanitation, Goal 9 on Industry, Innovation, and Infrastructure and Goal 13 on Climate Action also include such targets, focusing on water management, resilient infrastructure, and climate change resilience. In total, within Goals 2, 12, 14, and 15 there are 11 targets with 15 indicators directly related to agriculture and within Goals 2, 6, 9, and 12-15, there are 34 targets with 43 indicators indirectly related to agriculture.

Goal 2 (End hunger, achieve food security and improved nutrition and promote sustainable agriculture) includes five targets with nine relevant indicators that directly relate to agriculture.

Indirectly, Goal 2 includes three targets with five indicators. These indirect targets are important to agriculture as they serve as proxies for the effects of successful agricultural production. For example, although Goal 6 (Ensure access to water and sanitation for all) does not relate directly to agriculture, water resources are a crucial component of agricultural production. Goal 6 includes six targets with nine relevant indicators. Likewise,while Goal 9 (Build resilient infrastructure, promote sustainable industrialization and foster innovation) does not directly track agriculture, resilient infrastructure and control of CO2 emissions are important to agricultural production. Goal 9 includes two targets with three relevant indicators. Goal 12 (Ensure sustainable consumption and production patterns) includes one target and one indicator directly related to agricultural production. Indirectly, Goal 12 has two targets and three indicators on managing natural resources and pollution as proper management of natural resources and reduction of pollution both have significant impacts on agriculture. Although Goal 13 (Take urgent action to combat climate change and its impacts) includes targets and indicators that do not directly measure agriculture, efforts to mitigate climate change and increase resilience have a strong

[1] This paper benefited from inputs of ODW staff.

impact on agriculture as well. Goal 13 has four targets and four relevant indicators that relate to climate change mitigation and resilience. Goal 14 (Conserve and sustainably use the oceans, seas and marine resources) includes four targets and their four indicators directly related to agriculture in terms of fishing. Indirectly, Goal 14 has six targets and six indicators with impacts on agriculture related to fishing.

Indirectly, Goal 14 has six targets and six indicators with impacts on agriculture related to fishing. Marine conservation efforts are crucial to sustainable fishing activities. Goal 15 (Sustainably manage forests, combat desertification, halt and reverse land degradation, halt biodiversity loss) includes one target with a direct relationship to agriculture. This target focuses on fair and equitable sharing of the benefits of genetic resources in relation to plants and fauna.

As displayed by this list above, many of the Goals and measurable indicators are related to agricultural statistics.

2. Coverage of Agricultural Statistics in NSDS

Recently ODWconducted an assessment on how well National Strategies for Development of Statistics (NSDSs) adhere to guidelines from the Partnership in Statistics for Development in the 21st Century (PARIS21) where importance of sectoral statistics is prominent. As part of this project, ODW gathered 23 NSDSs of 20 countries and assessed the degree to which the NSDSs incorporate agricultural statistics. The results vary. Of the 23 assessments, fewer than ten NSDSs thoroughly detailed agricultural statisticsas a strategic task within its sectoral statistics. For example, Botswana's NSDS for 2015-2020 provided a subsection on agricultural statistics, consisting of current challenges, objectives, and priority initiatives as well as its total budget to address these challenges, objectives and initiatives. Additionally, Lao PDR's NSDS provides a working program on agricultural statistics within its objectives of increasing the development of sectoral statistics.Over ten NSDSs provided some references to agricultural statistics. For example, Benin's NSDS for 2014-2016 has a subsection on the current state of agricultural statistics, rather than a subsection on strategies for enhancing agricultural statistics. Furthermore, Macedonia's NSDSs, consisting of three publications for years 2014-2016, 2015-2017, and 2016-2018, do not address agricultural statistics as a detailed strategic task, but rather, elements of agricultural statistics are highlighted as an already-accomplished task.For other countries, the presence of agricultural statistics remains absent. For example, the NSDSs of the Dominican Republic (2014-2017), New Zealand (2010-2020), and Palestine (2014-2018) do not incorporate agricultural statistics. This brief assessment demonstrates that the coverage of agricultural statistics is uneven in the NSDSs. With the increasing demand for data on agriculture and rural development as per SDG indicators the future NSDSs will have to demonstrate actions for improvement in this sector more prominently.

3. Agricultural Statistics in ODIN

It is not only important to plan for improvement of statistics and to collect and process data but to publish data as open as possible. We would like to demonstrate how agricultural data are being open in countries around the world. ODIN is an assessment conducted by ODW of the coverage and openness of data provided on the websites maintained by national statistical offices (NSOs). In 2015, ODIN assessed the coverage and openness of official statistics in 125 mostly low- and middle-income countries across 20 statistical categories, two of which relate directly to agricultural statistics: Land Use and Resource Use.Both of these categories were assessed on five elements of coverage and five elements of openness. Each category is made up of a set of indicators. The indicator that comprises the category Land Use is: land area, and the indicators within the category Resource Use are: fishery harvests, forest coverage and deforestation, water supply and use, and major mining activities. The overall ODIN score for each category is an indicator of how complete and open an NSO's data offerings are.

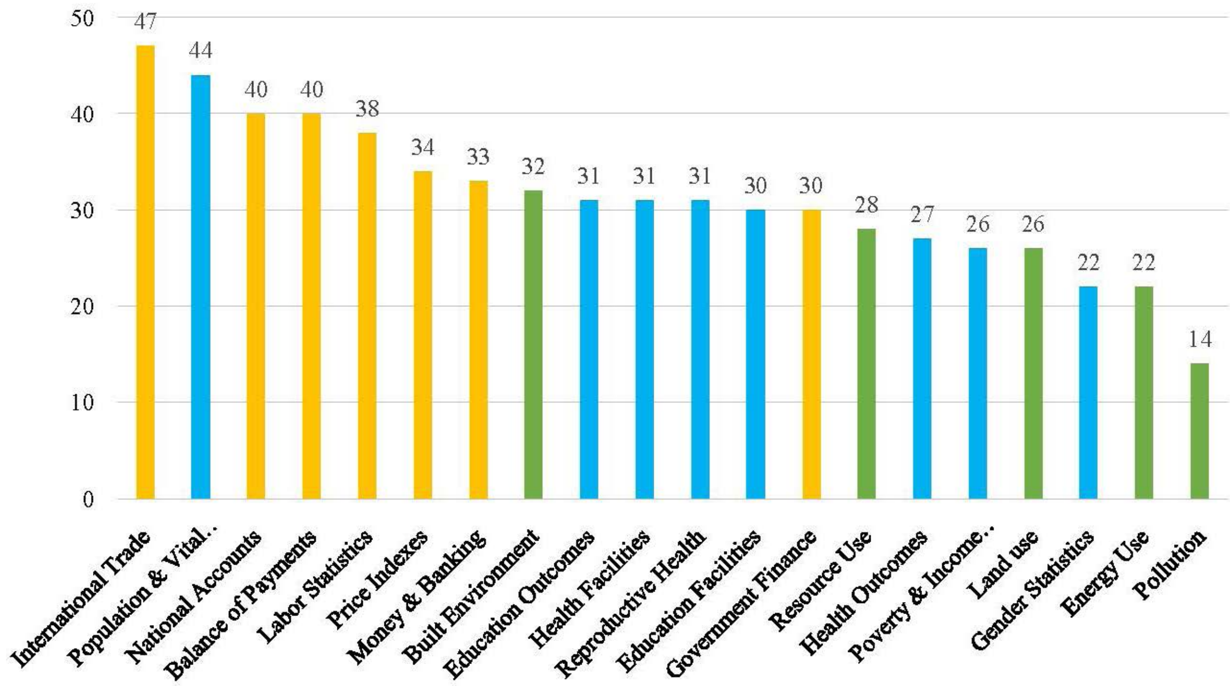
The following is a summary of the global and regional trends in agricultural statistics that emerged from ODIN 2015, as well as two unique examples that illustrate different scenarios on each side of the spectrum.The average score for the 125 countries in the category Land Use is 26 percent and the average score for the category Resource Use is slightly higher at 28 percent (Table 1). In general, ODIN assessments found that environmental categories (which include Land Use and Resource Use) score among the lowest compared to economic and social data categories.

In addition, openness subscores for the categories Land Use and Resource Use tend to be lower than other categories with median scores of 10 and 20 percent. However, this trend is less specific to agricultural data as no data category received a median openness score upwards of 30 percent.

PL04

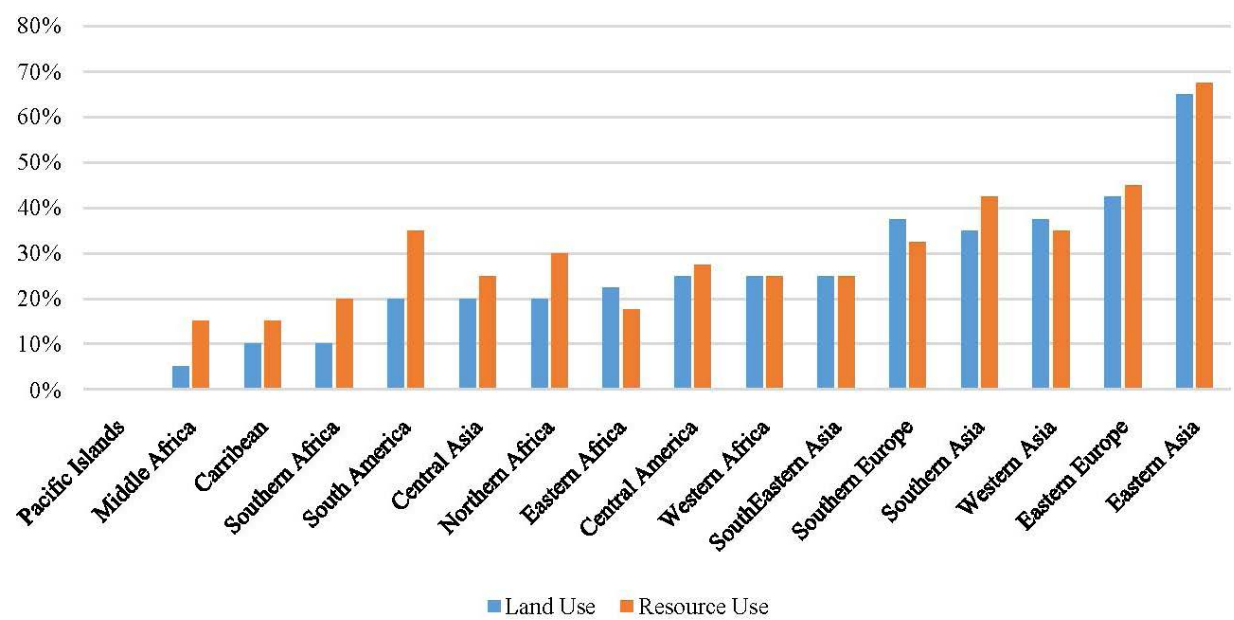
Across the 16 regions which ODIN spans, there is great disparity between ODIN scores within the categories Land Use and Resource Use. Looking at median scores between regions, the Pacific Islands received a median score of 0 percent across both categories. On the other end of the spectrum is Eastern Asia which scored 65 percent in Land Use and 68 percent in Resource Use (Table 2).

Table 1 - Average ODIN Scores by Data Category



Despite the great score variations between regions, the overall trend shows that the coverage and openness of agricultural data is often neglected. Thirteen of the 15 regions did not score over 40 percent in either agricultural data category and eight of those countries did not score over 25 percent in either category. The poorest performing regions in agricultural data include: The Pacific Islands, the Caribbean, all regions of Africa except Northern Africa, and Central and SouthEastern Asia. The highest performing regions include: Eastern Asia and Eastern Europe. Vietnam, showcases how agricultural statistics can be prioritized in a country's national statistical system. Vietnam is the only country included in ODIN 2015 assessments where the agricultural categories Land Use and Resource Use scored the highest out of all social, economic, and environmental categories. In the category Land Use, Vietnam scored 80 percent and in Resource Use they

Table 2 - Median ODIN Scores for Agricultural Data Categories by Region



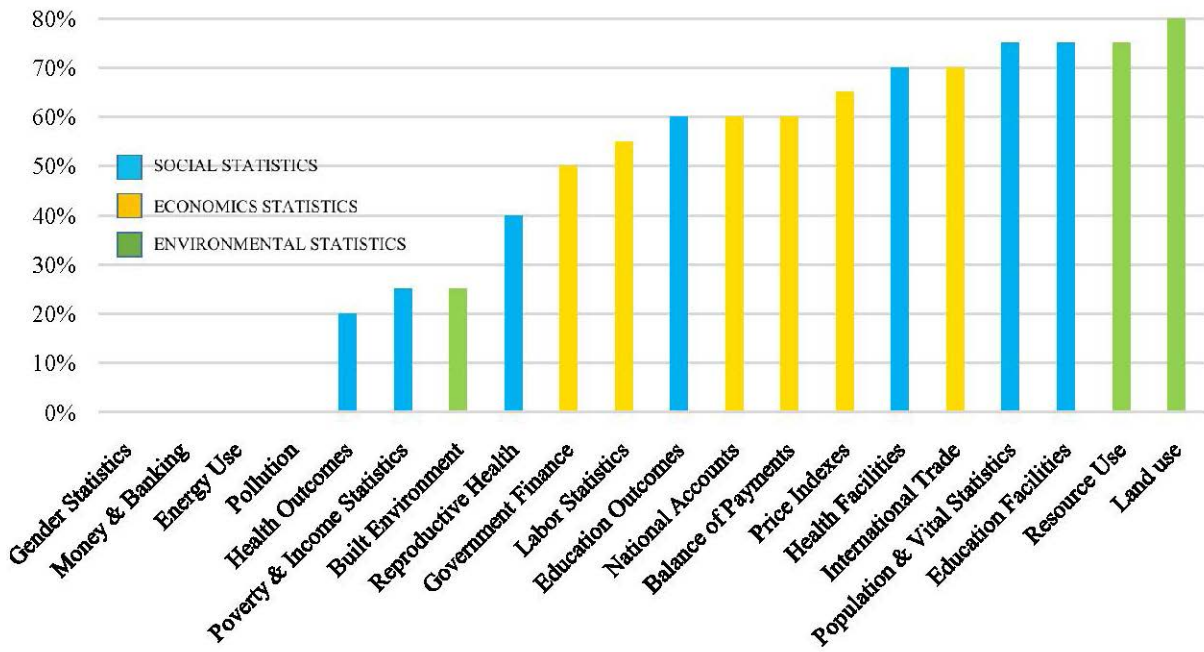
PL04

received a score of 75 percent (Table 3).

The country's national statistical office, General Statistics Office of Vietnam, hosts an interactive data portal in which users can select a number of agricultural indicators under the categories "Administrative Unit, Land and Climate" and "Agriculture, Forestry and Fishery" to download, often displaying data over 10 years old and at multiple administration levels.

Though the country scores highly in two of the lowest scoring categories across all countries, their overall ODIN rank is 15th place, partly because data in four out of 20 data categories is not made

Table 3 - ODIN Scores for All Data Categories for Vietnam



available. Nonetheless the country is an excellent case of how agricultural statistics can and should be made available to users.

According to ODIN assessments, agricultural and other environmental data are currently a low priority in many national statistics systems across all regions and particularly in comparison with social and economic data. While certain countries provide exceptions such as in Eastern Asia (China and Mongolia) and Vietnam, there is still room for improvements, especially in regards to the openness of such data.

4. Financing Measurement of SDG's

In the Marrakesh Action Plan in 2004 the international community costed out six actions needed to measure the achievement of MDG's. A similar exercise was done recently to see how much measurement of SDG's will require additional resources (SDSN,2015). The "Data for Development: A Needs Assessment for SDG Monitoring and Statistical Capacity Development" looked through the sources of data needed to cover the SDG's which includes census data, household surveys, agricultural surveys, administrative data, civil registration and vital statistics, economic statistics, including laborforce and establishment surveys, and trade statistics, geospatial data and other environmental data. The annual needs estimate for 77 IDA countries are between 902 and 941 million USD. The report compares the need assessment with the data provided by Paris21 (PRESS 2013) and other sources and come up with the annual gap in official development assistance (ODA) between 100 and 200 million USD. In 2016 two new reports, The State of Sustainable Development Data Funding (SDDF) and

PARIS21's Partner Report on Support to Statistics (PRESS 2016), review the financing of statistics in developing countries. These reports provide valuable information on the status of development data funding and propose concrete actions to increase and sustain funding for measuring the SDGs. They show that the financing needs for statistics are far greater than currently mobilized funding. According to the SDDF report, the total estimated annual costs for producing SDG data is $2.8 billion and $3.0 billion while the total estimated annual aid to support the production of SDG indicators is $635 to $685 million. This total cost is for 77 IDA-eligible and 67 IRBD countries. Based on current funding levels for statistics and data, an annual increase in aid of $350 to $400 million will be needed to support the production of SDG indicators.
An inventory of instruments used to finance statistics (ODW, 2016) looks at the ecosystem of aid for statistics. The study looks at the financing instruments such as loans, trust funds, technical

assistance provided financed with trust funds and other relevant instruments. The 2016 report contains expanded coverage from the 2015 report to include of multilateral development banks, intergovernmental organizations, bilateral donors, and private foundations. The major instruments used to finance agricultural statistics in this report are the Global Trust Fund for the Global Strategy to Improve Agricultural and Rural Statistics (GAO) managed by the Food and Agriculture Organization of the United Nations, a similar trust fund for Africa managed by African Development Bank, Living Standard Measurement Program managed by the World Bank, and Global Open Data Agriculture and Nutrition. The estimated annual value for agricultural statistics reported by participants in the 2016 survey was approximately $32.5 million USD. Of course the support for agricultural statistics is not fully captured by these trust funds and deeper analysis is needed as to come up with more precise estimates. The fact that the ODA gap to support statistics is quite sizable and the agricultural statistics cover many SGD indicators calls for a sizable increase in financing of agricultural statistics.

THEMATIC SET

INDICATORS OF RURAL DEVELOPMENT

A01

Session Organizer
F. Sotte | Università Politecnica delle Marche | Ancona | Italy

ABSTRACT

The first assumption with rurality measures is that the concept is not univocally determined. Rurality evolves over time and takes different features in space. As a consequence it is difficult, ifnot impossible, to find a synthetic solution for rural development statistics, suitable for all times and latitudes. The traditional indicators based on the weight of agriculture (measured in some way: rate of employment, output, etc.) or even with demographic density (as the one proposed by OECD in the Nineties and subsequently adopted by the EU and others) need to be integrated with other measures useful to help in analyzing the potential development and convergence. Two are the relevant directions for this integrations. The first takes into account and adapt to rural areas the measures of well-being. The second considers the peripherality: rural territories have different opportunities in terms of cohesion and convergence in relation to their localization close or far from urban areas and the physical and virtual connection opportunities. The aim of the session is to explore how the diversity of rural areas can be measured in the different geographical and historical contexts.

Possibilities to improve rural development statistics in support of the sustainable development goals in Mongolia

D. Enkhzaya | National Statistics Office | Ulaanbaatar | Mongolia
E. Erdenesan | National Statistics Office | Ulaanbaatar | Mongolia

DOI: 10.1481/icasVII.2016.a01

ABSTRACT

Since Sustainable Development Goals (SDG) post-2015 agenda that will shape the next 15 yearsof world development has been commenced, it is important to propose possible new ideas,specifically in agriculture and rural development. As of being one of the countries where SDGs willbe implemented, Mongolia is in favour of supporting the SDGs and its further activities due to highexpectations of results from SDGs.Until recently, Mongolia has been recognized as agricultural based country, heavy dependence on livestock husbandry. Even though, share of agriculture sector has been diminishing in overall economy as rise in share of mining sector and service industry for last decade, contribution of agricultural sector on livelihood of population is remaining high.

Mongolia has unique agricultural practice as form of agricultural holding, which is mostly a single household. As of 2014, around 1 million people are living in rural area out of total population of 3 million, which is one-third of the total population. The livelihoods of these 1 million people in rural area are directly and indirectly depending on the agriculture and livestock. In that rural population, 0.3 million herders livelihood source is primarily livestock husbandry. The poverty is the one of the primary focus of SDGs as well as for Mongolia. About 20 percentof population is living under some degree of poverty and poverty levels for urban and rural areas are 18.8 per centand 26.4 percent respectively. Therefore, it could be evidently said that agriculture has great importance for reducing poverty. Promoting well-being and achieving SDGs would directly support livelihood of rural population of Mongolia. In order to do so, first thing to be done is identifying and measuring necessary indicators of agriculture. Main focus of this paper is to identify the measures of well-being of rural development statistics rather than localization opportunity measures and propose possible ways to improve well-being indicators of rural statistics that can provide possibility for tracking performance of the SDGs. Firstly, comparative analysis of SDGs as well as national statistics of Mongolia will be conducted broadly. The result from this section will provide information on capacity and coverage of the national statistics for measuring SDGs performance. Secondly, based on comparative analysis, paper will propose possible indicators for rural development statistics in several different pillars to be included in national statistics. Some indicators could be already included as a part of national statistics (rural poverty, income, expenditure and some rural well-being indicators),some indicators could require only segregation between rural and urban, and some could be totally new. Finally, possible cost-effective ways to produce proposed indicators of rural statistics for Mongolia will be produced.

Keywords: Sustainable Development Goals,urban areas, rural areas, rural development statistics, agricultural sector, poverty, national statistics,comparative analysis of SDG, possible indicators, cost-effective ways, sustainable income growth, environment and natural resource

PAPER

1. Introduction

SDG post-2015 agenda was an outcome of deliberations by the global society, through the United Nations, to try and find ways of addressing socio-economic and environmental challenges following the expiry of the Millennium Development Goals (Sovacool & Drupady, 2016). The global society realized that in the fight to eliminate poverty and improve living standards, it was important to ensure that there is sustainability in the economic activities. Scientists have raised concern over the rising global temperatures and a change in climate due to massive pollution. As such, the global society is trying to find ways of achieving development that is sustainable. Mongolia is one of the nations that have strongly supported the post 2015 SDG as a way of improving its economy without jeopardizing the ability of the future generation to meet their needs. For a long time, Mongolians have heavily relied on agriculture as the main source of their income. About one third of the country's population lives in the rural areas. Most of these rural dwellers depend directly or indirectly on agriculture.

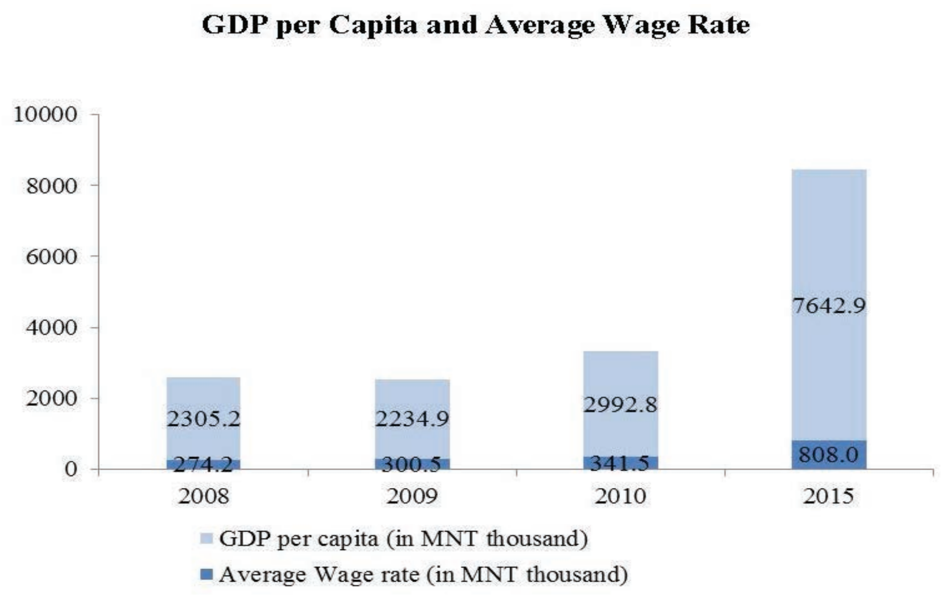
Gungaadorj (2002) says that agricultural production in Mongolia has significantly dropped within the last two decades. The reduction in agricultural production has been blamed on climate change. The regular rains that benefited farmers have become erratic. Cases of destructive storms are also on the rise. There is also the issue of rural to urban migration, especially among the younger population whoare now seeking white-collar jobs. A comparative analysis of the lifestyle of the city dwellers to that of the people living in rural settings shows that rural dwellers have lower living standards. They are more vulnerable to poverty. In this paper, itseeks to identify the measures of well-being of rural development statistics and propose possible ways to improve well-being indicators of rural statistics that can provide ways of tracking performance of the SDGs.

2. Comparative analysis of SDG in Mongolia

2.1 Focus on SDG in Mongolia

It is important to understand the fundamental differences between millennium development goals (MDG) and sustainable development goals (MDG). According to Smith (2015), while MDG primarily focused on poverty eradication, SDG looks athow livelihood of people can be improved today and in the future. SDG goes beyond achieving economic success and complete poverty eradication. It also looks at ways of protecting our environment and a number of other socio-political factors that not only affects the current but also the future generation. SDG is one of the nations that have embraced SDG as a way of addressing the socio-economic and environmental issues affecting it. The country is very optimistic that this program will help its population lead a better life than what is currently witnessed. The figure below shows the progress that has been made in achieving the MDG from 2008 to 2015.

Figure 1 - Progress made in achieving MDG in Mongolia



Source: the Millennium Development Goals Implementation in Mongolia: Fourth National Report, Ulaanbaatar, 2011

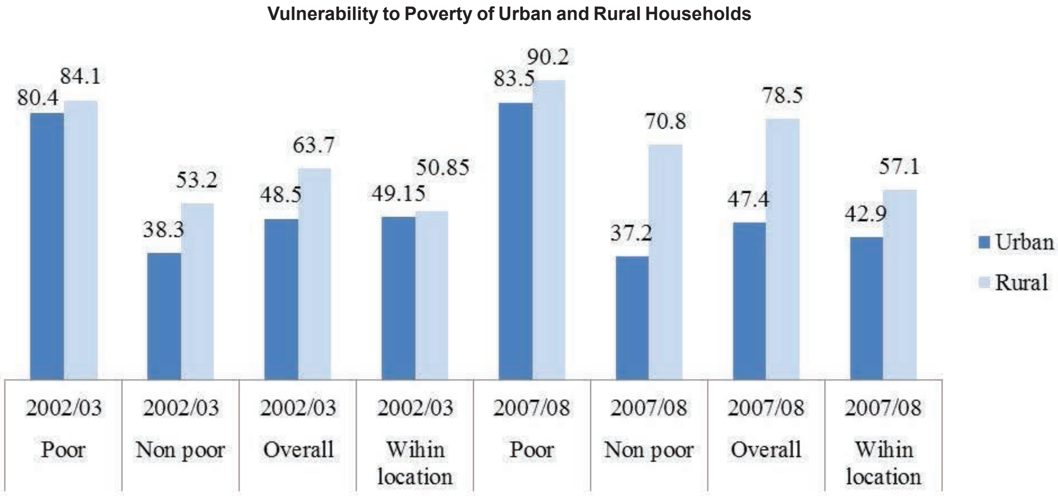
As shown in the above statistics, Mongoliahas made impressive steps in achieving MDG. The statistics show that the Average Wage Rate (AWR) increased consistently since 2008. It means that on average, Mongolians' earnings are on the rise. The Gross Domestic Product per Capita (GDP per Capita) is also increasing consistently. The GDP per Capita in 2015 was about triple the value that was registered in 2008. It is a sign that on average, life is getting better in Mongolia. The well-being indicator shows that more people are migrating from below the poverty line to the middle class. However, Smith (2015) warns that GDP per Capita often makes a major assumption that may make the nation forget a section of its population. The GDP is an average earning. As more people become very rich, the GDP will rise even if a section of the society still lives in object poverty. It means that this measure do not give a clear picture of wealth distribution in the country. In an effort to achieve SDG, it is important to have a more comprehensive focus on the entire population, including the new section of the poorest that have for a long time been ignored in the statistical surveysof the past. In this paper, the focus of SDG will be narrowed down to the fight against poverty as one of its fundamental principles.

2.2 Poverty profile in Mongolia

When MDG was developed in 2000, it was expected that by 2015, poverty shall be completely eliminated among the nations that had ratified it. However, it became apparent that many people still live in object poverty when SDG was developed in 2015. As such, poverty eradication was one of the key objectives of SDG that was developed in 2015. In Mongolia, poverty is still an issue that the government is still trying to address among its people. A Living Standards Measurement Survey conducted by Gungaadorj (2002) showed that poverty headcount remained unchanged in Mongolia for the period of 1995-1998. Poverty level was estimated to be 36%. Another statistics conducted by the World Bank showed that there was a new trend in wealth gap that most studies have always ignored, the gap between the poor and the poorest. The statistics showed that the gap between the poor and the poorest was widening almost at the same rate as that between the rich and the poor. This worrying trend was confirmed by a survey conducted by the National StatisticsOffice of Mongolia which indicated that there was an emerging population among the rural dwellers whose annual earnings were way below the poverty line (Gungaadorj, 2002). As a section of the society continued to amass more wealth that rival that f the richest people in the world, another section was sliding deep into poverty than what had previously been captured.

According to Smith (2015), it is possible that this new segment of the poorest had been ignored for a long time because of the parameters used in measuring wealth and income in the past. Studies often focused on asking the respondents if their earnings were below a specific level that was considered a poverty line. However, the recent surveys that ask respondents to state their average income per given period has revealed that some Mongolians are barely managing to get the basic needs such as food, shelter, and clothing. Majority of them are rural dwellers who rely on subsistence farming to earn a living. When rains fail, they get seriously affected because they rely on their crops almost entirely. A small section is urban dwellers that lack properly defined jobs and have no skills to be hired in some of the emerging companies in the region. The figure below shows a comparative analysis of the vulnerability to poverty among the rural and urban households in Mongolia.

Figure 2 - Comparative analysis of vulnerability to poverty among the rural and urban households



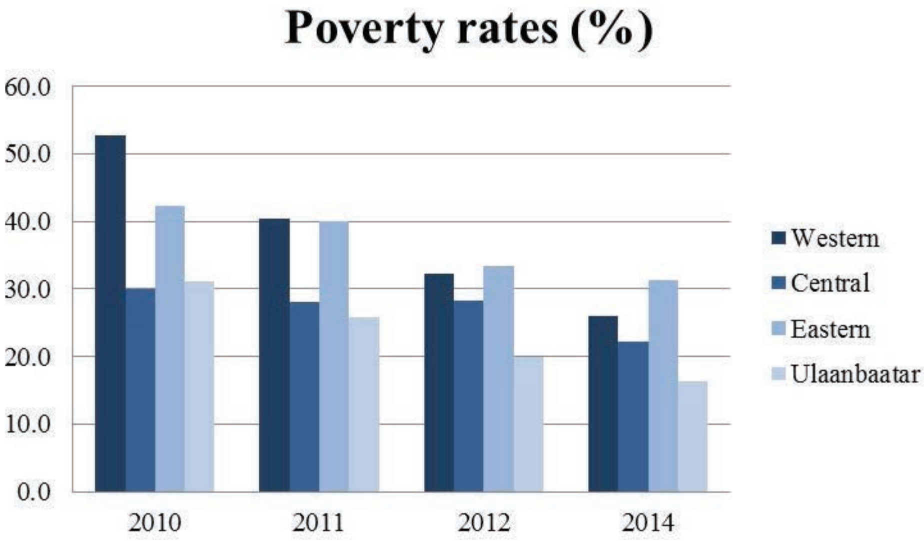
Source: Findings of ADB-financed "Analysing Triangle Relationship between growth, Inequality and Poverty in Mongolia, based on Household Socio-Economic Survey of 2002/03, 2007/08 studies

In this comparative analysis, the population is classified into three different groups and the overall. They include the poor, the non-poor, and those within location. There is a multiple comparison of people in different social classes, in different years, and based on their residence (rural and urban). As would be expected, the poor are more vulnerable as compared to the other groups. Smith (2015) attributes thisvulnerability to the rising trend where the rich are amassing more wealth at the expense of the poor. Although the average wage rate has been on the rise, there are still some people who earn very little because they lack alternative jobs due to their limited skills. A comparative analysis of vulnerability to poverty for the years 2002/2003 and 2007/2008 shows a shocking outcome as shown in the above statistics. It is clear that people are becoming more vulnerable as time goes by.

The poorest are the worst affected group, possibly become they rely more on subsistence farming that has become very unreliable become of erratic weather patterns. This is evident when comparing the vulnerability of the rural dwellers to that of the urban dwellers. In 2002/2003, 84.1% of the rural poor households were vulnerable compared to 80.4% of the urban poor households. The vulnerability increased in 2007/2008. In this period, it was estimated that 90.2% of the rural poor were vulnerable compared to 83.5% of the urban poor. A further comparative analysis of those within location shows the gap in vulnerability among those in urban centres compared to those in rural settings. In 2002/2003, it was estimated that 49.15% of the urban households and 50.85% of the rural households were vulnerable. The gap between the two groups was about 1.7%. In the period 2007/2008, it was estimated that 42.9% of the urban households and 57.1% of rural households were vulnerable. The gap between the urban and rural households in vulnerability had increased by over 4%.

In the above comparative statistics, one fact that comes out clearly is that the rural households are becoming more disadvantaged economically than the urban households. The vulnerability of the poor rural dwellers is now over 90%, and there are clear signs that show it may become worse if actions are not taken soon enough. The comparative statistics below confirms the argument that those in the rural areas still have to deal with the issue of poverty more than their colleagues in the urban centres.

Figure 3 - Regional poverty rates in Mongolia



Source: World Bank

As shown in the above statistics, the average poverty rate in Mongolia is dropping. However, it is clear that reduction rate is greater in urban (Ulaanbaatar city) than in the rural settings. Improving rural development statistics in support of SDG is, therefore, very important and the stakeholders should focus on improving the existing measures. As the lifestyle of the urban households improves, efforts should be made to ensure that rural households are not left behind.

3. Possible Indicators for Rural Development Statistics

It is estimated that about one third of the Mongolians (1 million people) live in the rural setting. Most of these rural dwellers largely rely on agriculture. According to Sovacool and Drupady (2016), "the country has very little arable land as most of its area is covered by grassy steppe with mountains to the north and west and the Gobi Desert to the south," (p. 56). It is clear that farming using traditional methods which wholly rely on nature is almost impossible in the region. It explains why the rural dwellers are more vulnerable to poverty than those in urban centers. It is important to find indicators for rural development statistics in different pillars for these rural households. Based on the above comparative analysis, the following are the proposed pillars that should be given a serious focus.

3.1 Sustainable income growth for the rural households

Rural poverty can only be eradicated by creating sustainable income growth in these regions. The aim is to ensure that their expenditure capacity is improved significantly and sustainably. As Gungaadorj (2002) says, the solution should be long-lasting other than being a quick-fix. The government should find ways of increasing the rural household's income through various strategies discussed in the section below. The approach should be broad based on the source of livelihood of individual families. Whether they are employed hence expect to be paid salaries or they are self-employed in the agriculture or mining sectors, there should be a consistent rise in their income. This will help in reducing their vulnerability to poverty.

3.2. Quality social service delivery for the rural people

Social services such as healthcare, access to sporting and entertainment facilities, good security, clean water supply, and many other government-sponsored services also define the quality of life of people. In most cases, these amenities tend to be more concentrated in the urban settings as opposed to the rural areas. This should not be the case anymore. The rural households need these social amenities just as much as the urban dwellers. Their well-being is dependent on them.

3.3. Sustainable use of environment and natural resource

The rural households are better placed to enjoy natural resources than those who are in urban centers. Farming and mining are some of the best ways of using the environment and natural resources sustainably. The fact that the country is sparsely populated makes it easy to practice commercial farming if modern methods are effectively employed. Livestock keeping can also be another aspect of farming that the rural households can consider. A report by Smith (2015) indicates that over 80% of Mongolia's exports are minerals, a sign that this industry is doing well. However, more can be done to help improve the living standards of the people living in rural areas.

3.4. Increased involvement in policy making

Public participation in policy making is becoming a major issue in various parts of the world. People now demand to be consulted whenever it is necessary to come up with major policies that may affect their life in one way or the other. The well-being of the rural people depends on the policies embraced by the government. There is no better way of taking care of the well-being of these people than to involve them in making policies. It may be an involving process but it is important as the country tries to achieve SDG.

4. Cost effective ways to produce proposed indicators

The proposed indicators should be realized in order to help improve the well-being of the rural dwellers in Mongolia. It is necessary to come up with cost effective ways to produce each of these indicators.

4.1. Sustainable income growth for the rural households

In order to have sustainable income growth for the rural households, the national government, in collaboration with the local authorities and foreign investors, should invest in local industries in the rural settings, especially the areas where the population is high. These industries will assure the locals of sustainable income through stable jobs. Farmers should be supported through grants and soft loans to mechanize their production.

4.2. Quality social service delivery for the rural people

Affordable healthcare should be considered a basic need for all the Mongolians, whether theyare staying in rural or urban areas. More healthcare facilities should be put up in the rural areas. These hospitals should be fully equipped. These people should also have access to properly equipped learning institutions. Running water is important, especially for those staying in the drier parts of the country. Other social amenities such as banks should also be available. This can be achieved through public-private partnerships.

4.3. Sustainable use of environment and natural resources

The environment is one of the three pillars of sustainable development. There should be a sustainable use of natural resources and environment. This can be done by avoiding pollution and overexploitation of these resources. In the mineral industry, the use of state-of-the-art machines can help in reducing wastage, pollution, and increasing productivity. Farming should be done in a way that it poses no threat to the country's biodiversity.

4.4. Increased involvement in policy making

The government should come up with community-based organizations (CBOs) that will allow the public to express their views on matters that affect their life either directly or indirectly. Through relevant departments, the government can coordinate with these CBOs to get to know the views of the people over various policies, especially if the policy turns out to be of public interest. The people of Mongolia have representatives in the parliament. In most of the cases, it is these representatives who ensure that public opinion is treated as such. However, sometimes it may be necessary to directly involve the people themselves. This is specifically so if the policy targets a small group of people whose needs cannot be effectively addressed by the parliament.

5. Conclusion

Improving rural development statistics in support of the sustainable development goals is in the interest of the government of Mongolia. It is easy to assume that the country is making positive economic progress while in real sense it is only a few people who are making abnormally high income while the rest of the population are getting poorer. The comparative statistical analysis shows that rural households are more vulnerable to poverty than those living in the urban settings. These rural dwellers have a higher percentage of people who fall in the category of the poorest. In an effort to improve rural development, focus should be laid on sustainable income growth, quality social services delivery, sustainable use of environment and natural resources, and increased involvement of the locals in policy making.

Indicators on rural development in Kenya

J. Mburu | KNBS | Nairobi | Kenya

DOI: 10.1481/icasVII.2016.a01b

ABSTRACT

Agriculture is the mainstay of the Kenyan economy with 70.1 per cent of the population residing in the rural areas. The sector contributes about a quarter of the Gross Domestic Product, and is a major source of export earnings and rural employment. However, the quantity and quality of agricultural statistics in Kenya has deteriorated over time due to a multitude of factors. To address these challenges, the Kenya National Bureau of Statistics (KNBS) with support from the African Development Bank (AfDB) and in conjunction with stakeholders in the Agricultural Sector has developed a seven year Strategic Plan for Agriculture and Rural Statistics (SPARS) spanning the period 2015/16 to 2021/22. The Kenyan SPARS is the first of its kind in Anglophone Sub-Saharan Africa and is in tandem with the recommendations of the Global Strategy for the development of agriculture statistics and the African Action Plan for 2011-2017. The SPARS for Kenya is expected to form a major input into the yet to be finalized National Strategy for the Development of Statistics (NSDS) in Kenya.

The Global Strategy in one of its key pillars proposes the development of a minimum core set of indicators to address the dearth in availability of quality agricultural statistics. While the set of plausible and measurable agricultural indicators is clear, the same may not be the case with rural indicators. The probable set of rural indicators for Kenya provides a particularly interesting scenario due to the rapid progress in ICT that has taken place in recent times affecting many sectors of the economy across the country. This paper proposes a critical set of indicators that are relevant and key to the development of the rural areas in particular. The proposed indicators are expected to be Specific, Measurable, Achievable, Realistic and Time- bound (SMART) and easy for development practitioners among other users to utilize to monitor and evaluate progress or lack of it in rural areas. In Kenya, a set of statistical activities have been proposed in the SPARS_KEN that will make the generation of these indicators plausible when you factor in the requisite technical support from the KNBS.

Keywords: Rural indicators, Global Strategy

PAPER

1. Introduction

The Kenyan economy is dependent on agriculture with the sector accounting for about a quarter of the Gross Domestic Product. The sector is a major source of foreign exchange and rural employment (GOK 2015). The leading sub-sectors and major export earners include tea and horticulture. In 2015, the two commodities earned the country a combined KSh 208.8 billion equivalent to over US$ 2 billion (GOK 2016a). About 70.1 per cent of the population is resident in the rural areas. This is also where the bulk of agricultural production continues to take place through smallholder crop and livestock production. This is typical of several African countries as documented by Wiggins (2009) and Salami, et al, (2010). Despite this impressive performance, the quantity and quality of agricultural statistics in Kenya has deteriorated over time due to a multitude of factors. Key among them being limited funding for the requisite surveys and censuses (GOK 2016c).

However, in the recent past, financing of Statistical activities has risen in tandem with the rise in the profile and visibility of official Statistics. This has been amplified by renaming of the former Ministry of Devolution and Planning to the Ministry of Planning and Statistics (MPS). In addition, the current Principal Secretary in the MPS is a former Director of the Kenya National Bureau of Statistics. The promulgation of the 2010 Kenya constitution brought with it the county system of government as well as devolution of resources and services to the rural areas. However, the new system of government increased demand for data and statistics for county level planning, monitoring and evaluation The Bureau is in the process of developing annual County Statistical Abstracts (CSAs) using data that is currently available in the counties as well as data from ongoing household surveys.

1.2 Global Strategy for Agriculture

The Global Strategy proposes a multidimensional approach to address the deteriorating situation of agriculture statistics especially in developing countries. First through a core set of Agriculture and Rural Indicators coupled with the development of a master sampling frame for agriculture surveys (United Nations, 2011a). Africa is the first region to implement the Global Strategy through the development of the Action Plan for Africa. In this plan, while taking into account the comparative advantage of institutions, the African Development Bank (AfDB) was assigned the responsibility of providing to African countries technical assistance and governance; the United Nations Economic Commission for Africa (UNECA) was assigned the responsibility of providing training; while the Food and Agriculture Organization of the United Nations (FAO) was assigned the responsibility of conducting research (United Nations, 2011(b) and GOK 2016c).

1.3 Strategic Plan for Agriculture and Rural Statistics for Kenya

To address these challenges, the Kenya National Bureau of Statistics (KNBS) with support from the AfDB and in conjunction with stakeholders in the Agricultural Sector developed in 2014/15 a seven year Strategic Plan for Agriculture and Rural Statistics (SPARS_KEN) spanning the period 2015 to 2022. The Kenyan SPARS is the first of its kind in Anglophone Sub-Saharan Africa and is in tandem with the recommendations of the Global Strategy for the development of agriculture statistics and the African Action Plan for 2011-2017. The SPARS for Kenya is expected to form a major input into the yet to be finalized National Strategy for the Development of Statistics (NSDS) in Kenya.

1.4 Rural versus Urban areas

Rural areas are characterized by scattered population and tend to lack most if not all the facilities/amenities found in the urban areas such as proper sanitation, road infrastructure among others. Urban areas tend to have higher population density and are more endowed in terms of facilities. Peri-urban areas are somewhat to urban area but to a lesser extent. In these areas, only some of the facilities found in urban areas exist and the population concentration is moderate (GOK 2010). Rural statistics refer to broad range of statistics (economic, social, demographic, agricultural, etc.) covering the rural areas of a country. In this case rural statistics refer to those statistics that are agriculture related (GOK 2016b).

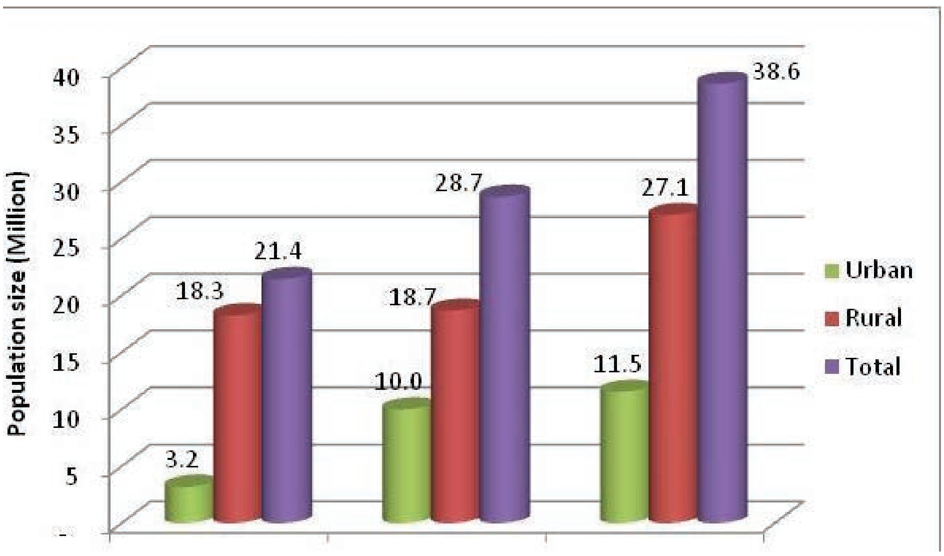
1.5

Generation of rural statistics though important is not sufficient without the urban component, if only for comparison sake. Available population statistics indicate that Kenya has been urbanizing very rapidly. Areas that were previously rural have changed to urban areas with time as population rose and in-migration took place. Indeed, some of the former agricultural farms near Nairobi have changed use to real estate. The desire to produce own food and hence ensure own food security in urban areas has resulted in urban and peri-urban agriculture. This needs to be considered in agriculture production as well as part of consumption. The Figure 1 below shows trends in population growth in urban and rural Kenya over the last three census years.

1.6 The Policy Environment

The long term development planning in Kenya is guided by the Vision 2030 through the Medium Term Plans (MTPs). The Vision has three pillars namely economic, social and political and envisions a prosperous and globally competitive country by year 2030. The policy recognizes Agriculture, Livestock

Figure 1 - Trends in Kenya's Population by Rural and Urban areas, 1989, 1999, 2009



Source: Kenya National Bureau of Statistics and Fishries as well as the Information Communication and Technology (ICT) sectors as a key enabler of this vision (GOK, 2007). Towards this end, the National Information Communication and technology (ICT) Authority developed the national ICT policy and subsequently the 2014-2017 National Master Plan with the aim of facilitating the realization of Vision 2030 (GOK 2006 and GOK 2014). The implementation of the ICT masterplan has some of the outcomes expected by 2017 as the creation of 180,000 direct jobs, recognition of Kenya as a regional ICT hub and increased public value of e-Government services with 50 per cent of adults accessing atleast one e-Government service (GOK, 2014). This has been backed up by several positive developments in several areas such as the deployment of five under sea fibre optic cables, Electricity connection to more households and most of the public primary school as well as all government institutions both at the national and county levels as well as high schools and other institutions of learning have operational websites. Provision of laptops/tablets for every child joining standard one in all public primary schools in Kenya is currently underway and it is supposed to facilitate e-Learning in public primary schools. The Government has institutionalized e-Government where services are shared through Huduma centres. This is also the case with e-Procurement and e-Recruitment where procurement and application for Government jobs is done online. The KNBS is gradually shifting from paper based questionnaires in survey administration to Computer Assisted Personal Interviews (CAPI) using tablets and smart phones in data collection.

1.7 The ICT Context

Annan *et al* (2015) in one of the articles observes that Africa has gone digital with investments in fibre optic technology, increased access to mobile broadband and use of low cost smart phones and smart phones. Analogously, the number of mobile-cellular telephone subscriptions by population aged three years and above in Kenya rose from 82.5 per 100 inhabitants in 2013 to 86.2 per 100 inhabitants in 2014 as reflected in Table 1. The figures are based on. The access to mobile-cellular telephone has cut across both rural and urban areas. Mobile phones have multiple uses which include calling, Short Messaging Service (SMS), internet connectivity as well as mobile money transactions. In Kenya, mobile money transactions have been used very extensively and include transfers, payments, loans (i.e M-Shwari), mobile banking among others. Table 1 further shows that the total funds transfers through mobile telephony rose from KSh 1,902 billion in 2013to KSh 2,372 billion in 2014. This has resulted in significant financial inclusivity especially in rural areas. According to GOK (2016b), financial exclusion of the rural populations reduced from 40.7 per cent in 2006 to 22.0 per cent in 2016. Similarly, financial exclusion of the urban populations reduced from 42.8 per cent in 2006 to 9.5 per cent in 2016.

The use of mobile telephony has resulted in Kenyan youth joining social media (facebook, whatsap, instagram, twitter, you tube etc). This has facilitated learning and information exchange among the youth and farmers in general. Some examples of relevant information exchange groups include: a) Kilimo Biashara; b) Onion and water melon farming gurus; c) Mukulima smart d) Mkulima bora e) Mkulima ni ujuzi f) Smart farm g) Shamba shape up Closely allied to this innovative extension approach is the agribusiness oriented farming where smallholder irrigation of horticultural produce under green houses is gradually taking root in Kenya. The farmers produce French beans, tomatoes, onions among others for local and export market, The benefits of this information exchange coupled with green house irrigation are bound to positively transform productivity at the farm level resulting in a shift from subsistence small holder rural agriculture to commercial market oriented, profit driven farming in Kenya.

Table 1: Selected Internet and Mobile telephony indicators, 2010-2014

Indicator	2010	2011	2012	2013	2014*
Internet subscribers per 100 inhabitants (Both wireless & fixed)	8.0	15.6	20.9	31.6	38.3
Mobile-cellular telephone subscriptions per 100 inhabitants	71.5	75.1	82.4	82.5	86.2
Wireless internet subscribers per 100 inhabitants	8.9	17.1	-23.0	-34.7	-42.2
Broad band subscriptions per 100 inhabitants (wireless)	0.5	0.6	5.0	6.4	10.7
Mobile money Transfer Agents	32,949	42,313	49,079	93,689	121,924
Mobile money Transfer Service Subscribers ('000)	10,615	17,396	19,319	26,016	26,023
Total transfers (KSh billion)	732	1,169	1,544	1,902	2,372

Source: Economic Survey, 2015
* Provisional

1.8 Local on-line platforms

Kenyans have developed several online platforms such as „iprocureč which prescreens its vendors to provide reliable local procurement services connecting agricultural businesses and institutional buyers. „Sendyčprovides a platform that connects customers with motor cycle couriers to offer delivery services payable with mobile money. „Ushahindič and „Uchaguzičare crowd sourced applications that report and map election violence in Kenya. „Nairobitsča youth organization in Kenya exposes underprivileged young people from informal settlements to web design and other ICT skills while „Akirachixčreaches out to „geek girlsčamong others (United Nations, 2016).

1.9 Indicators of Rural Development

Indicators are very useful in monitoring, and evaluation. Good quality indicators are Specific, Measurable, Achievable, Realistic and Time-bound (SMART) and easy for development practitioners among other users to utilize to monitor and evaluate progress or lack of it in rural areas. At the international level, indicators that had been developed to monitor the Millennium Development Goals are examples of SMART indicators . The Wye Group has in the recent past compiled a set of indicators for monitoring rural livelihoods as shown in United Nations (2007). More recently, Bryden J. (2011) did compile rural development indicators in the European Union. The Global strategy proposes on a minimum set of core indicators that countries should focus on in an effort to improve the quality and quantity of agriculture statistics. This paper does not dwell on the core indicators which very clear but focuses on the less clear rural development indicators using the Kenyan context as the basis. Table 2 below shows selected indicators for monitoring various aspects of rural development in Kenya.

Table 2 Selected Indicators for Measuring Rural Development in Kenya

Issue	Indicator	Sub-Populations	Source
Agriculture	Green house irrigation	Number, Area, Crop types	Economic Survey
Demography	Population Density	Rural, Urban	Population and Housing Census
	% population aged 64 years and above	Sex	Population and Housing Census
	Infant Mortality rate	Sex	Demographic and Health Survey, Population and Housing Census
	Under 5 Mortality Rate	Sex	Demographic and Health Survey, Population and Housing Census
Employment	% of the population that is self employed	Rural, Urban	Economic Survey
Health	Life Expectancy at Birth	Sex	Population and Housing Census
ICT	Internet access	Rural, Urban	ICT survey, Population and Housing Census
Malnutrition	Proportion of children under five who are underweight	Sex, Rural, Urban	Demographic and Health Survey
	Proportion of children under five who are stunted	Sex, Rural, Urban	Demographic and Health Survey
	Proportion of children under five who are wasted	Sex, Rural, Urban	Demographic and Health Survey
Poverty	Food Poverty	Rural, Urban	Kenya Integrated Household Budget Survey
	Absolute poverty	Rural, Urban	Kenya Integrated Household Budget Survey
	Hard core poverty	Rural, Urban	Kenya Integrated Household Budget Survey
Sanitation	Population with access to clean water	Increased specialisation	Demographic and Health Survey, Population and Housing Census
Water	Population with access to clean water	Rural, Urban	Demographic and Health Survey, Population and Housing Census

1.10 Conclusion

While agriculture continues to be the mainstay of the Kenyan economy the state of agricultural statistics has not been very good. In response to this state of affairs, the Global Strategy for the improvement of agricultural statistics provided the necessary impetus which culminated in the development of SPARS_KEN. The Kenya government has provided an enabling environment for the proliferation of various forms of ICT. Through Public Private Partnerships (PPP), the government has partnered with a leading telecommunication firm in Kenya so as to facilitate provision of affordable fertilizer to smallholder farmers through a fertilizer e-Subsidy programme. A crop insurance initiative is being piloted in selected counties by the government along a similar PPP approach. In Kenya, technology adoption especially around mobile telephony has been very vibrant and has had a major positive impact in the development of the rural areas in Kenya. The introduction of laptops and tablets in public primary schools is expected to lead to consumption of less paper. This will over time earn environmental dividends over time leading to reduced deforestation, less pollution and hence a cleaner rural environment. The KNBS is gradually shifting from paper based questionnaires in survey administration to Computer Assisted Personal Interviews (CAPI) using tablets and smart phones in data collection. This is similarly expected to result in similar benefits. The focus of this paper was on indicators of rural development within the foregoing Kenya context. The paper acknowledges that there are an infinite number of indicators that can possibly be generated but as Table 2 below shows, only afew very crucial rural indicators have been selected bearing in mind the unique Kenyan context.

Measuring EU rurality: an updated peripherurality indicator

F. Pagliacci | Università di Modena e Reggio Emilia | Modena | Italy
R. Esposti | Università Politecnica delle Marche | Ancona | Italy
B. Camaioni | CREA | Rome | Italy
F. Sotte | Università Politecnica delle Marche | Ancona | Italy

DOI: 10.1481/icasVII.2016.a01c

ABSTRACT

In the last decades, EU rural areas have been experiencing major transformations, which have made any traditional urban-rural divide outdated (OECD, 2006). Going beyond urban-rural dichotomy, the paper moves from the analysis of the PeripheRurality Indicator (PRI), computed by Camaioni et al. (2013) for all EU NUTS 3 regions. For each of them, PRI includes both conventional socio-economic indicators and geographical characteristics. Nevertheless, this paper enriches PRI's original territorial and geographical dimension, by taking explicitly into account even the degree of rurality of neighbouring regions. Eventually, it returns 16 EU typologies of urban-rural areas. Then, such a classification is tested on 2007-2011 Common Agricultural Policy (CAP) expenditure data. Indeed, the paper considers the coherence of fund allocation with the real characteristics of EU rural space.

Keywords: Rurality, Peripherality, Spatial analysis

PAPER

1. Introduction

This paper aims to enrich the role of territorial and geographical dimensions in assessing the degree of rurality of EU-27 NUTS 3 regions. Rural regions still play a key role within the EU economy and society, although major transformations and an increasing heterogeneity have occurred since EU Eastern enlargements. With regard to those transformations, Camaioni et al. (2013) introduced a composite and comprehensive PeripheRurality Indicator (PRI), which updates traditional urban-rural divides suggested by OECD (2006). PRI provides a new representation of EU rural geography, jointly considering conventional rural features (e.g., low population density, key role of agriculture, etc.) and geographical aspects, such as remoteness.

Nevertheless, space and geography play an even larger role in defining rurality at local level. Indeed, when considering remoteness, even neighbouring areas' one may affect it: two regions, which share the same extent of rurality according to the PRI, can actually differ if the former is close to a large metropolitan area while the latter is surrounded by other rural areas. Indeed, the current post-industrial rurality framework (Sotte et al., 2012) stresses integrations across rural space and between rural and urban territories as critical. When sharing a neighbouring space, two regions may affect each other on given common issues (e.g. policy implementation). Thus, any indicator of rurality should carefully consider even the degree of rurality across the neighbourhood (Camaioni et al., 2013). Furthermore, a more spatially-integrated approach in policy formulation could also result in better framed policies (Esposti, 2011): for instance, the policy Common Agricultural Policy (CAP), which supports the EU agriculture and its rural space, would largely benefit from a more spatially-integrated approach at local level. In fact, CAP fund allocation is largely unbalanced across EU urban-rural regions.

The paper is organised as follows. Section 2 shortly discusses the PRI in the light of the wider debate about defining EU rural areas, from the most "conventional" approaches to more innovative and multidimensional ones. Section 3 analyses PRI territorial distribution across Europe, by also considering the role of the neighbouring regions in affecting major differences observed at local level. By jointly considering those two dimensions, it is possible to disentangle 16 different typologies of urban-rural regions. Section 4 applies this classification to the analysis of the allocation of CAP expenditures across Europe. Section 5 concludes the paper.

2. The PeripheRurality Indicator in the light of alternative definitions of rurality

In a multidimensional perspective, the need for a new classification of rural areas comes from the evolution of the concept itself of rural areas. Lacking a strong theoretical foundation, the concept has largely evolved over time (Johnston, 1970; Timmer, 1988; Esposti and Sotte, 2002; Sotte *et al.*, 2012). Changes in the main definitions of rural areas call for new approaches in their classifications (Camaioni *et al.*, 2013). Since the 1990s *post-industrial rurality* has emerged. Accordingly, two features now characterise rural areas (Sotte *et al.*, 2012): i) a greater importance of territorial issues (e.g., stronger integrations across the rural space and between rural and urban areas[1]); ii) their polymorphism (i.e., the co-existence of different forms of rural-rural and rural-urban integration patterns).

In particular, polymorphism has been seldom tackled by conventional measures of rurality (especially those based on sector-based or demographic indicators). It couples with the lack of homogeneous definitions of rural areas[2], which is due to remarkable differences in terms of demographic, socio-economic, and environmental conditions occurring across the EU rural space (European Commission, 2006; Hoggart *et al.*, 1995; Copus *et al.*, 2008).

Despite those difficulties, some homogeneous definitions of urban-rural typologies have been provided at EU level. Both OECD (2006) and the EC (Eurostat, 2010) follow a similar approach in defining them: they just refer to population density at local level and the presence of large cities. Such an approach just measures rural areas through a single indicator, eventually collapsed into a discrete ordinal variable. Such a measure returns just three urban-rural typologies, seeming too rough to capture increasing polymorphism across Europe.

Moving from those major pitfalls, many works have classified EU rural areas, adopting a multidimensional approach (Copus, 1996; Bollman *et al.*, 2005; Copus *et al.*, 2008; Terluin et al., 1995; Psaltopoulos et al., 2006; Lowe and Ward, 2009). Camaioni *et al.* (2013) suggest further improvements to this field of study, by defining a PeripheRurality Indicator (PRI). They apply conventional Principal Component Analysis (PCA) to a 24-variables dataset, which covers socio-demographic features, economic structure, land use, accessibility/remoteness (over different territorial scales). Their analysis refers to NUTS 3 territorial level, considering 1288 regions[3]. Firstly, PCA returns a standardised score for each region on five uncorrelated Principal Components (PCs)[4]. Eventually, according to them an ideal urban benchmark (i.e., a region with the most urban features across Europe) is identified. In particular, the urban benchmark is represented by the cities of Paris and London. Secondly, the statistical "distance" between any EU region and this benchmark is computed (Camaioni et al., 2013). So, by construction, the greater the PRI the more rural and peripheral a given region is. Thus, the PRI captures both a socio-economic and a spatial distance from urban features, hence its definition (Camaioni *et al.*, 2013).

Besides the large number of regions taken into account[5], an additional novelty of that work refers to the fact it explicitly refers to geographical issues: indeed, the PRI considers both the physical distance of each region from major EU urban areas and its accessibility according to physical infrastructures. Thus, it provides an original representation of the EU urban-rural geography, shedding light on the integration between rural and urban areas (Camaioni et al., 2013).

Nevertheless, the set of territorial information the PRI provides can be enhanced further. Indeed, a spatially-enriched PRI can be obtained by explicitly including more information on the rural-urban characteristics of the neighbouring space, as well.

3. The PeripheRurality Indicator: Which Role for Neighbouring Regions?

Figure 1 (left panel) returns PRI main patterns across Europe: the greater its value, the more rural and peripheral is any given region. Camaioni et al. (2013) already observe that the lowest values occur across capital-city regions and, more generally, across the central Europe urban space. On the contrary, PRI highest values occur throughout EU peripheries (Mediterranean regions, Eastern Europe, Northern Scandinavia). From a more general perspective, PRI wide variability sheds light on a new EU geography, suggesting a long-standing core-periphery pattern.

Additional information on those territorial divides also comes from the analysis of the spatially-lagged values of the PRI, which were already computed in Camaioni *et al.* (2015). Per each NUTS 3 region, the right panel of Figure 1 returns the average value of the PRI across its neighbours. This value is computed through a (*n* x *n*) row-standardized spatial weights matrix (**W**), whose generic element w_{ij}, is defined as:

$$w_{ij} = w^*_{ij} / \sum_{j=1}^{n} w^*_{ij} \qquad (1)$$

In (1), the generic element w^*_{ij} can take two different values: $w^*_{ij} = 1$ when $i \neq j$ and $j \in N(i)$; $w^*_{ij} = 0$ when $i = j$ or $i \neq j$ and $j \notin N(i)$, where $N(i)$ is the set of neighbours of the i-th region. Here, a *first-order queen contiguity matrix* defines neighbourhood: two regions are considered as

[1] Rural regions are now assigned the role of supplying urban societies with a larger set of services associated to public goods, such as environmental and cultural goods (Sotte et al., 2012).

[2] Even the identification of those areas where rural development policy (i.e. a EU policy) is expected to be implemented is assigned to Member States, which are autonomously in charge of defining their own rural areas.

[3] They adopt the NUTS 2006 classification, excluding those regions that are located far away from Europe (e.g. the French Departements d'outre-Mer). Further comments and caveats on the dataset selection are returned in Camaioni et al. (2013).

[4] They range from "Economic and geographical centrality" to "Manufacturing in rural areas" and to "Land use: forests vs. agricultural areas" (Camaioni et al., 2013).

[5] Previous studies, such as Shucksmith et al. (2005), had just focused on NUTS 2 level regions.

neighbours only if they share a common boundary or vertex (Anselin, 1988)[6]. A major issue refers to islands, which show no contiguous regions. For the purpose of this work, we assume that for those regions the lagged PRI equals the PRI itself[7]. As for the PRI, the greater the spatially-lagged PRI value, the more rural and peripheral the neighbours of a given region are.

By jointly comparing these two values, it is possible to disentangle those regions that show different urban-rural characteristics compared to their neighbours. In general terms, we observe the PRI showing a positive spatial dependence across EU NUTS 3 regions. Both the value of the Moran's I statistics (Moran, 1950; Cliff and Ord, 1981), being equal to 0.547, and the Moran's plot shown in Figure 2 confirm it: most of EU regions show similar levels of rurality compared to their neighbours. Nevertheless, deviations from this tendency also arise: some rural regions are close to urban neighbours, while some cities are surrounded by rural areas. To detect those different regional typologies, we can split the Moran's plot, by referring to PRI's quartile distribution. Thus, 16 (i.e., 4X4) different partitions of the EU space are returned (Figure 2).

Figure 1 – PRI and lagged PRI across Europe (values by NUTS 3 region)

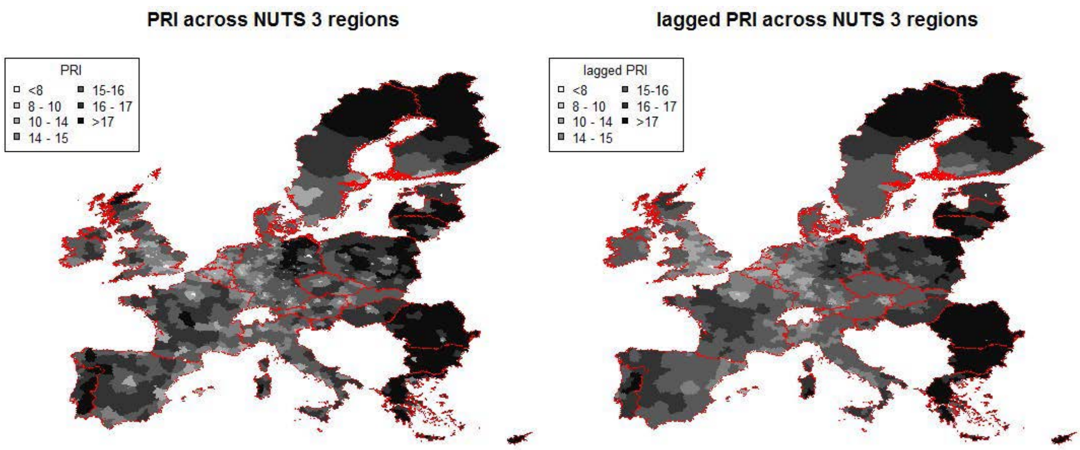

Figure 2 – Moran's plot for the PRI and typologies of regions

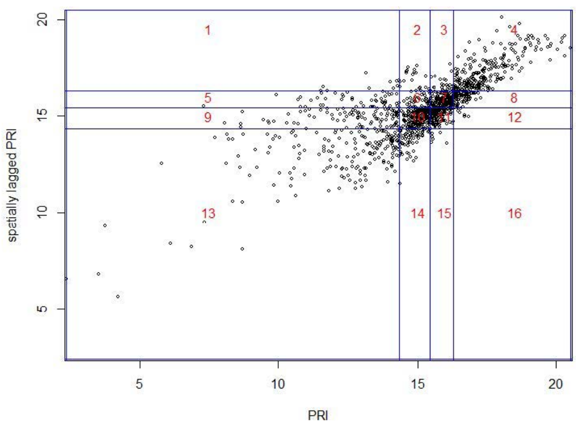
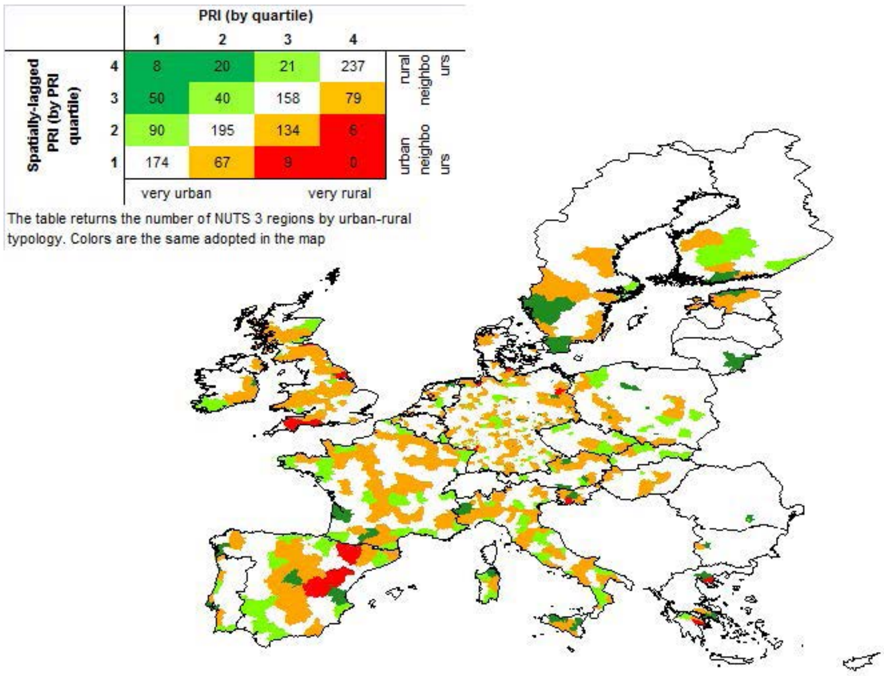


Each regional typology comprises a different number of regions. As already pointed out, most of observations occur along the main bisector: those regions share similar urban-rural features with their own neighbours. Nevertheless, 78 urban regions are surrounded by more rural areas (typologies #1, #2, #5 in Figure 3). Other 15, rural regions are spatially close to urban areas (typologies #12, #15). The territorial distribution of each of the aforementioned urban-rural typologies sheds light on a new urban-rural EU geography. For instance, some EU capital cities such as Madrid or Helsinki are urban areas, but they are surrounded by very rural regions. Conversely, some of the UK rural areas, which show very high PRI values, have urban contexts as their neighbours, being highly affected from them. In more general terms, the regions across the Eastern and Northern peripheries of the EU seem to share similar values of the PRI and spatially- lagged PRI. On the opposite side, in Western Europe, urban and rural are more deeply intertwined (e.g. in France, Germany, Italy and Spain). This is probably due to the specific characteristics of the medium-sized cities network, which exists in those countries.

[6] The first-order queen contiguity matrix and the spatially-lagged PRI are computed using the package 'spdep' (Bivand and Piras, 2015) in the R software (R Core Team, 2013).

[7] Camaioni et al. (2015) make alternative assumptions on islands and their neighbours.

Figure 3 – Urban-rural typologies across Europe and number of NUTS-3 regions in each typology



4. The allocation of CAP expenditure across different urban-rural typologies

This new urban-rural classification, which takes into account even spatial spillovers, may widely improve the analysis of CAP expenditure allocation throughout the EU. The topic has been widely debated: Camaioni *et al.* (2013; 2015) have already analysed the territorial distribution of Rural Development Policy (RDP) ex-post expenditure. In particular, they have stressed the importance of three main drivers: a 'country effect'; a 'rural effect' (i.e., the more rural a region the larger the amount of support); a 'pure spatial effect' (i.e., the influence of the neighbouring space and of its degree of rurality), which has been estimated adopting alternative spatial model specifications (Camaioni *et al.*, 2015). Camaioni *et al.* (2014) have also analysed the distribution of the overall CAP expenditure across the EU space, disentangling it by pillar (Pillar One and RDP) and by measure. Eventually, correlation between CAP expenditure at NUTS 3 level and rurality (as expressed by the PRI) is assessed: CAP expenditure seems to be less "rural" and less "agricultural" than stated. Indeed, when considering expenditure per unit of land and per unit of labour, the CAP supports urban and central regions more than rural ones (Camaioni *et al.*, 2014).

This work updates that descriptive analysis, by underlining major territorial unbalances in CAP ex-post expenditure across the aforementioned 16 urban-rural typologies. This analysis refers to the same data used by Camaioni *et al.* (2014), namely 2007-2011 payments from both EAGF and EAFRD. Data source is the European Commission (DG Agriculture): here, individual data have been aggregated to NUTS 3 level, to keep the anonymity. For the sake of simplicity, here we just refer to three broad typologies of expenditure, namely total CAP expenditure, Pillar One expenditure and Pillar Two (RDP) expenditure. Two pillars largely differ in their own ultimate goals: Pillar One is aimed at supporting agricultural activities and farmers' income; the second Pillar (namely RDP) implements several measures to support competitiveness of agricultural holdings in rural regions, diversification of the economy in rural areas, improvement in the qualit y of life within rural areas. In particular, here we refer to three indices of CAP expenditure intensity: expenditure per hectare of utilised agricultural area (Euro/UAA); expenditure per annual work unit employed in agriculture (Euro/AWU); Expenditure per thousand Euros of agricultural gross value added (Euro/.000 Euro)[8].

Nevertheless, Camaioni et al. (2014) point out that when expressing the intensity of CAP support by means of agriculture-related variables, extremely high values may occur across urban areas. This situation happens when values for UAA, AWU and agricultural gross value added are particularly small: it implies artificially-high levels of expenditure intensity for some of the most urban regions, throughout Europe. Thus, in order to get rid of those distortive effects, 30 urban regions were already excluded from the analysis in Camaioni et al. (2014). Here, same decisions are undertaken: of the excluded observations, more than a half (16 out of 30) are in typology #13 (i.e., the most urban regions with the most urban neighbours); 7 are in typology #9; 6 are in typology 5 and 1 is in typology #2. Even latter typologies refer to urban regions, but, in this case, they show rural neighbours.

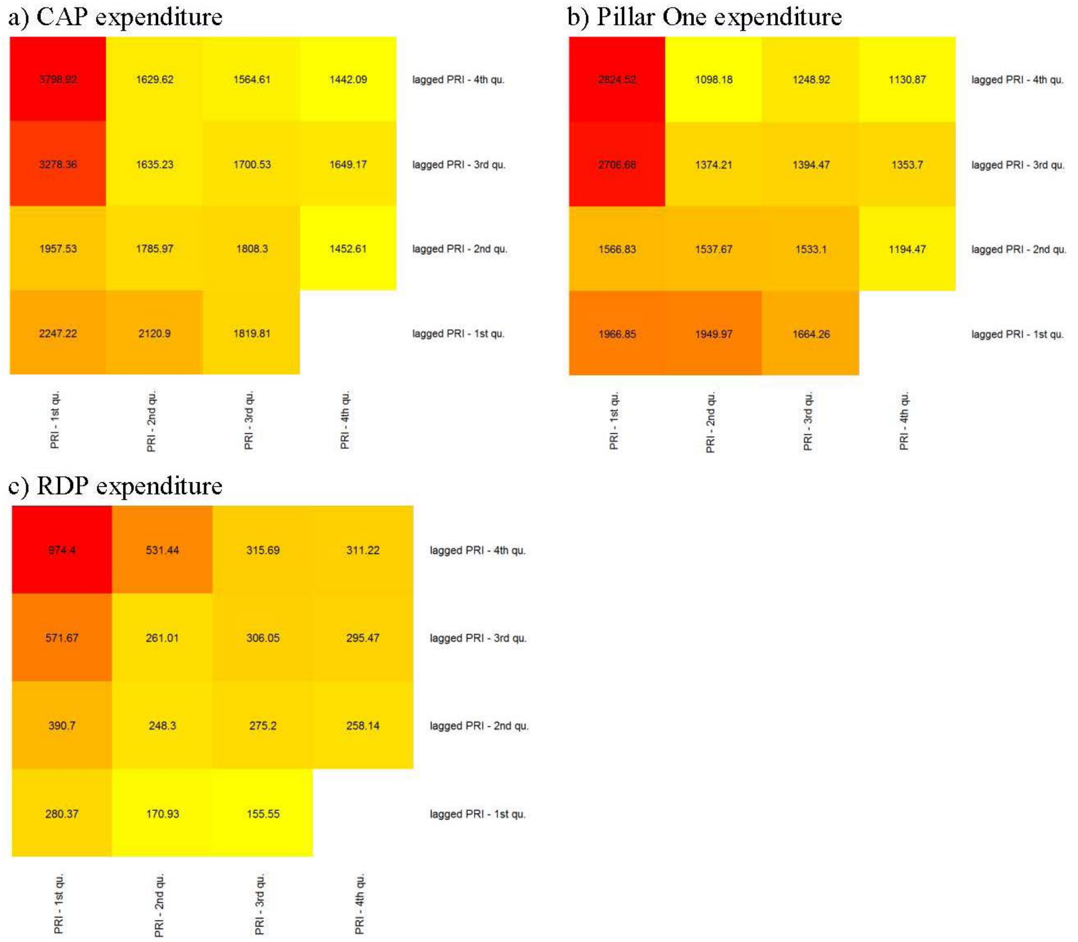
For the sake of simplicity, Figure 4 just refers to the expenditure intensity per hectare of UAA. Average

[8] Further details about adopted methodology to compute those indicators are shown in Camaioni et al. (2014).

expenditure intensities of total CAP, of Pillar One and of Pillar Two are returned for each of the aforementioned urban-rural typologies[9]. These results represent a refinement of previous studies. They confirm that urban regions are generally more supported than rural ones throughout the EU. Nevertheless, some specific typologies of EU urban regions appear to be extremely supported by the CAP (in both its first and second pillars): they mostly are very urban regions that are also surrounded by very rural areas. Results slightly change when disentangling both Pillar One and Pillar Two expenditure. Indeed, Pillar One expenditure intensity is also above the average for those regions that, although showing mixed urban-rural features, are surrounded by urban areas. On the opposite side, when focusing on RDP expenditure intensity, rural regions which are spatially close to other rural areas appear to be supported as well. By converse, all those regions that show more urban neighbours are expected to receive a lower amount of intensity support. Indeed, in this case, the least supported regions are the ones in the second and third range of the PRI quartile distribution, whose neighbours are in the first range of the PRI quartile distribution.

Furthermore, and in more general terms, even this analysis confirms the well-known compensation effect between Pillar One and Pillar Two expenditures at territorial level. Indeed, some typologies of regions that are little supported in terms of Pillar One expenditure tend to be more supported by Rural Development expenditure and vice-versa (Camaioni *et al.*, 2014).

Figure 4 – Expenditure intensity (Euro per hectare of UAA), by urban-rural typology



5. Conclusion

This paper aims to update previous works on the analysis of major urban-typologies across Europe. Moving from the composite and comprehensive PRI, computed by Camaioni et al. (2013), this paper returns 16 different urban-rural typologies, which also include information about urban- rural characteristics in the neighbouring space. Indeed, according to a multidimensional approach in defining rurality, geography plays an important role in shaping the integration (and the

relationships) between urban and rural areas. Although showing the same extent of rurality according to the PRI, two regions actually differ if the former is close to large metropolitan areas while the latter is surrounded by other rural areas. Furthermore, the returned taxonomy is definitely richer than the three urban-rural typologies suggested for instance by the OECD (2006). In fact, a more complex urban-

[9] Figures referring to alternative intensity expenditure indices are available upon request.

rural geography characterises the EU space, and policy-makers could benefit from being supplied with new enhanced tools to measure their own policies at territorial level.

Indeed, the complexity of EU geography is likely to matter in affecting the spatial allocation of CAP expenditure throughout Europe. This paper actually confirms the results obtained by Camaioni et al. (2015), which have already pointed out two major findings: the existence of a negative rural effect in the allocation of RDP expenditure (namely, the less the region is rural, the higher the expenditure intensity) and the existence of a positive spatial effect. Furthermore, by jointly considering these two drivers (i.e. rurality and space together), some more detailed results seem to be returned. Indeed, this analysis makes possible the identification of the most supported regions in Europe: they are those urban regions that are also surrounded by very rural areas. This is true for the overall CAP expenditure, as well as when considering disentangled expenditure.

Thus, the 'urban-rural integration', whose existence was found by Camaioni et al. (2015), mostly results in the allocation of additional resources to the urban areas rather than to the rural countryside. When being located close to cities and other metropolitan areas, rural regions are likely to be even weaker in their ability of attracting EU funds.

THEMATIC SET

A02 INDICATORS OF RURAL DEVELOPMENT

Session Organizer
F. Sotte | Università Politecnica delle Marche | Ancona | Italy

ABSTRACT

The first assumption with rurality measures is that the concept is not univocally determined. Rurality evolves over time and takes different features in space. As a consequence it is difficult, ifnot impossible, to find a synthetic solution for rural development statistics, suitable for all times and latitudes. The traditional indicators based on the weight of agriculture (measured in some way: rate of employment, output, etc.) or even with demographic density (as the one proposed by OECD in the Nineties and subsequently adopted by the EU and others) need to be integrated with other measures useful to help in analyzing the potential development and convergence. Two are the relevant directions for this integrations. The first takes into account and adapt to rural areas the measures of well-being. The second considers the peripherality: rural territories have different opportunities in terms of cohesion and convergence in relation to their localization close or far from urban areas and the physical and virtual connection opportunities. The aim of the session is to explore how the diversity of rural areas can be measured in the different geographical and historical contexts.

ABSTRACT

This work aims at exploiting a set of data collected from a prospective agricultural diagnosis conducted on the local authority named "Communauté de Communes de Desvres-Samer" (CCDS in Pas-de-Calais (France). Agriculture and agricultural sectors are a pillar of this land: that's why elected officials needed a precise analysis in order to adapt local policy to local needs. Based on data collected during this diagnosis, this classification intends to establish a territorial agriculture typology. Statistical and analytical processing-based, this typology has enabled to characterize more finely the landscape entities constituting the study area, with coherent farm units and similar issues. This work therefore provides a useful tool to deepen the understanding of the field reality and to guide future community's choices and territorialized action plan.

Keywords: Territorial statistical classification, diagnosis, data analysis, decision support tool

PAPER

1. Introduction

Territory development issues evolved from a local level to transversal approaches, which transformed process from a simple plots to multifactorial classification methodologies. Local urban masterplans ("Plan Local d'Urbanisme Intercommunal" - PLUI in French) are development tools built through a co-constructed and shared territory project. Besides the cadastral management, it is important for the concerned community to act on all components of its territory, whether in the environment fields, living environment, or economy (any activity sector including agriculture). Indeed, local urban masterplans require communities to achieve common agricultural diagnostics, to characterize local agriculture and to identify weakness sources (urbanization, for example), Melot (2009), Martin (2006).

Working on regional agriculture knowledge, GRECAT[1] laboratory has built from its multidisciplinary skills, its own analysis and regional foresight tool: the OPCRA®[2], several times amended since its inception, in order to fit to local authorities expectations.

In the context of CCDS agricultural diagnosis, GRECAT realized statistical data analysis to better exploit collected territorial information. In next section, a brief contextualization of this area is needed.

With 31 communes, the CCDS, territory of "Caps et Marais d'Opale" regional natural park remains mainly rural (fewer than 100 inhabitants/km2 and 250 farms in 2013). However, CCDS is close to the coast and various urban centers, which makes it an attractive region and causes suburbanization at the cost of agricultural lands. A strong agribusiness presence (Novandie Andros group) explains the major economic position of agriculture, with 20% of local jobs and over 30% of local businesses related to agriculture. Moreover, dairy farming is predominant in this territory, with almost 71% farms concerned in 2013 with a milk total production of 60 million liters (5% of regional production). This explains the bocage landscape: nearly 31% of total CCDS area were grassland in 2009 and almost 1 151 km of hedgerows were identified in 2012. Beyond loss of land, this landscape is threatened by serious difficulties in the dairy sector (e.g. milk price volatility, particularly given that production costs are high in this type of territory). Thus, nearly 38% of dairy farms have doubts about their medium-term life, which would imply a weakening of territorial dairy industry and impacts on environment and landscapes territory.

It is therefore essential for this territory to find appropriate responses to maintain its rural and agricultural character. Even if milk farming is dominant, other agricultural systems are observed too, which demonstrates the link between agriculture systems, environment and territory. Then, it was necessary to take into account these local disparities by crossing spatial and statistical approaches in order to provide appropriate and relevant recommendations.

[1] Research and concerted studies group on agriculture and territories in Nord-Pas-de-Calais (HEI-ISA-ISEN group).
[2] Permanent Observatory of rural and agricultural change.

The issue is to demonstrate coherent agricultural entities, which defined using a data segmentation tool based on collected information during surveys of farmers.

2. Materials and methods

The aim of this work is to develop a communal farm typology of the CCDS. Indeed, the study produced a large amount of data. This database is a valuable source to divide the whole territory by the most representative agricultural indicators.

2.1 Survey and collecting data

In the literature, the agricultural typologies are often based on two types of methods: Those based on surveys, Perrot (1990), and those resulting from an analytical and statistical processing of existing data, Ilari & al (2003), Trouve & al (2004), Alvarez-Lopez & al (2008).

For this study, data was collected through surveys conducted face-to-face with farmers. This choice resulted from the absence of complete and updated data characterizing the territory, and from the need of local authorities to understand local agricultural issues (land data, for example).

The study was conducted from November 2012 to December 2013. Preliminary work began with a literature review and interviews with resource persons whose activities cover CCDS. All these territorial actors have also been regularly consulted through technical committees (e.g. agricultural commission) in order to monitor the study (in co-construction scheme). Other actors (economic actors, consumers, agricultural industries ...) have been also associated to improve the competitiveness of territorial agriculture and its various sectors.

After those preliminary steps, all farmers have been interviewed about their farms and territorial issues: 348 famers involved in 250 farms located in 31 municipalities.

The final questionnaire fit to various CCDS' expectations: make an inventory of territorial agriculture (past, current and future dynamics), identify strengths and weaknesses of the local agricultural sectors, highlight causes of farmland fragilities in some sectors and finally suggest territory evolution scenarios which better consider agriculture. The questionnaire was based on both quantitative and qualitative data collection, but also on parcel data. A significant variables number was collected, however, only 40 were used in the quantitative analysis (Table 1). All Open questions were excluded, as well as closed questions with too few responses.

Table 1: Summary of variables used for statistical analysis

Quantitative variables	Qualitative variables
- Farmer Age	- Farmer gender, marital status
- UAA (utilized agricultural area)	- Commune name
- Agricultural work unit (AWU)	- Farming type
- Milk Quota	- Landscape category
% fruit, market gardening	- Status : individual, societary
% industrial crops	- Direct selling: presence, types, forms…
% animal farm turnover	- Acces to property
% vegetal farm turnover	- Financial health
% cereals, oilseeds and protein crops	- Succession in 10 years
% grassland area % woodland area	- Permanent and temporary grassland
	- Diversification: activities, interest …
	- Membership structures (cooperatives, syndicates…)

2.2 Data analysis methodology

Before analysis, a preliminary step of validation was performed in order to check data coherence and ensure information quality (outliers, missing data ...).

Statistical analysis was structured around the factorial multivariate statistical methods, Izenman (2008). The interest of such methods is their powerful ability to synthesize a large mass of data and identify significant relationships between discriminating variables. These approaches have also proved effective in various agricultural issues, Choisis & al (2012), Debeljak & al (2007).

In this work, three main methods were used.

A. Principal Component Analysis (PCA). This technique allows a simple description of a complex reality. In other words, it can extract the maximum information from a large number of quantitative variables and draw conclusions on these variables and associated individuals. Another - essential - objective is to identify the most relevant variables that characterize individuals from the whole variables set in order to optimize statistical analysis results. The last aim is to eliminate redundant variables and data without significant effect on the overall problem variability.

B. Multiple Correspondence Analysis (MCA). As for PCA, MCA aims to graphically represent a large set of data (qualitative in this case) by reducing problem dimensions. This method is also useful because it highlights the relationship between the terms of used variables. PCA and MCA techniques will serve as "pre-classification" stages as they bring out the most characteristic variables of the desired typology. These variables will be used as input data for the classification stage.

C. Hierarchical Ascendant Classification (HAC). An iterative classification technique that may -according to the quality of the input data - get a partial or complete typology of analyzed individuals, based on their most relevant indicators. This method involves building a partition of the population into homogeneous clusters (low within-variability) which are different the ones from the others (high between-variability).

The expected objectives with this analysis scheme are summarized as follows:

- Highlight communes with farmers groups showing similar characteristics, and determine homogeneous agricultural entities;

- Compare these agricultural entities with landscape categories previously established by CCDS;

- Highlight the main agricultural characteristics of each entity.

- Identify agricultural issues and actions related to other dimensions such as environment and landscape. There is obviously a strong link between agriculture, economy, environment and landscapes on the CCDS;

- Identify priority areas in terms of difficulties to optimize needed actions.

In summary, this both additional analytical and decision making tool is the subject of this work, which is also dedicated to help CCDS to develop a rational and efficient agricultural policy.

3. Results

The methodology described in the previous section achieved a territorial farmers classification (and therefore the associated farms). Moreover, six classes have been obtained, all 348 farmers and 250 farms have been categorized. The size and the name of each class are detailed in Table 2 below. Moreover, a synthesis of the characteristics associated with each class is provided in Table 3.

Table 2: Distribution of farmers number per class

Farmers number per class	
Class 1 = Landscape 1 : « Coeur du territoire » in French (CT)	43
Class 2 = Landscape 2 : « Plateau Ouest et vallée de la Course » in French (POVC)	80
Class 3 = Landscape 3 : « Basse vallée de la Liane » in French (BVL)	25
Class 4 = Landscape 4 : « Clos du territoire et moyenne vallée de la Liane » in French (CTMVL)	63
Class 5 = Landscape 5 : « Fond de la boutonnière, la porte du bocage » in French (FBPB)	78
Class 6 = Landscape 6 : « Seuil Nord du territoire » in French (SNT)	59

The statistical analysis produced a very similar classification to six landscape entities characterizing CCDS (Figure 1). Differences are related to one or two farms located in "Le Wast" (attached to class 4) or "Desvres" (attached to Class 2). These small differences are explained by the fact that those two municipalities only have one farm, whose characteristics belong to other classes. Also, it should be noted that "Longueville" municipality is not attached to any class because no farm was based there.

Figure 1 – Comparison between the obtained typology and landscape categories

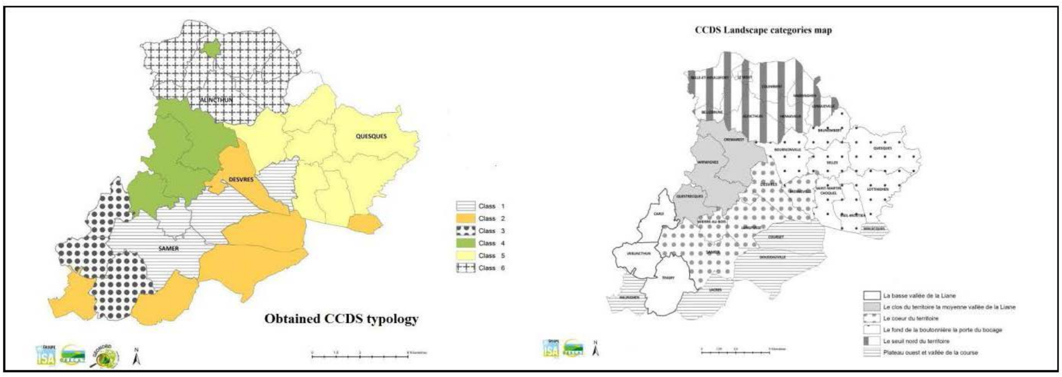

Table 3: Obtained classes characteristics

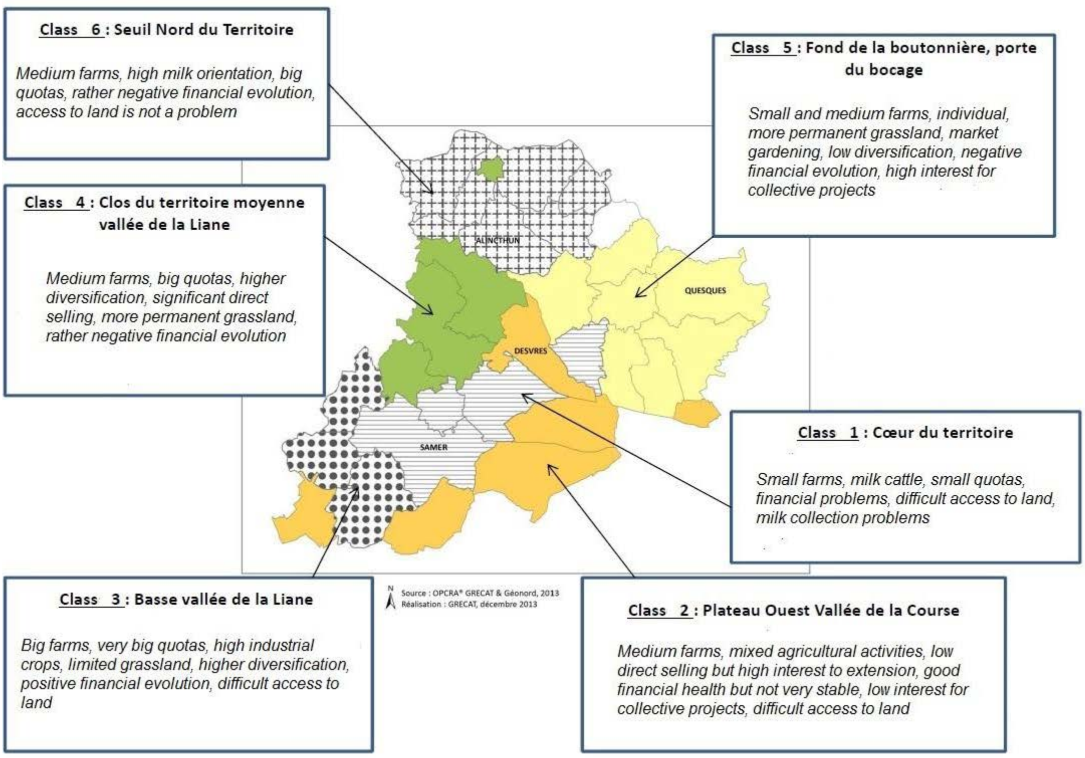
Criteria	Class 1	Class 2	Class 3	Class 4	Class 5	Class 6
size	43	80	25	63	78	59
Farming	Milk cattle	Milk cattle, mixed culture	Milk cattle, milk or meat + aboveground	Milk cattle, mixed culture	Milk cattle, mixed culture	Milk cattle, milk or meat + aboveground
Landscape type (in french)	CT	POVC	BVL	CTMVL	FBPB	SNT
Status	Individual	Societary - individual	Societary	Societary - individual	Individual	Individual
UAA	Small	Medium	Large	Medium	Medium	Medium
Direct selling (DS)	Medium	Low	Medium	High	Low	Medium
Diversification activities	Medium	Medium	More frequent	Less frequent	Less frequent	Medium
Land access problems	Yes	Yes	Yes	Medium	Medium	No
Agricultural work unit (AWU)	Medium	Medium	High	Medium	Medium	Medium
% Woodland area	High	Low	Medium	Medium	Medium	Medium
% cereals, oilseeds and protein crops	Medium	High	High	Medium	Medium	Medium
% Grassland area	Medium	Low	Low	Medium	Medium	Medium
% industrial crops	Low	Low	High	None	None	Low
% fruit, market gardening	Low	None	Low	Low	High	None
Dairy livestock	Low	Medium	High	High	Medium	High
Milk quota	Low	Medium	High	High	Medium	High
% Vegetal farm turnover	Low	Medium	High	Low	Low	Low
% Animal farm turnover	High	Medium	Low	High	High	High
Financial health	Medium	Good	Good	Medium	Medium	Medium
Financial evolution	Stable	Stable	Improved	Degraded	Degraded	Degraded
Collective projects interest	Maybe	No	No	Maybe	Yes	Maybe
Succession	Yes	Not concerned	Not concerned	Not concerned	Yes	Not concerned

Following this classification, it was possible to extract the most significant features of each class. The mapping of Figure 2 summarizes the most important indicators of the obtained typology.

Figure 2 – Significant characteristics of obtained typology classes



For example, class 5 has a weakened farms structure (compared to Class 3) with a large dependence on livestock farming. Thereby, grasslands are very important for agriculture and landscape identity. Moreover, these farms are rather "isolated" from the rest of CCDS (very rural area with few farmers' market).

Therefore, solutions that could be developed through an action plan supported by CCDS, could be the following (some measures could also be applied for other classes):

- Regulate afforestation (in progress in some communes);

- Assist farmers in the development of local agricultural production valuation, which could be part of existing procedures (collective points of sale or local farm networks);

- Discuss with farmers about workforce sharing strategies;

- Promote the use of "non-agricultural" products such as hedgerows to establish local wood energy industry.

4. Conclusion

Performed according to the specific requirements of the used statistical methods, this obtained statistical territorial typology provides an innovative vision for the studied territory. Indeed, it highlighted six agricultural geographic areas, which finely describe the similarities and differences within CCDS. Moreover, the similarity between the obtained typology and landscape categories consolidates the former CCDS' work, which were primarily based on empirical criteria. The statistical approach being more rigorous, it helped to enhance the contours of this territory by marking a link between landscape entity and agricultural type.

However, the undertaken work should go on as this typology will be only meaningful if it is facing the territory reality. Based on the obtained results and following a "decision support tool" methodology, an operational approach based on targeted actions will validate conclusions of this study. It will also open the way for further reflection on the possible extension of this work in other geographical areas, with as a possible outcome, obtaining a real statistical agro-territorial modeling tool.

Living in the countryside of Tuscany: are they really better off?

S. Turchetti | IRPET | Florence | Italy

DOI: 10.1481/icasVII.2016.a02b

ABSTRACT

Rural Tuscany is commonly considered as a delightful place characterized by natural and cultural amenities and widespread wellbeing. However, the possible differences at sub-regional level in terms of socio-economic conditions, available opportunities and access to services have not been enough investigated so far. Moreover, the changing picture of the countryside in Tuscany – decreasing agricultural areas and number of farms, depopulation, ageing – might have affected the standards of living of population and the motivations for staying there. This paper is a first attempt to assess the state of wellbeing in the different rural areas of Tuscany from a multidimensional perspective. The results of this study show that large differences still persist among different areas of the same region. First of all, a process of convergence between rural and urban areas is still far to come. In some rural areas, in particular the more agriculturalintensive, the rates of growth of income are positive and the distribution is fair; however, there are other rural areas where incomes have been decreasing over time together with a deterioration of the distribution. Moreover, job opportunities are scarce and the provision of public services is still insufficient. This further fuels dynamics of social exclusion, which might be triggered by the possible process of re-centralization of public services because of budget constraints.

Keywords: wellbeing, rural development, small areas, Tuscany

PAPER

1. Introduction

Rural Tuscany is commonly considered as a delightful place characterized by natural and cultural amenities and widespread wellbeing. Per-capita income in Tuscany is above the national average, the same as the per-capita expenditure on social services (ISTAT, 2012). However, the possible differences at sub-regional level in terms of socio-economic conditions, available opportunities and access to services – in other words, in terms of wellbeing - have not been enough investigated so far. Moreover, the changing picture of the countryside in Tuscany – decreasing agricultural areas and number of farms, depopulation, ageing – might have affected the standards of living of population and the motivations for staying there.

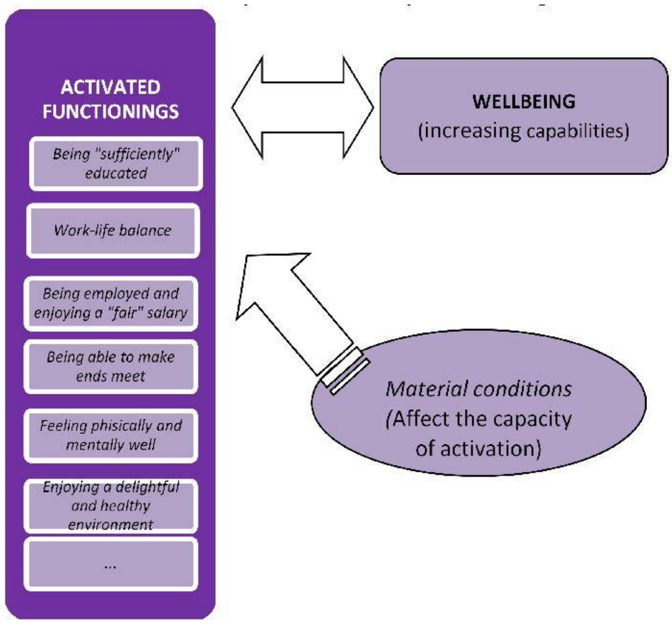
The definition and evaluation of wellbeing is the subject of a large debate among the social scientists (CNEL-ISTAT, 2012; Giovannini e Rondinella, 2011; Stiglitz et al., 2009; Alkire, 2008; Atkinson et al., 2008) and policy makers. Since 2012 the Italian National Institute of Statistics (ISTAT) issued the report about the conditions of fair and sustainable wellbeing in Italy, with the aim of combining the traditional economic measures, based on income and consumption, with some social and environmental indicators (ISTAT-CNEL, 2013). Traditionally, economists have measured the overall level of the standard of living in terms of accumulation of either resources or the utility that can be drawn from it. As stressed by Sabine Alkire (2008), "Many resources are not intrinsically valuable; they are instrumental to other objectives, yet the quality of life arguably depends not on the mere existence of resources but on what they enable people to do and be".

Therefore, the potentials for the conversion of these resources into wellbeing differ across individuals, their own personal characteristics and history and they are inevitably affected by the institutional surrounding. As shown by Stiglitz, Sen, & Fitoussi (2009), the factors shaping the wellbeing of people often depend on circumstances and they are not the product of a rational process based on individual preferences. As a result, perceptions about his or her state of living might be very different from an objective evaluation of it.

The aim of this paper is to assess the state of wellbeing in Tuscany from a multidimensional perspective. Wellbeing is conceived in terms of increasing capabilities, which can be defined as the ability of a person to widen its own available opportunities (functionings) depending on the socio- economic and political conditions of the context (see Sen 1998). Since the political dimension is excluded from the overall analysis[1], the paper focuses on the activated functionings, which are the set of life conditions truly achieved and observable.

As shown in fig. 1, a definitive list of the activated functionings cannot be easily defined and it is widely data-driven. However, the figure reports some examples and highlights that material conditions (as might be described using the standard economic indicators on incomes, inequality and poverty) positively affect the ability of activation of a person or a household but per se they do not improve wellbeing.

Figure 1 – Theoretical framework of wellbeing



Source: Author's own elaboration

In the following paragraphs, wellbeing in the rural Tuscany will be described in terms of both material conditions (section 3) and quality of life aspects (section 4). The latter refer to employment opportunities, with a focus on gender-driven asymmetries (section 4.1), education (section 4.2) and health and environmental conditions (section 4.3).

The analysis is carried out at the small area level (municipality), comparing five groups of municipalities with different level of urbanisation and variable features of the rural context (section 2). The empirical analysis is mainly based on the European Union Statistics on Income and Living Conditions (EU-SILC), which is a database of both cross-sectional and longitudinal multidimensional microdata on income, poverty, social exclusion and living conditions. It replaced the European Community Household Panel (ECHP) in 2004, because of the need for a more harmonized sample design among the Member States. The sub-regional focus adopted in the present study is supported by the use of proper statistical methodologies (section 2) yielding results which show an acceptable degree of reliability. Furthermore, with the aim of extending and supporting the results of our analysis, the evidence from the EU-SILC dataset has been compared with other primary and secondary sources of information on well-being available at the sub-regional level (e.g. administrative records on provision of education and health services, section 4).

The combination of the use of microeconomic information on wellbeing with the small territorial scale of the analysis is the main contribution of this study from a methodological point of view. Indeed, the smaller the territorial scale of the analysis, the greater the relevance of a multidimensional concept of wellbeing for policy design. The link between the features of rurality and the level of wellbeing is a further original aspect of the study. The practical relevance of the analysis is closely connected to the next 2014-2020 European Rural Development Policy, which, among other things, should provide measures to support "social inclusion, poverty reduction and economic development in rural areas". By extension, the study suggests a possible research path in applied socio-economic analysis supporting policy decision making at the small area level.

1 The political dimension has to do with the degree of available freedom, which allows for a larger set of capabilities. Since the territorial level of analysis is sub-regional, it would be very difficult to assess the differences in terms of freedom, which is reasonable to say that mostly depend on the socio-economic conditions of the territories rather than different political ones.

2. Data and methods

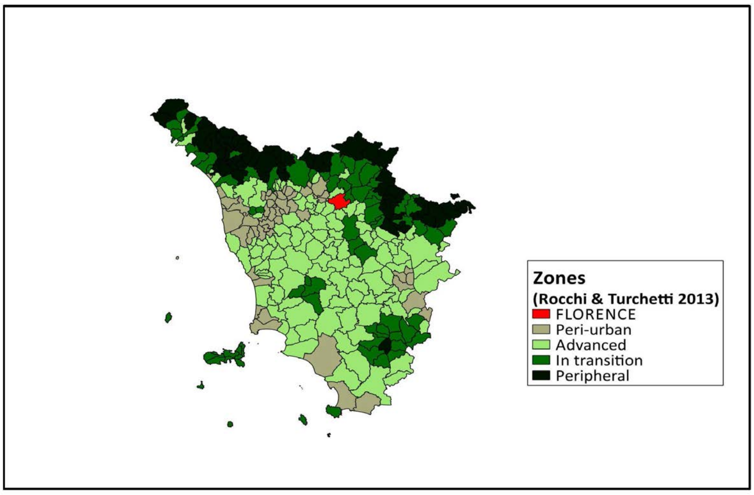
Measuring wellbeing at sub-regional level involves several methodological problems relating to data availability, characterization of territories on the basis of cross-cutting factors (zoning) and identification of relevant variables for quasi-symbiotic small areas. In this study rural and urban areas have been previously classified in a study carried out at the level of municipality (Rocchi & Turchetti, 2013) and clustered on the basis of four main dimensions:

- Urban function, which refers to the relative importance of residential vs. productive use of space.
- Territorial vocation, which highlights the role played by the agricultural sector and the limits imposed by the natural and human constraints;
- Demographic dynamics and commuting, which have an impact upon the use of space and, at the same time, are affected by the economic activities carried out on a territory;
- Productive specialization, which refers to the distribution of productive activities by sector of both employment and produced value added.

The classification of 287 Tuscan municipalities has been done by implementing a cluster k-means analysis, which allowed to a-priori choose the number of areas.[2] As shown in the map below, there are five different zones. Florence and the peri-urban areas are concentrated at north, along the route which carries to the sea. They are characterised by high urban functions and widespread tertiarization. The characteristic attractiveness of peri-urban areas, because of the cheaper housing especially for younger households, and the resulting widespread ageing and depopulation of Florence, are the main differences between Florence and the peri-urban areas.

The other three zones are characterised by low urban functions and, in general, widespread ageing. However, the advanced rural, which accounts for the highest number of municipalities, shows a more modern and stable agricultural sector, with a higher level of entrepreneurship[3]. The high level of entrepreneurship in agriculture depicts the rural in transition too, which is also characterised by a pervasive non-agricultural use of non-urban soil, the presence of several industrial districts and touristic and cultural amenities. Finally, the municipalities of the peripheral area are characterised mainly by natural constraints and high environmental protection (natural parks and protected areas) since they are located nearby the Apennine Mountains. Because of the shortage of productive activities and employment opportunities, apart from some well-developed rural touristic activities and traditional agriculture, ageing and depopulation are widespread.

Figure 2 – Classification of municipalities



Source: Rocchi & Turchetti 2013

Even if the classification satisfactorily discriminates for the functions of each territory, it does not say anything about the wellbeing of people. In order to evaluate it, we use as the main data source EU-SILC. EU-SILC survey is composed of four questionnaires, two at household's level (so called "primary sampling units", PSU) and two at individual level (so called "secondary sampling units", SSU). The units are selected on the basis of a national representative design, which assigns them "a known and non-zero probability of selection" (Eurostat, 2009, p. 22) for both the cross-sectional and the longitudinal data. For Italy the minimum effective sample size is 7250 households (5500 for the longitudinal component) and 15550 individuals (11750 for the longitudinal component).

[2] The number of areas has been a-priori chosen because the mentioned study updates and develops a previous analysis carried out by Rocchi and Caselli (2006).

[3] The entrepreneurship index used in the analysis is an updated and simplified version of the index proposed in (Rocchi and Stefani, 2005).

EU-SILC sample is designed for comparisons between states or administrative regions and not between areas at sub-regional level. However, the sub-regional focus might suggest valuable uses of data whether measures of interest are estimated by using proper weights and they vary within acceptable ranges.

There have been attempts of oversampling at the sub-regional level (Province of Pisa) with the aim of estimating more reliable indices of wellbeing (Pratesi & Coli, 2009) as well as attempts of estimating the variables of interest from covariate information from census of population (Giusti, Pratesi, & Salvati, 2009). Given the limited number of areas considered in this study and the difficult search for reliable covariates, we followed a different approach, based on the direct estimation of the measures of interest by post-stratifying the observations into the areas. In order to report the sample units to the universe, a proper weight has been calculated as:

$$Wnew = \frac{db090}{\sum_{i=1}^{5} db090} \sum_{i=1}^{5} HH$$

Whereas db090 is the EU-SILC household cross-sectional weight (db090) and $\sum_{i=1}^{5}$ HH is the total number of households by area (source: *Demostat*). As shown in the

Tab. 1, some areas are overrepresented –the rural and peripheral and in-transition areas – while Florence is underrepresented. Despite these differences, the distribution of the sample along the five zones is quite similar to the actual one:

Table 1: Total number of households by area, 2009

	Total number of households	%	Total number of households sampled	%
Florence	181944	11,36	135	9,32
Peri-urban	428852	26,78	369	25,48
Advanced	636961	39,78	547	37,78
In transition	283324	17,69	287	19,82
Peripheral	70312	4,39	110	7,60
TUSCANY	1601393	100	1448	100

Source: Author's own elaboration from Demostat and EU-SILC

The Tab. 2 reports the number of households sampled by area over the available years of the survey:

Table 2: Number of households sampled by areas, 2004-2009

	2004	2005	2006	2007	2008	2009
Florence	178	116	125	119	140	135
Peri-urban	477	414	409	381	389	369
Advanced	701	648	636	626	556	547
In transition	333	318	293	279	307	287
Peripheral	62	64	62	84	103	110
TUSCANY	1751	1560	1525	1489	1495	1448

Source: Author's own elaboration from EU-SILC

In order to assess the reliability of results, we have calculated the standard error of estimates through a bootstrap procedure. This procedure allows to "resample" with replacement from the sample data at hand thus "artificially" broadening the represented population in order to better approximate the distribution of a statistic and obtain proper standard errors (bootstrap SE; see Singh & Xie, 2009). Some of the estimated bootstrap SE are reported in the following sections, showing an acceptable degree of reliability of results.

3. The material conditions of rural areas

As shown by Amartya Sen, the economic dimension of wellbeing is not a goal per se but it should be assumed as a mean to enlarge the available set of opportunities (see fig. 1). The exploitation of these opportunities and the increase in the level of wellbeing depend on both exogenous (environmental factors) and endogenous conditions (personal characteristics and choices) affecting the more general quality of life. In a market-based economy the importance of the income level is supposed to be higher given the relevance of the private sector in providing goods and services.

The 2009 EU-SILC data show that, overall, more than two thirds of people say to difficultly meet their monthly needs. The situation is considerably worse in both the peripheral and the rural advanced areas, where the share of people in trouble amounts, respectively, to 81% and 78%. Conversely, in Florence they are only half of the total population. The Tab. 3 somehow confirms these picture but with some variations when considering different kind of purchases. For example, people living in both the advanced rural and the peripheral areas show major difficulties to pay for basic services such as school and health, which might suggest that the provision of public services to marginal areas is somehow troublesome.

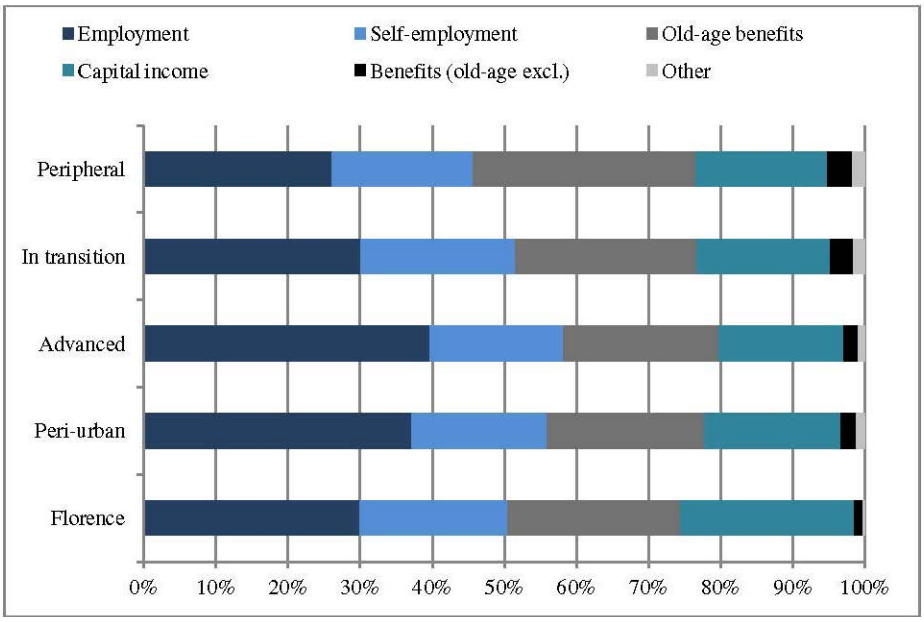
Table 3: Share of households who responded not to have enough money for the listed expenses, 2009

In the last 12 months, there have been any moments when your family did not have enough money to purchase:	Florence	Periurban	Advanced	In transition	Peripheral
CLOTHES	11,09	11,15	14,20	11,30	15,36
FOOD	6,54	4,33	6,02	4,71	1,88
HEALTH	9,14	8,97	10,30	7,11	4,39
SCHOOL	2,85	4,93	4,30	5,72	11,18
TRANSPORTS	8,50	6,47	8,06	5,08	3,63
TAXES	9,08	11,73	9,77	7,43	3,63

Source: Author's own elaboration from EU-SILC

The main sources of income in each area in 2009 are reported in Figure 3. As expected, income from employment is the first source of income almost everywhere, except for the peripheral area where about one third of the overall income is represented by the old-age benefits. The situation is similar in the rural in transition, where 30% of income comes from employment and 25% of income from old-age benefits. At the opposite side, there are the cases of both the peri-urban area and the rural advanced, where income from employment is almost 40% of the total income, while the oldage benefits are remarkably low (about 21%). Capital income is a relevant source of income only in Florence, where it represents about one-fourth of the total income.

Figure 3 – Main sources of income, 2009



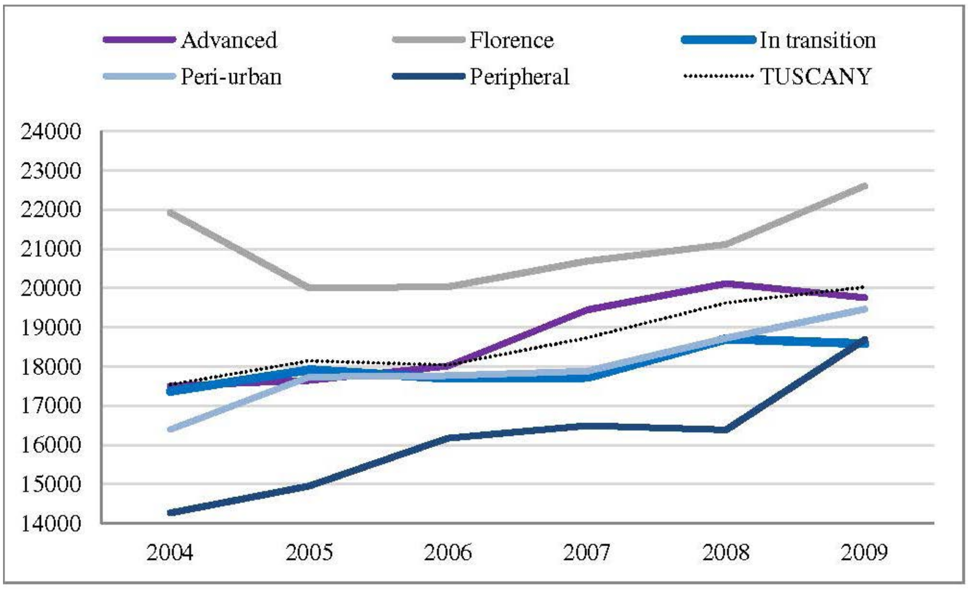
Source: Author's own elaboration from EU-SILC

The EU-SILC survey reports the disposable incomes of households including employee and self-employee incomes, pensions, social benefits and other cash transfers and any kind of other incomes, such as capital incomes (Atkinson & Marlier, 2010). The disposable income is indeed corrected by a within household non-response inflation factor and the household size[4] thus returning the equalized disposable income (EDI) which has been used for the next analysis:

EDI= (total disposable HH income* within HH non-response inflation factor)/HH size

The trend of EDI by area over the years 2004-2009 is shown in the Figure . On absolute terms, the municipality of Florence is the richest ever, even if over time the slope of the curve tends to flat. Both the peripheral and the peri-urban areas show the highest rates of growth (31% and 19%, respectively); while the trend of the rural in transition is almost steady, with no relevant increase over the years. As a consequence, in 2009 the rural in transition turns to be the poorest area of the region.

Figure 4 – Trend of EDI, 2004/2009



Source: Author's own elaboration from EU-SILC

In general, the bootstrap SE of estimates is always higher in Florence and in the peripheral area, because they are, respectively, under and over-represented. However, in the case of Florence this must be due also to the large variability of income because of a more uneven distribution.

Table 4: Average EDI and bootstrap SE, 2004/2009

	Florence	Peri-urban	Advanced	In transition	Peripheral	TUSCANY
2009	22609	19462	19757	18584	18687	20025

Source: Author's own elaboration from EU-SILC

The best combination between a good level of income and a fair distribution occurs in the rural advanced, where the mean EDI is on the regional average and the distribution of income is quite even. On the contrary, the rural in transition and Florence show the highest levels of inequality (Gini index =

[4] In term of equivalent adult members, according to a proper equivalence scale. Both household size and non-response inflation factor are provided by Istat together with the sample.

0.31, above the value of the index calculated for the whole region)[5].

Finally, we set the same poverty line[6] for all areas (60% of the median EDI of Tuscany: 10692č) in order to estimate some poverty indicators. As shown in the Tab. 5, the rural in transition is by far the poorest area with 21% of people below the poverty line, followed by the peripheral area (19%)[7] and the peri-urban area (18%). The poverty gap index (FGT1) measures the distance between the incomes of the poor and the poverty line and it is the minimum cost of eliminating poverty (as a share of the poverty line). This index is particularly useful from a policy perspective because it returns the exact amount of benefits which should be provided on average to each households lying below the poverty line. Therefore, in Tuscany each household should receive about 444čin order to fill the poverty gap, even if they ought to be differently distributed among areas. Since the rural in transition accounts for the largest share of the poor, each household should receive about 637č, followed by those living in the peri-urban area (514č).

As stressed by the World Bank (2005), the design of the policy targeting is the preliminary condition to any strategy of poverty reduction. The main problem with the poverty gap index is that it does not account for the inequality level among the poor; therefore, if the income of a household with a small poverty gap improves, then the poverty gap index improves proportionally even if inequality among the poor has increased. The poverty severity gap index (FGT2) weights more the incomes falling far below the poverty line so as to account for the inequality among the poor. Once again, the rural in transition shows the most severe gap, thus confirming that most of inequality is concentrated in the lower-middle tail of the income distribution; conversely, the rural advanced still shows the best condition (low incidence of poverty and low inequality).

Table 5: Poverty indexes, 2009 (%)

	Florence	Peri-urban	Advanced	In transition	Peripheral	TUSCANY
Headcount index (FGT0)	15.716	18.443	14.550	21.119	19.417	16.888

3.1. The quality of life in the rural areas

In this section the focus moves from material conditions to some "activated functionings". Social scientists and institutions often disagree upon what qualitative dimensions should be chosen, especially because they are always context and time-specific; moreover, the set of indicators measuring them are very often data-driven.

The next analysis is largely descriptive and tries to introduce further inputs to complete the analysis of the economic dimension of wellbeing. In particular, the following quality of life dimensions have been considered:

- Employment and gender perspective

- Education

- Health and Environment

3.2. Employment and gender perspective

Employment is a major component of wellbeing not only as a source of income but also as a central factor of psychological health and overall satisfaction with life. Conversely, it can be also a source of uncertainty and stress, especially whether temporary and almost unpaid. Eventually, even in case of permanent, satisfactory and well-paid job, it might turn to be difficult to reconcile the labour time with other life activities. This is particularly true for women, who are generally the main household's caretakers. Their unpaid work is often a substitution for an inefficient public provision of social services targeted to children and elderly people. Hence, the gender perspective is a crucial and cross-cutting

[5] The Gini index expresses the distance from a perfectly even distribution of income of the actual one. The index varies from 0 (corresponding to perfect equity, i.e., equal per capita income throughout the whole population) to 1.

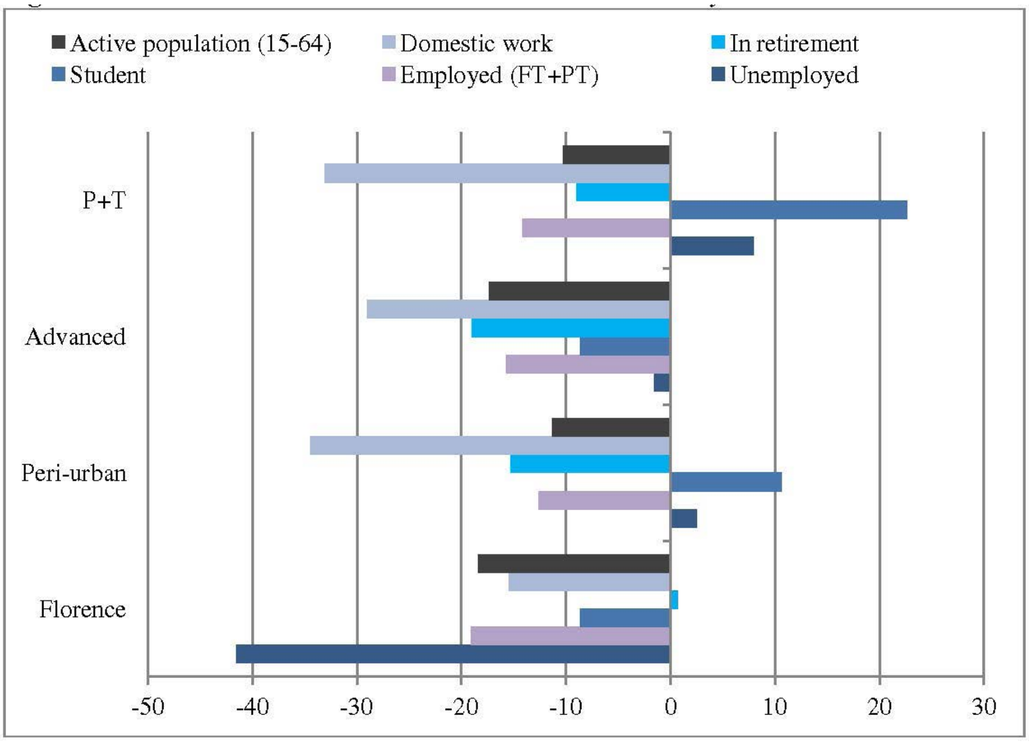
[6] Poverty line can be defined as the threshold which identifies the group of people "in poverty", thus not having enough command over resources, in terms of either income or consumption (World Bank, 2005).

[7] It must be noted that the standard error for the peripheral area is particularly high, so that the reliability of the estimation is quite low.

dimension for the description of the state of wellbeing relating to employment.

The Figure shows the percentage variations in the employment status.[8] Overall, the number of people employed decreases everywhere, with no significant differences by area. Unemployed people, instead, decline only in Florence and in the advanced rural, while increasing in both the peri-urban and the other rural areas. Such negative variations can be explained not only by improved conditions of the labour market but also by the decreasing share of economically active population. From this point of view, the situation in the rural areas is quite clear, since the number of both employed and active population decrease. Moreover, the increase in the number of students in both the peri-urban and the rural areas might be a further sign of the worsening of the economic conditions inducing young people to delay their exit from home.

Figure 5 – % Triennial variations in basic labor statistics by area, 2004/06-2007/09[9]



Source: Author's own elaboration from EU-SILC

Everywhere domestic work decreased over time. Nonetheless, it is not substituted by an increasing number of women at work and, in general, it remains a female job. In fact, the rate of employment of women decreases everywhere, except in Florence, where probably most of the active female population work (see **Errore. L'origine riferimento non è stata trovata.**6). A further difference with men is represented by one-fifth of women that are part-time employed in front of less than 4% of men. Part-time job may help women to better reconcile family needs and working time. However, it is also the heritage of the traditional division of labour within the households and the result of the lack of an adequate provision of nurseries and working hour's flexibility, factors pushing women outside the labour markets.

Table 6: Rate of employment of women by area (%), 2004/06-2007/09

	2004/06	2007/09
Florence	60,82	60,43
Peri-urban	61,32	56,55
Advanced	63,59	57,29
T+P	64,74	50,50

Source: Author's own elaboration from EU-SILC

[8] In order to obtain more robust statistics, the variations have been calculated between the mean values of two three- year periods.
[9] Because of the limited number of observations in the peripheral area, due to the large share of people in retirement, in this section the rural in transition and the peripheral area are considered together (T+P).

Hence, part-time jobs cannot be the univocal response of policy to increase the participation of women to the labour market. In Tuscany the number of public provided nurseries slightly decreased over time (-3,2% over the years 2007/11) in front of a large increase of the private services (+46%) (Regione Toscana, 2013). Even if public grants are provided in order to help households to pay for private services, they are strongly dependent on the yearly budget capacity of the local governments and on the political priorities. Moreover, the ability to pay for of each household inevitably affects the trade-off of women between extending the maternity leave (with consequent salary reductions) or further waiting for searching for a new job – thus decreasing the likelihood of re-entering the labour market – and paying for the nursery. In Florence in 2010 about one-third of kids in the 0/2 age class have been enrolled in a nursery in front of 16% laying into the waiting lists. On the other hand, kids enrolled in the peripheral area are only 10% but with a very short waiting list (1%). On average, both the rural in transition, the rural advanced and the peri-urban area show a coverage of more than 20%, but with the peri-urban area presenting a longer waiting list (7,30%).

3.3. Education

Education is one of the most important dimensions of wellbeing since it broadens the set of available opportunities by allowing people to access well-paid and less risky jobs and fostering social mobility. In developed countries the primary education is guaranteed to everybody and the differences at local level are more related to the distribution or quality of services provided and not to different policies. Moreover, in terms of job opportunities, what really makes the difference is the access to higher (secondary and tertiary) education and to what extent it meets the demand for skilled workers on the local job market.

The Tab. 7 shows that people with secondary education in 2009 survey are 40% of the sample, while people with tertiary education are nearly 20%. There are no relevant differences among areas in the distribution of secondary education, while most of graduates live in Florence and only few of them in the countryside. This explains why the largest share of farmers are not graduated (more than 90% of farmers, according with the last census of agriculture) thus highly reducing the development opportunities of the rural areas. Since their number is small, the share of graduate people in the 30/40 age class who define themselves as employed is quite higher in the rural areas.

Table 7: Secondary and post-secondary education by area (%)

	Florence	Peri-urban	Advanced	P+T	TOS
Share of active population with diploma	37,27	38,49	43,22	42,45	41,32
Share of active population with post-secondary and tertiary education	39,75	18,42	18,19	15,63	19,22
Share of people 30/40 with post-secondary and tertiary education employed	68,42	67,74	74,63	86,67	74,83

Source: Author's own elaboration from EU-SILC

The capacity of people to access higher education depends on the supply side too. While it is common that most of the universities are concentrated in urban centers and it might be desirable that people move from the place of origin to attend their courses elsewhere, when secondary schools at the territorial level are poorly supplied it is less likely that people will continue to study. For example, the number of classes out of 1000 people of the 14/20 age class is much lower in the rural areas, especially in the advanced rural and the periphery.

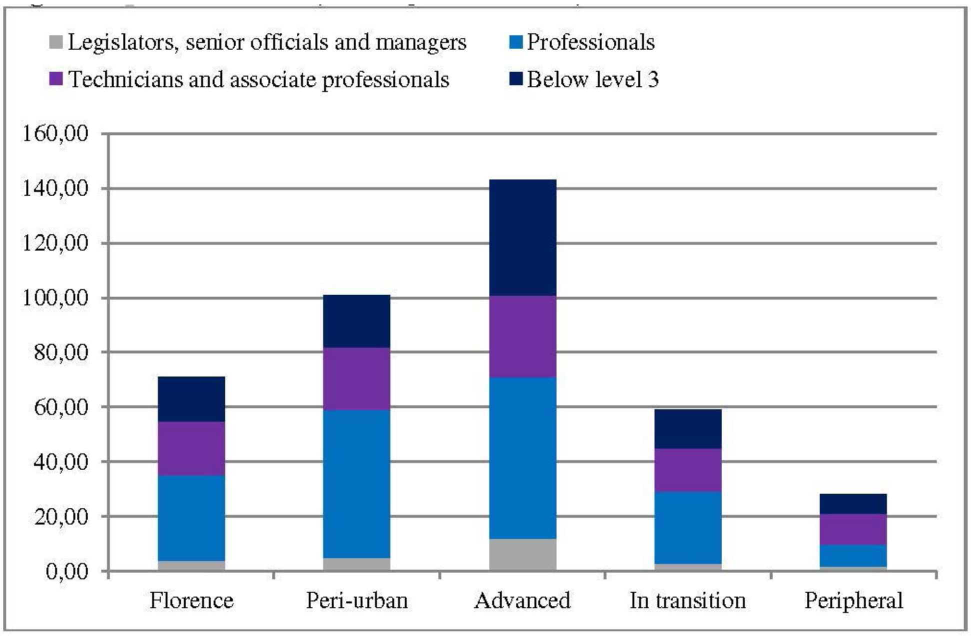
Finally, to what extent graduates find a job fitting with their educational qualifications? First (Fig. 6), one out of five of graduates claim to be unemployed. Among employed graduates, most of them are professionals (44%), followed by technicians (25%) and legislators, senior officials and managers (7%); the rest of them (about 25%) is hired as more unskilled workers fitting also undergraduates' profiles. Summing up, almost half of graduates do not find a suitable position, although there are significant differences by area. The share of professionals living in rural areas is very low since most of the services are provided in urban areas, so it is reasonable that they choose to live there. At the same time, it seems that graduates living in rural areas tend to accept more easily jobs not fitting their level of education: in rural areas the share of people doing a job which requires a lower degree of qualification (below-level 3) is higher with respect to urban areas.

3.4. Feeling good, the access to health services and the environmental conditions

A good state of health is the pre-condition to the overall wellbeing and the ability to live an active life. In 2007[10] more than two third of the sample declare to enjoy a very good or good state of health even

[10] Since 2008 the EU-SILC health module is no longer available.

Figure 6 – ISCO*ISCED by area (post-secondary education)



Source: Author's own elaboration from EU-SILC

if men are more satisfied than women; this datum is almost the same in any area, while most of the differences concern the share of people not feeling good. Overall, approximately 10% of people claim to be in a very bad or bad state of health. The largest share of them lives in Florence (16%), followed by the advanced rural (10%) and the peripheral area (9%), while both the residential area and the rural in transition show the lower shares (8% and 7%, respectively). However, the distribution of responses by sex is more uneven in all the rural areas: for instance, in the rural in transition 10% of women claim not to feel good in front of 4% of men.

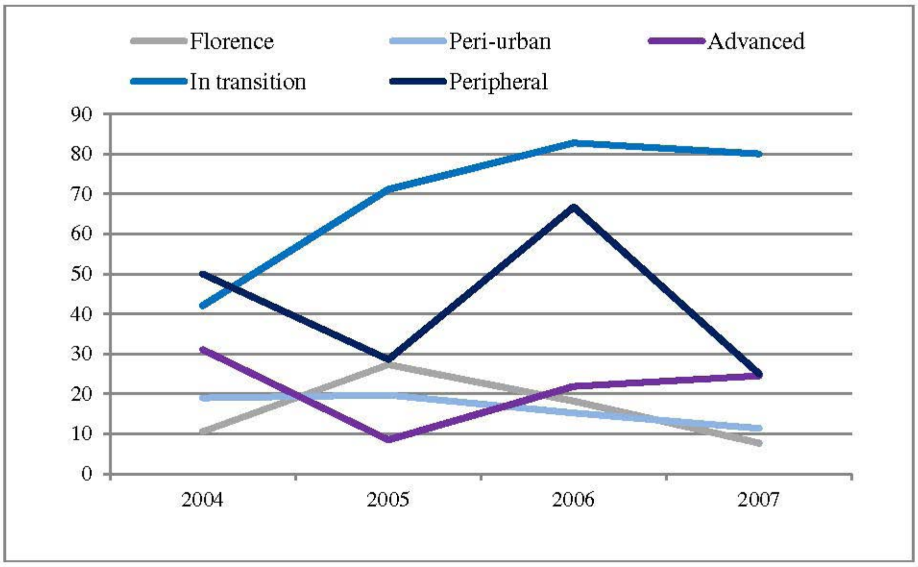
The state of health of a person depends on personal characteristics, especially age, so it is not surprising that areas with younger population claim to feel better. However, there are some other factors affecting health, namely the access to health services and the conditions of the environment where people live. Available data about health services (data source: Minister of Economic Development) confirm that both the peripheral area and the rural advanced have more difficult access to health services because of the limited number of places into the hospital with respect to the population. While in Florence they are 8,38/1000 inhabitants, in the peripheral area they are only 1,74 and in the advanced rural they are 2,86. Both the rural in transition and the peri-urban areas are in the middle. Moreover, the access to more advanced health services might be further hindered by poor infrastructures.

In order to understand to what extent people are really bounded in accessing health services, we provide some trends from the 2004-2007 EU-SILC health modules (Fig. 7). In 2007 people who responded not to have met the need for a medical examination or treatment are 198, about 5% of the whole sample; this share remains quite stable along the yearly surveys. 38% of them live in the rural in transition, followed by the peri-urban area (27%) and the rural advanced (25%). The main reasons why they did not meet the medical examinations or treatments concern either the long waiting lists (41%) or the inability to afford it (31%). Figure 7 shows the trend of the shares of people not meeting their medical needs because of the long waiting lists. In 2007 the number of people reporting this answer in the rural in transition is three times higher than 2004; elsewhere, it remains quite steady, except for the peripheral area where the trend is rough, with slight decreases in both the urban areas.

The picture changes when it comes to consider the ability to pay, which seems to be perceived as a problem especially in the urban areas, where about half of the total urban population report this answer (Fig. 8). However, since waiting lists are not reported as a problem, as well as the supply of health services, it is suggested that these answers have more to do with much specialized treatments not covered by public health services.

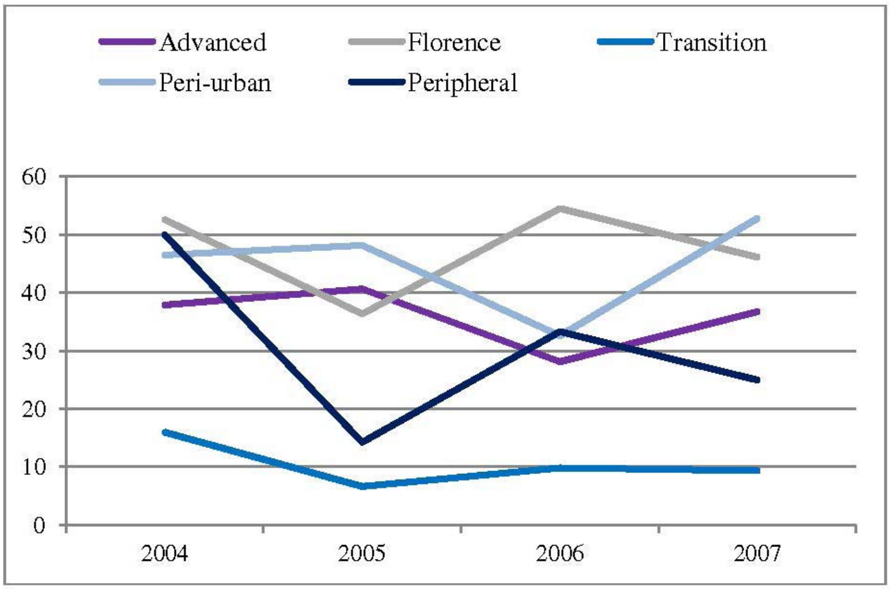
This suggestion would need further studies to be confirmed. We show some data about the distribution of the Avoidable Mortality Rate (AMR) by area, provided by the Regional Agency for Health of Tuscany (Agenzia Regionale di Sanità della Toscana – ARS). The AMR can be defined as the share of "unnecessary, untimely deaths" (Rutstein et al.,1976) which can be avoided through primary prevention, early diagnosis and hygiene & health care. While there are no significant differences in terms of diagnosis and only limited differences for hygiene and health care, the AMR due to scant prevention is higher in both peripheral and peri-urban areas and less in the rural in transition (Fig. 9). Differences by sex

Figure 7 – Share of people not meeting medical examination/treatment because of the LONG WAITING LISTS



Source: Author's own elaboration from EU-SILC

Figure 8 – Share of people not meeting medical examination/treatment because of the LONG WAITING LISTS



Source: Author's own elaboration from EU-SILC

are even more remarkable, since especially the feminine AMR due to both prevention and hygiene and health care are much higher in all the rural and peri- urban areas.

Hence, it can be suggested that while people living in the peri-urban area are more unable to pay for prevention, the difficult access to health services in the rural in transition is not specific but it is related to all the three aspects. With respect to the peripheral area, even if the number of health services is limited, probably they are well-targeted or in any case sufficient to respond to the needs of the residents.

Another factor affecting the state of health is the quality of surrounding environment (Fig. 10). Even if environmental data at municipal level are not available, we show some data from the EU- SILC survey about the perceived main problems reported by the respondents. Not surprisingly, the lack of sufficient light is troublesome especially in the peripheral area, where this is the most remarkable problem, but also in the advanced rural. Crime and pollution are perceived as more troublesome in Florence, while noise in both the peri-urban and in the rural in transition.

4. Concluding remarks

This paper is an attempt to assess of the state of wellbeing in the rural areas of Tuscany from a multidimensional perspective. Following the capability approach proposed by Sen, the concept of wellbeing adopted in this study goes beyond economic grounds, including subjective and objective indicators of people's activated functionings in a set of wellbeing dimensions (labor, gender equality, education, health, quality of surrounding environment). The results show that large differences still persist at territorial sub-regional level. The Tab. 8 recaps the main differences among five sub-regional areas which have been identified in the earlier sections.

Even if Tuscany is a region of a developed country where the standards of living are quite high, the results of this study highlight that large differences at sub-regional level still persist. First of all, a process of economic convergence between rural and urban areas is still far to come. In some rural areas, in particular the more agricultural-intensive, the rates of growth of income are positive and the distribution is fair; however, there are other rural areas where income decreased over time together with a deterioration of the distribution. For example, the municipalities included in the "rural advanced" group show positive growth rates over time and a fair distribution of income; moreover, this area can enjoy a good milieu for entrepreneurship, including a modern and well- developed agricultural sector (Rocchi & Turchetti, 2013). However, when it comes to consider other dimensions of wellbeing, the picture changes because job opportunities are scarce and the provision of services still insufficient.

Table 8: Differences by area along the dimensions

	Florence	Peri-urban	Advanced rural	Rural in transition	Peripheral Rural
Material conditions	Highest income but steady growth and unfair distribution	Stagnant trend of income growth but fair distribution	Balance between income growth and fair distribution	Low income growth and unfair distribution	Positive growth of income and fair distribution
Employment and gender	Both unemployment and employment decrease	Unemployment increases and employment decreases, especially among women. Long waiting lists for nurseries	Both unemployment and employment decrease, especially among women	Unemployment increases and employment decreases, especially among women. Scarce demand for the provision of nurseries	
Education			Poor provision of secondary schools. Tendency to more easily accept unskilled jobs with respect to qualification	Lower share of people in the 30/40 age class with post-secondary/tertiary education. A large share of them is employed. Tendency to more easily accept more unskilled jobs with respect to qualification.	
Health	Large share of people saying not feeling good, although the best provision of services in the region	Inability to pay, especially for prevention	Poor provision of services	Poor provision of services, long waiting lists	Poor provision of services, but well-targeted

Source: Author's own elaboration

The situation is even worse in the "rural in transition" and the "rural peripheral" areas, where incomes are lower and, in the case of the former, poverty and inequality are widespread and increasing. Differences in the quantity and quality of public services for education and health likely affect the well-being of people living in areas with prevalent rural features. In the rural areas "in transition" and "peripheral" this disadvantage is combined with controversial trends in economic conditions, resulting in an increasing lag from the rest of Tuscany.

From a methodological point of view, this study shows the relevance of EU-SILC Survey for the analysis of well-being and the opportunity to adopt it for sub-regional studies by using proper techniques of post-stratification. The results show an acceptable degree of statistical reliability, suggesting a wide range of possible analysis based on available micro-economic information. We also attempted to gather some concluding remarks by comparing information about both subjective and objective wellbeing from EU-SILC database with information from other primary and secondary data sources about the supply of local public services. We are convinced that this research path should be further pursued. Indeed, the relevance of a multidimensional concept of well-being, such as the one adopted in this study, for policy design increases moving from larger to smaller territorial scales. Empirical evidence on territory-specific lags in one or more dimensions of well-being might suggest a better targeting of policy measures, improving the efficiency in the use of public resources.

This is the case of regional rural development policy. The ongoing revision of the Rural Development Programme in Tuscany is an opportunity to address some of the issues highlighted above. The case of rural Tuscany shows how "social inclusion, poverty reduction and economic development" should be more clearly considered as a fundamental part of the policy design for rural areas, also in terms of budget allocation. Indeed, the thread for a re-orientation of policy towards the consideration of regional differences turns to be extremely urgent whether also well-developed regions like Tuscany cannot grant to everyone the same access to well-being because of the diverse provision of public services and/or economic opportunities.

A03

MEASURING THE SOCIAL DIMENSION OF AGRICULTURE

Session Organizer
B. Davis | FAO | Rome | Italy

ABSTRACT

Within the context of the development of the SDGs and the most recent generation of integrated household surveys, the importance and relevance of the interconnectedness of the social and economic dimensions of agricultural households is gaining prominence. While a recognition of the role in influencing behavior of the inseparability of the agricultural household in the context of market failure is well established in the literature, more generalized collection of the necessary broad types of data is more recent. This session will focus on the measurement and analysis of social topics within the context of agricultural households and the particular environment and constraints in which they live. Papers can focus on such diverse topics as the multi-dimensional nature of resilience, the implications of social protection for agriculture, the role of human capital in agricultural productivity, the role of agriculture in youth un- and under employment, etc. Papers can focus on an application to a specific topic in a given country, or focus on methodological issues.

Economic growth and poverty reduction: the role of the agricultural sector in rural Indonesia

K. Kadir | BPS | Statistics Indonesia | Jakarta | Indonesia
A. Ratna Rizki | BPS | Statistics Indonesia | Jakarta | Indonesia

DOI: 10.1481/icasVII.2016.a03

ABSTRACT

Agricultural sector has emerged as the engine of economic growth in Indonesia. The sector is expected to contribute to poverty reduction in rural areas which is the largest contributor to poverty in Indonesia. Growth in the agricultural sector can induce the growth of the non-agricultural sector through linkages between the two sectors. Thus, the growth of the agricultural sector is not only a positive impact on poverty reduction through the rising of incomes in the sector, but it can also encourage non-agricultural activities in rural areas. This study aims to determine how much the growth of the agricultural sector impacts on the non-agricultural sector in rural areas and how much the growth of these two sectors impacts on poverty reduction in rural areas. Data used in this research is panel data from 2002 to 2008. Data are analyzed using simultaneous equations model estimation and the estimation of panel data regression model. The results of simultaneous equations model analysis show that growth in the rural agricultural sector by 1 percent will induce the growth of the rural non-agricultural sector at 1.35 percent. Meanwhile, the results of estimation of panel data regression model reveal that productivity growth in both the agricultural and the non-agricultural sectors in rural areas by 1 percent will reduce the rural poverty rate by 3.91 percent and 3.97 percent, respectively. Both these findings affirm that the agricultural sector is still the driving force of economic growth and is critical to the success of poverty alleviation in rural areas. In addition, the government also needs to develop the non-agricultural sector to support poverty alleviation efforts.

Keywords: sectoral linkages, growth multiplier, panel data regression

PAPER

1. Introduction

During the last five decades, Indonesia has experienced a massive economics structural transformation from a country that mostly relied on the agricultural sector to a country whose economy is dominated by industry and service sectors. Over the period, the share of the agricultural sector to the total Gross Domestic Product (GDP) has declined dramatically from 45 percent in 1970 to 14 percent in 2016. This change, in turn, triggers a question: Is the sector still important for Indonesia's economic development?

Although the structural transformation has reduced the role of the agricultural sector in the country's economy, the sector clearly still plays a very important role in terms of its contribution to the output of Indonesia's economy as measured by GDP. In 2015, the sector accounted for 13.52 percent of the country's GDP, the second largest after manufacturing sector. The agricultural sector also has a significant contribution to labor absorption, especially in rural areas. BPS estimated that approximately 32.88 percent of the total labor force in August 2015 work in the sector. With these important roles, the agricultural sector is expected to be the engine of economic growth, especially in rural areas.

Until recently, poverty was still one of the main development challenges that must be addressed by the government. Although the number of poor people generally has decreased during last five decades, the number of Indonesians living below the poverty line is relatively high. In March 2016, for instance, the BPS estimated that the number of poor people was 28.01 million or approximately 10.86 percent of the total number of population.

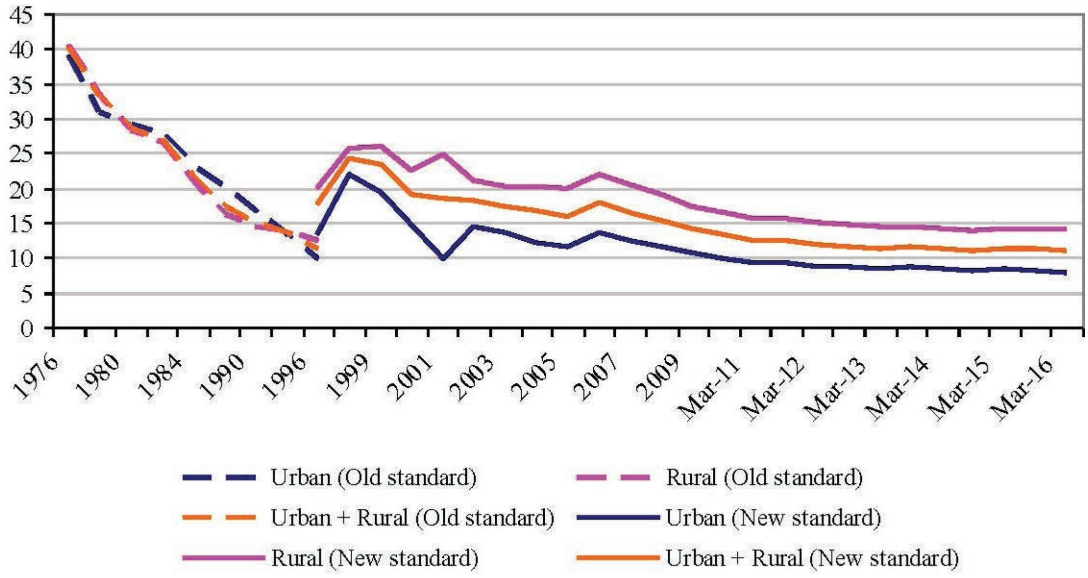
As such, it is clear that poverty is basically a rural-agricultural phenomenon because around 63 percent of the poor people live in rural areas, and most of them rely on the agricultural sector as their livelihood. BPS estimated that in 2014 approximately 67.26 percent of poor households in rural areas were agricultural households. Therefore, the success of poverty reduction measures in Indonesia has a strong connection with the performance of the agricultural sector. In other words, the agricultural sector is the key factor in reducing the number of poor people in the country, especially in rural areas. The growth of the sector definitely gives impacts on poverty reduction not only by increasing the income level of rural people working in it, but also by stimulating the growth of the non-agricultural sector in rural areas.

The focus of our study is to examine the role of the agricultural sector growth as the main driving machine in rural economy, notably in stimulating the growth of the non-agricultural sector in rural Indonesia. In addition, the study aims to assess the role of the rural agricultural growth in reducing poverty in rural Indonesia.

2. Poverty and Agricultural Sector in Indonesia

Indonesia has an impressive experience in curtailing the poverty rates. The success story of the country in poverty alleviation asserts the crucial role of the economic growths in eradicating poverty. It can be traced from 1976 to 1996 when the country experienced a high economic growth period before hit by the Asian Financial Crisis (AFC) in 1997-1998.

Figure 1 - Poverty Rate Trend in Indonesia (%), 1976 - 2016



Source: BPS (various years)
Note: In 1998 BPS revised the method of setting the poverty line. The new method resulted in an increase in the poverty threshold, and the poverty rate in 1996 was adjusted accordingly from 11.3 percent to 17.3 percent

Over the two decades period, through an impressive economic growth performance, reaching around 7 percent per annum on average, Indonesia succeeded in lowering the incidence of poverty from 40.1 percent in 1976 to only 11.3 percent in 1996. Timmer (2008) argued that over the period, there were some main sources of the economic growth in Indonesia, including the growth in the agricultural sector. The dominant contribution of the sector ended up in the 1980s when its role began to be replaced by manufacture industry sector. Although the trend of poverty has been declining after the AFC, its velocity has been relatively slower than the period before the crisis. Even the poverty reduction has experienced a plateau since 2009 due to the low performance of the agricultural sector that has grown below 4 percent on average in recent years.

In fact, from 1976 to 1996, poverty reduction in rural area was faster than that in urban areas. Over the period, the number of poor people in rural areas had plunged approximately 20 million. This impressive trend basically affirms the decisive role of the agricultural sector as the leading sector in the rural economy. The growth of the sector clearly gives a significant contribution to this remarkable poverty reduction because over the period the agricultural sector growth was able to push the level of income and jobs creation in rural areas, not only in the agricultural sector itself but also in the non-agricultural one. This is because the agricultural growth also had stimulated other non-agricultural activities in rural areas that had vigorous connection with agriculture such as trade, agro-industry, transportation and services.

At the same time, the structure of Indonesia's economy experienced a substantial change. Economic structural transformation over the last five decades has eroded the role of the agricultural sector gradually. It was marked by a decrease in the share of the sector on GDP from around 45 percent in 1971 to only 14 percent in 2015.

Unfortunately, although the contribution of the agricultural sector to GDP has been declining, until recently most of the workforce still rely on the agricultural sector as their livelihood. The share of the sector on labor absorption remains the highest compared to other sectors in the economy. It happens because the expansion of the industry sector has failed to absorb more workforce. In other words, the shifting of the labor force from agriculture to industry has not happened in an ideal way. As a result, productivity of the agricultural sector has been declining consistently. For Indonesia, it is a critical problem in the context of pro-poor development because poverty in the country basically a rural agriculture phenomenon.

3. Sectoral Linkages and Poverty Reduction in Rural Areas

The agricultural sector has strong linkages to the non-agricultural sector in rural areas. Through the linkages, the growth of the agricultural sector not only pushes the increase of income in the agricultural activities but also stimulates the growth of the non-agricultural sector in rural areas. Therefore, the agricultural sector has a significant growth multiplier in the areas. The growth multiplier of the sector in an economy dominated by agricultural activities always more than one percent (Hazell and Haggblade in Timmer 2008). Hazell, Haggblade, and Brown (1989) estimated that the growth multiplier of the agricultural sector in Asia was 1.80 percent. Moreover, Suryahadi, Sumarto, and Molyneux (2006) estimated that from 1989 to 2002 one percent growth in the rural agricultural sector in Indonesia would induce the growth of the rural non-agricultural sector by 1.20 percent on average.

The sectoral linkages between the agricultural and the non-agricultural sectors that usually happen in rural areas are in the form of demand linkages that cover both production and consumption linkages. From the production side, the growth of the agricultural sector needs inputs provided by the non-agricultural sector. In addition, the growth of the agricultural sector can also boost the development of economic activities using its outputs as the intermediate inputs. From consumption side, the rising of income in the agricultural sector can enhance agricultural households consumption that, at the end, will raise the demand for goods and services produced by the non-agricultural sector in rural areas (Harianto 2006).

A significant number of empirical studies show that the economic growth that relies on the agricultural sector expansion benefits the poor. The compilation of the empirical studies that affirm the impressive contributions of the agricultural sector growth on poverty reduction in developing countries can be found in Mellor (1999). In the context of Indonesia, many studies also confirm that the growth of the agricultural sector has noticeable impacts on poverty reduction, notably in rural areas. They include among others Sumarto and Suryahadi (2003), Suryahadi, Suryadarma, and Sumarto (2006), and Tambunan (2006).

Enriquez and Stamoulis (2007) argued that the channels through which the growth of the agricultural sector lowers poverty in rural areas consist of two ways. Firstly, the growth of the agricultural sector directly raises the income/consumption level of small farmers that are commonly poor farmers. Secondly, the growth of the sector can indirectly reduce poverty by lowering the price of unprocessed foods, pushing the level of income generated by the non-farm rural economy activities, and raising the jobs creation and the level of wages, particularly for unskilled labors.

4. Methodology

4.1. The Model

Most studies used in estimating the growth multiplier of the agricultural sector are roughly classified into three types: (1) studies using micro-econometrics approach; (2) studies using macro-econometrics; and (3) studies using input-output table, social accounting matrix, and computable general equilibrium model (Suryahadi, Suryadarma, Sumarto, and Mlyneaux 2006). In this study, we apply macro-econometrics approach to examine sectoral linkages in rural Indonesia.

Considering the interdependence relationship between the agricultural sector and the non-agricultural sector in rural areas, we use simultaneous equation model to examine the impacts of the agricultural sector growth on the non-agricultural sector growth in rural areas.We use double log-linear regression, so the estimation of regression coefficient can be interpreted as elasticity. The specification of system of equations that we estimate is presented below:

$$ln(ragdp)_{it} = \alpha_1 + \beta_{11}\, ln(rnagdp)_{it} + \beta_{12}\, ln(land)_{it} + \gamma z'_i + \varepsilon_{1it} \quad (1)$$

$$ln(rnagdp)_{it} = \alpha_2 + \beta_{21}\, ln(ragdp)_{it} + \beta_{22}\, ln(ugdp)_{it} + \gamma z'_i + \varepsilon_{2it} \quad (2)$$

$$ln(awage)_{it} = \alpha_3 + \beta_{31}\, ln(ragdp)_{it} + \beta_{32}\, ln(pmw)_{it} + \beta_{33}\, ln(rlf)_{it} + \gamma z'_i + \varepsilon_{3it} \quad (3)$$

$$ln(awork)_{it} = \alpha_4 + \beta_{41}\, ln(ragdp)_{it} + \beta_{42}\, ln(rnagdp)_{it} + \gamma z'_i + \varepsilon_{4it} \quad (4)$$

$$ln(nawage)_{it} = \alpha_5 + \beta_{51}\, ln(rnagdp)_{it} + \beta_{52}\, ln(pmw)_{it} + \beta_{53}\, ln(rlf)_{it} + \gamma z'_i + \varepsilon_{5it} \quad (5)$$

$$ln(nawork)_{it} = \alpha_6 + \beta_{61}\, ln(rnagdp)_{it} + \beta_{62}\, ln(pmw)_{it} + \gamma z'_i + \varepsilon_{6it} \quad (6)$$

The variables in the system consist of Gross Regional Domestic Product (GRDP) of the agricultural sector in rural areas (*ragdp*), non-agricultural GRDP in rural areas (*rnagdp*), urban sectors GRDP (*ugdp*), wages in the agricultural sector in rural areas (*awage*), agricultural labor—defined as the number of 15+ years old population working in the agricultural sector—in rural areas (*awork*), wages in the rural non-agricultural sector (*nawage*), non-agricultural labor in rural areas (*nawork*), labor force in rural areas (*rlf*), area of agricultural land (*land*), provincial minimum wages (*pmw*), vector of initial variables (e.i. poverty rate in rural areas in 2002 and proportion of 15+ years old rural population who did not complete nine years education in 2002 as a proxy of education level).

By using the order condition, the result of identification process shows that all of the structural equations in the system are overidentified, so they could be estimated. Our focus of estimation is the value of B_{21} that shows the percent growth of the rural non-agricultural sector due to the growth in the rural agricultural sector by one percent. The coefficient also represents the strength of the linkages between the agricultural sector and the non-agricultural sector in rural areas. Meanwhile, in scrutinizing the impacts of the agricultural growth on poverty in rural areas we use panel data regression model. As in equation (1) to (6), we also use the double log regression model. The model that we estimate is:

$$RP_{it} = \alpha + \beta_1 \, ln(aproductivity)_{it} + \beta_2 \, ln(naproductivity)_{it} + \beta_3 \, ln(awage)_{it} + \beta_4 \, ln(nawage)_{it} + \beta_5 \, ln(rcpi)_{it} + (u_i + \varepsilon_{it}) \qquad (7)$$

The model asses the impact of the rural agricultural sector productivity (aproductivity) growth and the rural non-agricultural sector productivity (naproductivity) growth on the incidence of poverty in rural areas.The term of productivity is defined as the output per worker of each sector.We also investigate the impact of other related variables on poverty in rural areas such as the growth in agricultural and non-agricultural wages as well as inflation rates in rural areas (*rcpi*).

4.2. The Data

All data used in our study are from BPS-Statistics Indonesia. We use panel data consisting of 23 provinces that were observed for the period of 2002-2008. We only observed those provinces instead of the total 33 provinces because of the limitation of data availability for certain variables in some provinces. In estimating the growth multiplier of the agricultural sector in rural areas, we use Gross Regional Domestic Product (GRDP) at the provincial level. Because BPS does not disaggregate the GRDP data by rural and urban areas, we have to estimate the proportion of GRDP by sector in every province that goes to rural areas. As the solution, we use the share of the agricultural sector labor in rural areas as the allocator. The share is the proportion of the agricultural labor living in rural area of the total number of labor in every province. We consider that the distribution of the GRDP data by area could be explained very well by the distribution of labor in rural and urban areas. Moreover, the poverty rate data used in our research is derived from The Foster–Greer–Thorbecke (FGT) index estimated by BPS.

5. Results

We use the three stages least square (3SLS) method to estimate all of the structural equations. The estimation results of equations (1) to (6) are shown in Table 1. The results show that the growth of the rural agricultural sector has positive and significant impacts on the growth of the rural non-agricultural sector. The impacts are considered relatively high. One percent growth of the rural agricultural sector will induce growth of the rural non-agricultural sector by 1.35 percent.

Our findings basically confirm that there are strong linkages between the agricultural sector and the non-agricultural sector in rural areas. The linkages include both production linkages and consumption linkages. The strong linkages between the two sectors mean that an increase of income in the rural agricultural sector will stimulate the increase of income in the rural non-agricultural sector through the rising of demand for goods and services produced by the non-agricultural sector in rural areas. At the end, such mechanism will boost the non-agricultural activities in rural areas and create more opportunities for rural people including the poor to gain more income. In addition, the growth of the rural non-agricultural sector also has positive and significant impacts on the rural agricultural sector although it is relatively lower than the impacts of the rural agricultural growth on the rural non-agricultural growth. This study finds that one percent growth of the non-agricultural sector will induce 0.41 percent growth in the agricultural sector in rural areas. It confirms that an increase of income in the rural non-agricultural sector will also stimulate the demand for the agricultural products in rural areas.

The interdependence relationship between the agricultural sector and the non-agricultural sector in rural areas has the implication that the development of the two sectors in rural areas must be conducted simultaneously through an integrated policy. In other words, the development of the agricultural sector in rural areas should not only focused on food production but also should be directed to produce agricultural commodities needed by the non-agricultural sector in rural areas. Moreover, the development of the non-agricultural sector in rural areas must support the rural agricultural sector and creates more opportunities

Table 1: Results of Estimation of Simultaneous Equations Model

Dependent Variables	Independent Variables	3SLS	Dependent Variables	Independent Variables	3SLS

	Number of observations = 161; R2 = 0.966; P(Chi-stat) = 0.000			Number of observations = 161; R2 = 0.902; P(Chi-stat) = 0.000	

Notes: Number in parentheses are Z-values. ** Is significant at 1% level.* Is significant at 5 % level

for rural people, especially small farmers, so they do not only rely on the agriculture sector as their source of income. Besides having significant impacts on the growth of the non-agricultural sector in rural areas, the results of estimation also show that the growth of the rural agricultural sector stimulates jobs creation and lift up the level of wage in rural areas, not only in the agricultural sector itself but also in the non-agricultural sector. These facts obviously affirm that the agricultural sector is still the main driver of the rural economy in Indonesia.

Table 1: Results of Estimation of Simultaneous Equations Model

Independent Variables	Fixed Effect (GLS)
Log of rural agricultural productivity	-3.909** (-3.721)
Log of rural non-agricultural productivity	-3.971** (-3.441)

Notes: Number in parentheses are t-values. ** Is significant at 1% level.* Is significant at 5 % level

Meanwhile, for the model of the agricultural productivity growth impacts on poverty in rural areas we use the Generalized Least Squares (GLS) method for the panel data. We estimate equation (7) using fixed effect model. The estimation results show that both an increase in the productivity of the rural agricultural sector and the productivity of the rural non-agricultural sector have a significant contribution in reducing the incidence of poverty in rural areas. One percent growth in both sectors productivity will reduce the number of poor people in rural areas by 3.9 percent and 4.0 percent respectively. These findings basically give a clear evidence for two things. First, the agricultural sector still plays a very crucial role in the eradication of poverty in rural Indonesia, which for a long time has been the center of poverty in the country. Second, the role of the non-agricultural sector in rural areas becomes more essential in boosting the welfare of rural poor people.

6. Conclusion

Although the economic structural transformation has occured massively over the last five decades, our study firmly proves that the agricultural sector still plays a very significant role in the Indonesia's economy, particularly in rural areas, where approximately 47 percent of the Indonesian population live. We found out that the sector is still the driving engine of the rural economy that can stimulate the growth of the non-agricultural sector in rural areas in many ways as well as enhance the jobs creation and the level of wage in the areas.

Our study also asserts the powerful impacts of the rural agricultural sector growth together with the rural non-agricultural growth on poverty reduction in rural areas, the home for 63 percent of Indonesian poor people. It means that the rural sector is the key to success in poverty eradication measures in Indonesia, and the role of the rural non-agricultural sector becomes more decisive in the context of rural development in the country. As a consequence, besides enhancing the growth of the agricultural sector productivity, Indonesia also must pay more attention to the development of the rural non-agricultural sector to support poverty reduction in rural areas.

Growth and inequality in Sub-Saharan Africa: insight from a linked ABG method and CGE modeling

S. Ligane Massamba | IFPRI | Dakar | Senegal

DOI: 10.1481/icasVII.2016.a03b

ABSTRACT

This paper uses survey data from a sample of Sub-Saharan African countries and showsthe heterogeneity in the shape and the structure of inequality between countries and over time.Based on the new Alpha Beta Gamma method (ABG), inequality is considered as an anisotropicdimension along the income scale.In the second part of the paper, we show that the growth-inequality relationship is defined in local domains. Different sector-led growth profiles are found to have heterogeneous effects on inequality at the median, the top and bottom ends of the income distribution.

Keywords: Growth, Inequality, Income, Africa

PAPER

1. Introduction

Africahas the highest poverty rate in the world and is the second most inequitable region after the Latin America. Giving the relation between poverty and inequality, there is timely research question to assess detailed analyses of inequality across and within countries and to find out the growth strategies that lead to more redistribution of wealth.

This paper uses a new representation of inequality developed by (Chauvel, 2014) in order to shed a new light on income distribution in Sub-Africa In this representation, inequality is then considered as anisotropic and varies along the income side. This is contrary to the traditional approachesthat consider inequality as stable and relyingonly onpartial summary statisticslike the Gini coefficient.The study uses survey data from a sample of 10 African countries, especially West African countries[1] to assess the inequality disparities along the income scale, between countries and over time.

The growth realized in the continent did not translate into inequality reduction and an interesting researchquestion could focus on identifying alternative sources of growth that could generate a high poverty reduction and more equal distribution of wealth[2].The second part of the paper tackles this question by using Senegal as a study country. It applies a Quasi-Dynamic Computable General Equilibrium (CGE)model linked to a micro-simulation module to identify the sectors that when driving growth have the highest impact on poverty reduction and inequality. Despite the long debate and the huge literature about growth-inequality linkage no consensus and clear relationship have been found. We contribute to this debate by turning our attention to the possibility that the growth-inequality relationship is defined in local domains along the income scale and by considering the fact that the pattern of growth might be an important factor.We explore the impact on inequality in the different parts of the income distribution in order to better take into account the complex nature of the inequality-growth linkage. This investigation could help to see the conditions in which economic growth impacts on economic inequality and poverty. The analyses of growth-poverty-inequality linkage for Senegal serve as a touchstone for future research including several countries.

Different sector-led growth profiles might have heterogeneous effects on inequality at the median, the top and bottom ends of the income distribution. Moreover, determining the condition under which economic growth impacts inequality requires an in-deep country specific analysis in a general equilibrium framework in order to integrate all the spillover effects in the economy. However, many of the previous studies on poverty-growth-inequality linkage use cross-countries data that often leadto limited and broad conclusions by failing to account for the idiosyncratic factors, and by using samples which include countries at various stages of economic development. A complex and unknown inequality shape combined with an appropriate choice of growth profile might lead to sub-optimal development policies.

The rest of the paper is organized as follows. In section 2, we provide some background knowledge on

[1] Many empirical analyses focused on the Southern African region where we have six countries among the continent's top ten most unequal countries in the world (ADB, 2012).

[2] The GINI coefficient increases from 0.42 to 0.46 over the period 2000 to 2010 (ADB, 2012).

the issue of anisotropic inequality and growth-poverty-inequality linkage.

Section 3 presentsthe methodology we used to address the research questions. Section 4.1 presents the pattern of inequality along the income scale and over time for selected countries in Africa. Section 4.2 identifies the growth profiles that have the highest impacts on poverty and inequality taking into account the heterogeneity along the income scale.

2. Background

2.1 Poverty-inequality-growth linkage

It is widely recognized that Sub-Saharan Africa is one of the most unequal region in the world. The Gini coefficient is estimated at 0.46 and isthe highest, behind Latin America (Table 1). However, beyond this general statistic, there might exist different levels and structures of inequality between countries and between the individuals within each country. This calls for a deep analysis of the structure and the evolution of inequality over the years and along the income scale. Besides, the presented framework allows analyzing how inequality responds to the different economic growth profiles. While there is a consensus that growth is a necessary condition for poverty reduction (Ravaillon and Chen 1997;Deininger and Squire 1997; Fan, Hazell and Thorat,2000; Ravallion, 2004; Fields, 2001; Kraay, 2006), the relationship between inequality and growth was subject to controversial debate in the literaturethat makes the link between the two factors no clear. For instance,a cross-country study by Ravallion (2004) finds that a one percent increase in income level results in a poverty reduction of between 0.6 and 4.3 percent. Likewise, Kraay (2006) found that growth in average incomes can explain 70 and 97 percent of changes in poverty headcounts in developing countries in the short and long-run.

Regarding growth-inequality linkage,Kuznets (1955) identifies an inverted U shape of inequalities over time. However, this relationship was criticized by some authors (Ravallion and Chen 1997; Atkinson, 1999; Arjona, Ladaique and Pearson, 2001) that cast doubt on the direction of the causation and the robustness of the relation.Pardo-Beltran (2002) finds a negative and but non-linear effect of growth on inequality.While Hausman and Gavin (1996) showed that the volatility of growth increases income inequality measured as the ratio of the income received by the richest 20 percent of the population to the income received by the poorest 40 percent.

In contrast to the growth-poverty nexus, the literature review shows that there is little consensus regarding growth-inequality linkage. However, our study investigates whether this relationship might depend on the nature of the growth, the parts of the income distribution that is considered and on the shape of inequality.In fact, different growth sources might have heterogeneous effects on inequality at the different parts of the income distribution because they affect household income differently and are not all growth-neutral. The link between inequality and growth can be multidimensional. However, this paper focuses on one direction of the interaction that is how growth might impact income inequality. There have been many indexes used in the literature to measure inequality at the top and bottom of the distribution, such as the quintile ratios, namely Q5/Q3 and Q3/Q1 and the percentile ratios, namely P90/P50 and P50/P1 or P90/P70 and P10/P30. However, the choice of these indexes might be arbitrary and might lead to various results. The Alpha Beta Gamma method (ABG) defined in section 3 allows a straightforward combination of the information along the income scalewithout losing generality. This paper sheds a light on the difference of structure of inequalities between and within selected sub-Saharan Africancountries by taking into account the heterogeneity in the income distribution.In a second step, this contribution investigates if it is not more the sources of growth that is crucial in determining the effects on inequality. Our framework allows identifying the growth profiles that lead to more egalitarian economies.

Table 1: Income Inequalities in the world

2.2. Agricultural sector in Senegal

Determining the extent to which different growth profiles affects household welfare and anisotropic inequality can be helpful for designing development policies. We use Senegal as our pioneer work for a better understanding of the potentials for inequality reduction, in addition to poverty reduction, by assessing the complex impacts of each specific sector-led growth on inequality along the income scale. The ABG method is used in order efficiently measure inequality.

In Senegal, as in many sub-Saharan countries, there has not been sufficient work in the sense of investigating the linkages between the several household groups and economic sectors and the various economic mechanisms that are specific to the sectors. The study provides insight on the extent different sector-led growth affect local inequality and household welfare. We will show how these effects vary, in the context of the structural transformation and growth promoted by the Senegalese Emergency Plan (PSE). In fact, the Senegalese government has recently started a new challenge that is the one of rapid progress toward successful economic emergence. This latter is the new reference framework for economic and social policy in the medium and long-term. One of the three axes of the new released PSE is growth and the structural transformation of the economy through the consolidation of the actual growth engines and the development of new sectors that are able to create wealth, employment, and social inclusion. The plan also seeks to promote sectors thathave the strongest export capacity and are attractive for investments (Senegal Emergent Plan, 2014). This new development strategy looking ahead to 2035 comes in addition to the large set of initiatives undertaken by the government like the establishment of the SCA (Accelerated Growth Strategy) at broader level or the implementation of agricultural development initiatives such as the Great Offensive for Food and Abundance (GOANA), the program return to Agriculture (REVA), the agro - Sylvo - Pastoral Orientation Law (LOASP) and more recently the National Program of Agricultural Investment (PNIA), within the Comprehensive African Agricultural Development Program (CAADP).

The implication of an agriculture-led growth is not documented so far, nor has been empirical evidence on the impacts of non-farm sectors on the welfare of both non-agricultural households and agricultural households. On one hand, although occupying a high share of employment, Agriculture in Senegal contributes weakly to the national GDP, contrary to Services sector. On the other hand, it is widely recognized that the Services sector drives growth, but poverty and inequality are still persistent and at the current path of the economy, it is difficult to imagine that figures will change much better over the next decades. Therefore, an interesting research question is to identify the growth profiles that have higher contribution to poverty and inequality reductions. The general equilibrium modelling part wants to shed a light on the heterogeneity on the effects of different growth types on anisotropic inequality and poverty. The characteristics of the economic sectors are not identical and the patterns that ensure their linkages to populations are quite different. Therefore, inequality and poverty impacts of various growth strategies deserve to be analyzed by considering the full range of general equilibrium effects. Further, the analyses of the sector-led growth and inequality linkages will be extended to remaining countries once we have built the appropriate micro-

Table2: The general structure of the economy

simulated CGE model for each country.

Beyond the macro-economic models that are based on national accounts, it is important to explore growth-poverty-inequality linkage from household surveys. As pointed out by Bourguignon et al. (2008), linked micro-macro can help to deal with the limitations of single and pure micro (respectively macro model) that when taken solely, only provides partial responses of policies at the macro level (respectively the micro level). The Table 2 presents the structure of the Senegalese economy. Agriculture employs the most of the individuals (47.4%) but account for only 16% of the GDP. The agricultural sector is confronted with many difficulties, including an overall yield decline owing to the soil degradation, the dependence to the precipitation, the successions of sub-optimal government policies, and the difficulties facing the main fertilizer provider, the Chemical Industry of Senegal – ICS, etc. Services account for a large share of the GDP (60%), despite the fact that agriculture is the primary source of employment in rural areas. The country's key export sectors are in the Industry (mainly chemical industry that includes fertilizer and phosphate extraction). Besides, the Food processing with 14.8% and primary sector with 11.2% have a significant part in the national export level (for the primary sector, we have especially the fishing sector, the groundnut and the vegetable sectors).

The use of the CGE allows integrating all relevant economic aspects, especially existing spillover effects in the economy and resource re-allocation. The analyses give valuable information on the responsiveness of the inequality and poverty to growth driven by a specific sector, as many policies are formulated by targeting specific sectoral programs.

3. Methodology

3.1 Inequality analyses

To assess inequality we used a new method develop by Chauvel (2014) that relies on the fact that inequality is anisotropic and its intensity is variable along the income scale. This method differs from the traditional one that only considers a constant general inequality index in the population expressed as the Gini index. The Alpha, Beta and Gamma (ABG) method estimates three parameters of inequalities, compatible with the Pareto properties of the tails. These parameters provide the level-specific measures of inequality at the median (alpha), the top (beta) and the bottom (gamma).

Starting from the CF distribution (see Champernowne, 1937; Fisk, 1961; Dagum, 2006), the ABG method is based on the expression of power of income Y_i (measured as the logarithm of the medianized revenuey_i) as a function of the logit of the rank quantile p_i in the distribution, X_i = logit (p_i) = log (p_i /q_i) where q_i is the proportion of individuals (1 - p_i) having income above the income of the individual i.

$$Y_i = ln(y_i) = ISO(X).\ X_i \qquad (1)$$

With $ISO(X)$ expressing the local inequality at level $X_i$through the divergence between the median and log-income y_i and is defined as follows

$$\text{ISO(X)} = \text{alpha} + \text{beta B(X)} + \text{gamma G(X)} \qquad (2)$$

Where $B(X) = (\text{theta1}(X) + \text{theta2}(X))/2$ and $G(X) = (-\text{theta1}(X) + \text{theta2}(X))/2$

And $\text{theta1}(X) = \tanh\ (X/2) = \frac{e^{X/2} - e^{-X/2}}{e^{X/2} + e^{-X/2}}$ and $\text{theta2}(X) = \tanh^2(X/2)$

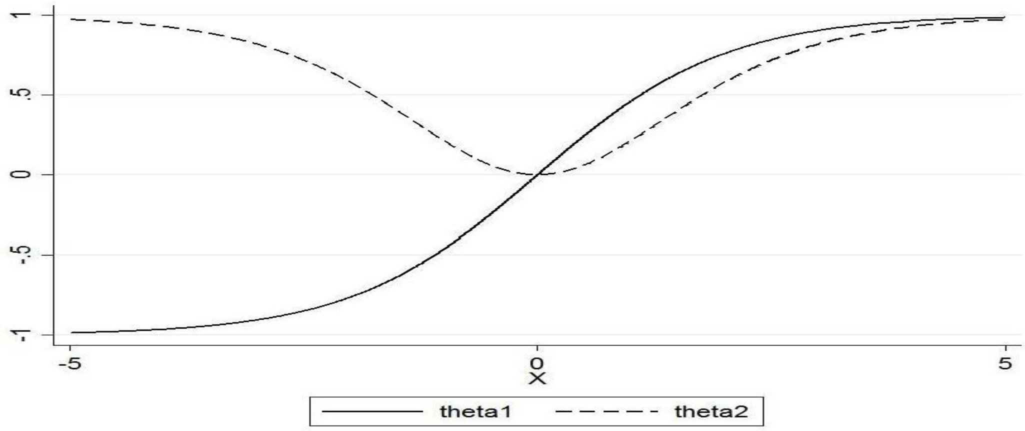
The coefficient alpha of the inequality level near to the median corresponds to the constant term in the equation (2). The uses of the two tangents hyperbolic related functions theta1 and theta2 allow the parameter beta to measure additional inequality at the top and gamma the additional inequality at the bottom. When beta and gamma are equal to zero, the distribution is a CF of coefficient alpha that will correspond to the Gini index. Otherwise the inequality is considered as non-stable along the income scale. The coefficient beta is positive when the rich are richer than in the CF distribution of coefficient alpha and gamma is positive when the poor are poorer than in the CF distribution of coefficient alpha (For more information see Chauvel, 2014).

To assess poverty, the calculated poverty indexes are the Foster-Greer-Thorbecke (FGT) family of poverty measures.

$$FGT = \frac{1}{N}\sum_{i=1}\left(\frac{z-y_i}{z}\right)^{\alpha}.\ I(y_i \leq z) \qquad (3)$$

For $\alpha = 0$ the FGT index collapses to the headcount ratio P_0 that quantifies the proportion of the population that is poor, but does not show how poor the poor are. $\alpha = 1$ gives the poverty gap index (P_1) that measures the extent to which individuals fall below the poverty line as a proportion of the poverty line. The poverty line corresponds to the level of expenditure that allows households to meet nutritional needs and essential non-food consumption.

Figure 1: theta1 and theta2 functions



3.2 CGE modeling and micro-simulation

As explained before, we use Senegal as a case study to see how different sources of growth might have different impacts on both poverty and anisotropic inequality. A dynamic extension of the standard model developed by the International Food Policy Research Institute (IFPRI) is used (see Lofgren and Robinson, 2002 and Thurlow, 2004). The model is constructed for Senegal and calibrated using the 2011 agricultural Social Accounting Matrix (SAM) that we build. The simulations are run over a ten year period from 2011 to 2020 at the midterm of the Sustainable Development Goals(SDGs)[3].

Table A1 and Table A2 in the appendix provide a description of the model, and further explanation can be found in the above-mentioned documents.

Households are disaggregated based on their location, activity, and initial poverty status (Rural agricultural poor, rural agricultural rich, rural non-agricultural poor, rural non-agricultural rich, urban agricultural poor, urban agricultural rich, urban non-agricultural poor, and urban non-agricultural rich). Their consumption levels result from the maximization of a Stone-Geary utility function. The aggregated domestic output is allocated between domestic sales and exports using a constant elasticity of transformation (CET) to reflect the imperfect transformability between these two types of sales. An Armington function (Armington, 1969) is used to model imperfect substitutability between domestic outputs supplied for the domestic market and imports (See Lofgren, 2002 and Thurlow, 2004 for more details on the CGE model)[4]. Labor is disaggregated into four categories: unskilled labor, primary labor, secondary labor, and tertiary labor.

To assess the impact on poverty and inequalities, we use a micro simulation that we calibrated to household survey ESPS II[5]. Endogenous changes in consumption resulting from the CGE model are passed down to the household by mapping each of the household in the micro simulation model to the corresponding household in the CGE[6].

3.3 Data Source

The study relies on data from household surveysavailable forthe different countries. These surveys are representative at the national level and collect detailed information on household characteristics (employment, housing, income, education, health, etc.). The source of these surveys is indicated for each country in Table 3.

4. Results and Discussion

4.1 Inequality and poverty

While there are many studies describing poverty, this study primarily focuses on inequality. The analyses of the isographs(Figure 2) and their summary in the ABG parameters (Table 4) show some heterogeneity between countries in both the level and the shape of inequality along the income scale, especially at the top income extremity. The isographs are not flat or constant over the income scale, revealing therefore the existence of local inequality. The difference of the parameters Beta and Gamma from zero indicates the limit of the Gini indicator as pointed out by (Chauvel, 2014).

[3] The new Sustainable Development Goals aim to end poverty by 2030 and are going to replace the Millennium Development Goals from January 2016.
[4] The Armington and CET elasticities are borrowed from the GTAP.

Source: Authors

Considering the last available household survey, the countries in our study are classified according to the sign of the parameters beta and gamma. Although the years of the different surveys are not the same, it is still insightful to compare the shape of inequality as we believe that inequality structure does not change drastically in the very short term.

All the countries have a negative gamma. However, the coefficient Beta allows the classification of the countries in two groups. Cameroon, Ghana, Niger, and Ivory Coast (Group N) have a negative beta while Senegal, Uganda, Burkina Faso, Mali, Togo, and Congo (Group P) have a positive one. In the first group countries have an isograph in the form of an inverted U with the peak observed around the zero and those in the second group have isograph with a positive slope. A positive Beta reveals more inequality at the top of the income distribution than at the median. The country typology reveals that despite being on the same continent and having similar economic structure, there are significant variations across countries in the structure of the inequality. Senegal and Togo have the highest inequality at the median of the distribution, Ghana and Ivory Coast have the highest inequality among the poor households, while Burkina Faso and Mali tend to have the highest level of inequality whenconsidering the richest households.

4.2 Dynamic inequalities for selected countries

A description of the temporal variation of the shape of inequality for some countries(two countries selected from each group) would allow seeingin detail potential heterogeneity in the change of the

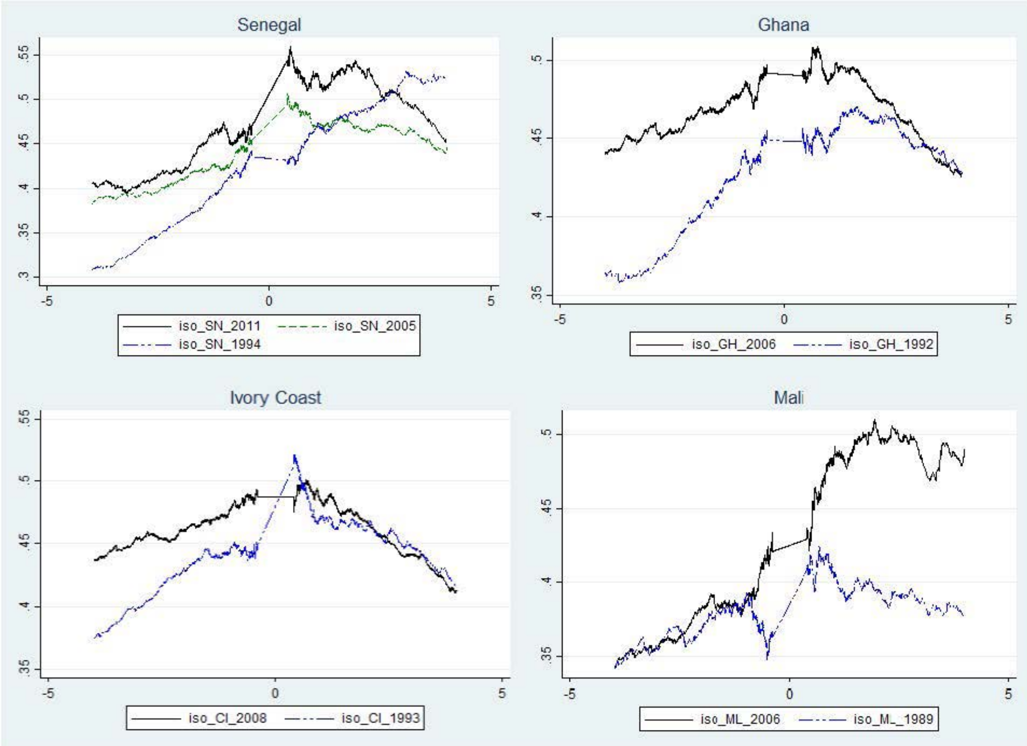
structure of inequality between the two last decades. The figure 3 shows the change and the persistent problem of inequality along the income scale over the years for the selected countries. The shape of inequality has changed less in Ivory Coast between the 1990's and the 2000's. In Senegal the inequality has increased over the years at the lower and middle level of income while the isograph decrease at the top. Senegal has observed a change in its shape of inequality that appears to be increasing throughout the mid-nighties and started charting an inverted U shaped type in the mid-twenties. Ghana and Mali show opposite patterns with either an observed widening or compression of inequality at the ends of the distribution over the years. Income inequality in Ghana has substantially increased at the low level of the income and has not changed much at the top while in Mali only inequality at the upper tail has

Figure 3: Dynamic of inequality



Source: Authors

changed drastically. Therefore, in Mali the increase of overall inequality is due to the diverging effect at the upper tail from the 1900's to the 2000's while in Ghana it comes from the diverging effect at the lower tail between the two periods. The differences of the inequality structures indicate that there should be no blueprints of the development policies' looking at the issue of inequality in Africa, each country deserves to be treated separately.

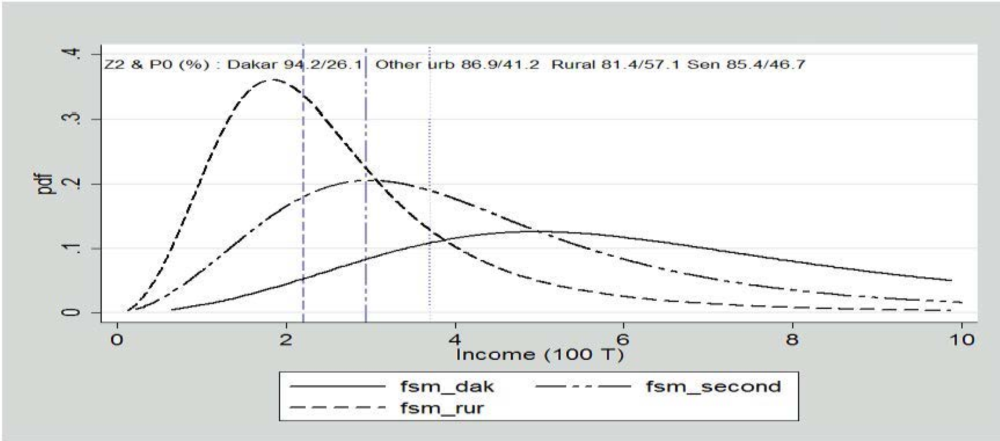
4.3 The engines for poverty and inequality reduction: Application to Senegal

A prominent debate is to identify the sectors and corresponding growth profiles that have the potential to be panaceas for both poverty reduction and income inequalities. This question is discussed in what follows by using Senegal as a case study country. The analysis will be extended to cover other countries in our future research, as there are no universal policy prescriptions and because of idiosyncratic characteristics of the growth-poverty-inequality linkage in each country. Moreover, the previous section has shown significant differences in the structure of inequality between African countries showing potential limitations of cross-countries studies analyzing the issue of inequality in Africa. The evidence from this analysis has the potential to contribute to development policy making and designing an optimal policy strategy in order to realize development targets in terms of poverty alleviation and inclusive growth. Using the quasi-dynamic CGE modeling framework linked to the ABG method, we simulate an additional slight growth of the GDP from the baseline (Business As Usual – BAU) value of 3.7 % to 4% through different scenarios where we assume that this additional growth is led by a specific sector. The size of the simulation here is not crucial as different shifts will generate the same mechanisms in the economy.

The figure 4 shows the initial income distribution in 2011 in Senegal assuming that the income generating process follows a Singh-Maddala distribution. The latter is a generalized Pareto distribution and is considered as providing a better fit for income distribution than distributions like Gamma or Log-normal (Singh and Maddala, 1976; Mac Donald and Ransom, 1979). Poverty headcount is estimated at 46.7% at the national level and is heterogeneous across locations with a widespread rural poverty (57.1%). The capital Dakar shows highest income variance compared to the rural areas and other urban locations. In the rural areas, poverty is not a marginal phenomenon as poor individuals are clustered around the poverty line. This indicates a difficulty in promoting policies that try to directly identify and target these poor individuals due to the concentration of individuals around the poverty line. There are many non-poor individuals that are closer to the poverty line as well as many poor individuals are not severely affected by poverty. These two groups might have the same characteristics.

The impact on poverty and inequality in each sector-led growth depends on the income and price effects. For each household, the significant part of the change in income can be expressed as a weighted sum of the factor earning from different sources. The importance of the direct income effect on poverty and inequality changes for a given household type following a production shift in each single sector *f*, will depend on the propensity of the sector to use a given factor *f* and on the share of this factor income

Figure 4: Income distribution across strata in 2011

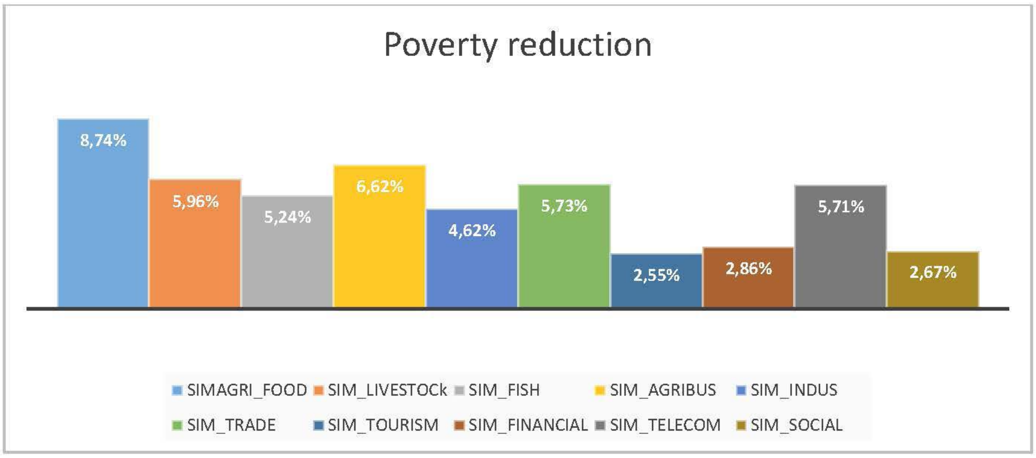


Note: Z2 = 100 − P_1 measures the intensity of poverty reduction.dak = Dakar; rur = rural areas; second = other urban centers.

Source: Authors

distributed to the household. The importance of the price effect for the households depends on the weight of the good that is produced by the sector driving growth in the composition of the household consumption basket. Furthermore, poverty and inequality tend to decrease more if the experienced growth is inclusive and associated with an equitable income distribution in the population. In addition to these effects that are directly related to the sector that is assumed to be affected by growth generated through sectoral productivity improvement, we have indirect effects that will determine the final size of the changes. These indirect effects depend on both production and consumption linkages between the targeted sector and the rest of the economy. A sector with important backward and forward linkage might have larger spillover effects.Agriculture-led growth has the largest impact on poverty with 8.74% reduction of the poverty rate in 2020 compared to its initial level. Agribusiness and Livestock follow with (respectively) poverty change of 6.62% and 5.96%. However, simulations where growth is led by non-agricultural sectors show also significant impacts on poverty reduction, especially for trade and telecommunication.

Figure 5: Change in poverty across the sector specific led growth$(P_{0\,2020}^{SIM} - P_{0\,2011})/\,P_{0\,2011}$



Source: Authors

Likewise, the evolution of the inequality in 2020 is displayed in Figure A1 in the appendix. Inequality achieved in 2020 and resulting from each sector-led growth can be compared to the initial inequality level. Figure A1 shows that agriculture-led growth (green line) generate the highest reduction of the inequality level compared to the case where growth is led by non-agricultural sectors. While some non-agricultural sectors might increase the level of inequality. The observed poverty reduction effects of the different sources of growth are partly related to the resulting income distribution. Figure 6 summarizes quantitatively the results by giving the change in the inequality level in the median, upper tail and bottom side of the income distribution. For the different simulations (SIM), the reduction of inequality along the income scale is calculated as follows:

- Reduction of inequality at the median: $(alpha\ _{2020}^{SIM} - alpha\ _{2011})/\ alpha\ _{2011}$
- Reduction of inequality at the top: $[(alpha + beta)\ _{2020}^{SIM} - (alpha + beta)_{2011}]/ (alpha\ + beta)\ _{2011}$
- Reduction of inequality at the bottom: $[(alpha + gamma)\ _{2020}^{SIM} - (alpha + gamma2011]/\ (alpha+gamma)\ 2011$

Considering inequality at the median, only growth led by the primary sector (namely Agriculture, Livestock, Fish), Agribusiness and Trade have reducing effects. Promoting growth profile led by these sectors can help to remedy inequalities instead of empowering relatively a certain class of individuals and impoverishing the weaker population. For the remaining sectors, the simulations show the potential trade-off between growth and inequality. Results also show that only agriculture and agribusiness tend to overcome inequality along all the income scale (median, upper tail and lower tail). The livestock, fishing sector, industry andfinancial sectorstend to reduce inequality at the top of the income distribution, but increase the one at the bottom while trade, tourism, telecommunication, and social services have the opposite effect by reducing inequality at the bottom and increasing the one among the richest households. The difference observed in inequality reduction between the growth profiles is due to the difference in income source between households and on the extent to which some sectors are linked to the household groups and to the poorest within each household group.

The simulations assume the same level of government payments to household compared to the baseline simulation. Therefore, the changes in household income will come from other sources. Household income is affected following the changes in wage and quantity of the different labor categories, on agricultural and non-agricultural capital, on land, the variation of intra-household transfers, and the

Table 6: Distribution of the household labor income across the labor categories (%)

Households	*Unskilled labor*	*Primary labor*	*Secondary labor*	*Tertiary labor*
Rural agricultural poor	70.1	9.8	5.8	14.3
Rural agricultural rich	76.4	5.2	2.7	15.8

Urban non-agricultural rich	13.6	11.6	16.4	58.4

Source: Authors

variation of transfer from the rest of the word. Wage and employment variation in the productive sector induces changes in the salaries of the workers associated with the concerned sectors and in turn change of household income. For example professionals are more represented in the urban non-agricultural households, while unskilled labor is predominant in the other household groups, especially for in rural and agricultural households (see Table 6). Secondary labor is the second more represented in the urban non-agricultural household. Thus, variation in the quantity and wage of this type of labor tends to have repercussions on the income of urban non-agricultural household compared to the other household groups andcompared to unskilled and primary labor.

For a better understanding of these linkages between sectors and households we compute an interdependence index through the different factors č These relationships help to understand the direct effects of sector-led growth scenarios. To take into account the heterogeneity with the agriculture sector, we consider the disaggregation into different crops which are further subdivided into 14 regions to cover heterogeneity in resource endowments, crop patterns, and farming activities.

$$Inter(h, s, f) = Inter(h, f).\ Inter(f, s)$$

Where $Inter(h, f) = \frac{YIF_{h\ f}}{\sum_{f\ \epsilon\ F} YIF_{h\ f}}$

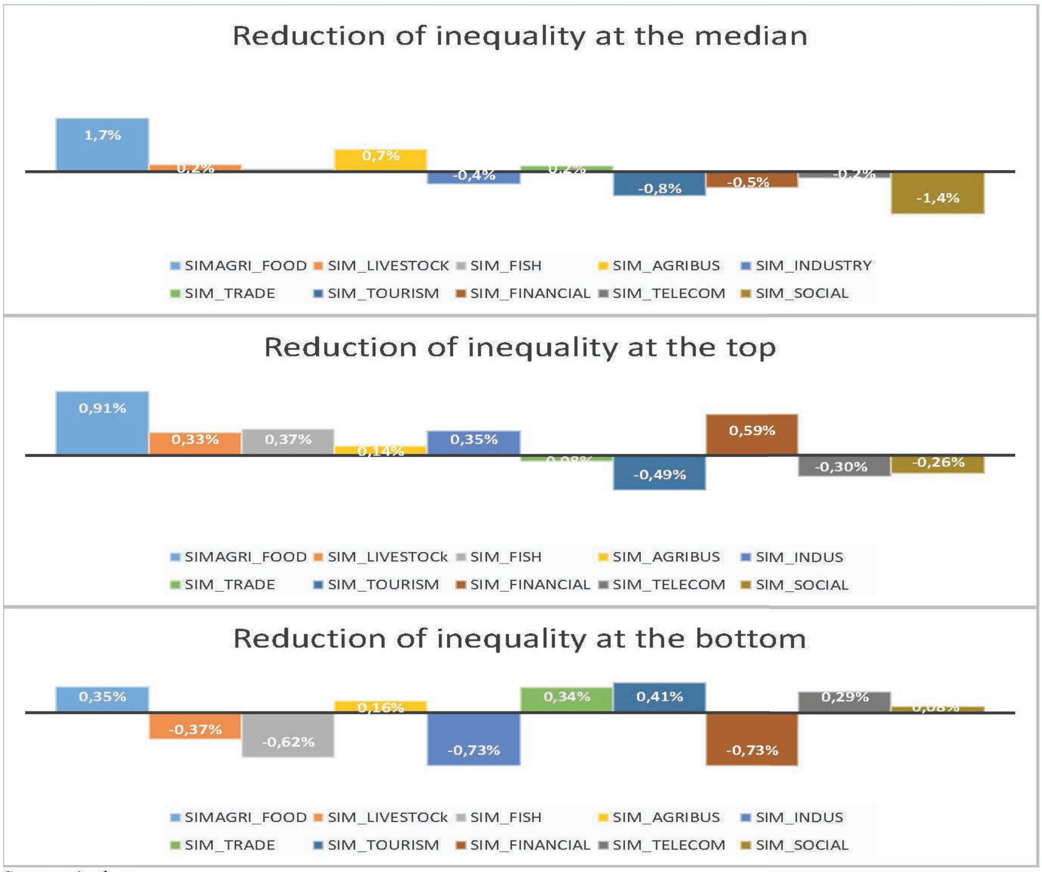
$Inter(h, f)$Indicates the extent to which the household groups are linked to the factors. This index evaluates the importance of the income from factor f in the total factor income of the householdh.

And $Inter(f, s)$=$\frac{WF_f \overline{WFDIST}_{f\ a} QF_{f\ a}}{\sum_{a\ \epsilon\ A} WF_f \overline{WFDIST}_{f\ a} QF_{f\ a}}$

$Inter(f, s)$considers the intensity of the sector in the use of f.

The calculated interdependence coefficients show the interdependence coefficients between households and sectors that occur through factors. In general, rural agricultural households are linked to agricultural sector and the degree of this relationship is higher for the poor households. Unskilled labor and agricultural capital are mainly at the base of this relation and allow the differentiation from the other sectors. Particularly through the capital factor, the rural and agricultural households are more linked to the fishing sector and through unskilled labor to the livestock sector. Rural and non-agricultural households are linked to the Agriculture sector through income from unskilled workers and slightly to services through professional labor and capital with a weaker linkage for the poor. Urban and non-agricultural households are more linked to the services mainly through professional workers and capital. This latter is more related to the richest than to the poor. The interdependence metrics also show that the non-agricultural and the richest households in urban areas are less linked to agriculture than the poor ones. In both urban and rural area rich households are more associated with land. Trade that is associated with transaction costs is linked to rural households and urban poor households, mainly through unskilled labor. For urban and rich households this occurs through professional labor and capital. These various linkages will determine the way growth profiles affect poverty reduction and inequality along the income scale. Growth in labor intensive sectors has more impact on poverty and inequality than growth in the capital intensive sectors. Results show that to reduce inequality along the income scale, future growth should be driven by Agriculture and Agribusiness. In addition, productivity growth in Staple crop and Livestock sub-sectors might lead to the highest impacts on poverty and

Figure 6: Reduction of inequality at the median, the top and the bottom



Source: Authors

inequality given theirrelative strong linkages with the poorest households, as shown by the calculated interdependence metrics.

Besides, we calculate a difference in difference indexes to see how the gap between inequalitie at the top (respectively inequality at the bottom) is reduced between the additional growtl scenarios and the initial situation. These differences are expressed as follows:

- Reduction in the difference between inequality at the top and inequality at the median:

$$(beta_{2020}^{SIM} - beta_{2011}) / beta_{2011}$$

- Reduction in the difference between inequality at the bottom and inequality at the mediar

$$(gamma_{2020}^{SIM} - gamma_{2011}) / gamma_{2011}$$

Agriculture is likely to create more homogenous and constant inequality profile along the income as agriculture-led growth close the gap between inequality at the top and bottom ends and the inequality

Figure 7: Reduction in the difference between inequality at the top (respectively at the bottom) and inequality at the median

Source: Author

level evaluated at the median. It is insightful to identify how the different growth profiles impact on inequality by controlling for all the scale of income. Effort to reach a specific level of targeted growth within formulated policy goals might be insufficient if they do not consider income asymmetries. The findings suggest that examining the level of growth and not its profile, and conducting analyses by using a single non-elastic measurement of inequality might be inappropriate when capturing the effect of growth on inequality. The majority of the results shows evidence that policies that aim to boost agricultural policies are the most egalitarian.

5. Conclusion

Africa's remarkable economic growth in recent years did not automatically translate into considerable welfare improvement andnegatively affected the equal distribution of wealth. This poor performanceleads inequality at the forefront of public debate.Yet there is still much to be learned about inequality in Africa and the complex relationship between growth-poverty-inequality. The paper uses a sample on Sub-African countries and show heterogeneity in the temporal change of the structure of inequality and in the shape with strong variations at the different level of the income scale. The use of the Alpha Beta Gamma method shows that there is a limitation to focus on the summary statistics. Policies that attempt to reduce inequality should not only lies on broad measurement indexes generally expressed at the median of the income distribution, but should also look atthe income distribution at the extremes. Based on the pattern of the isographs and structure of inequality we classify the countries in two different groups. Further, using Senegal as a case study the paper identifies Agriculture and Agribusiness-led growth as having reducing effect on poverty and on inequality along the income scale. Growth driven by these key sectors can make the majority of the people not be disconnected from income growth. As for Senegal, similar study will be conducted in other countries based on the same anisotropic concepts of inequality.

ABSTRACT

How does the amount of land youth expect to inherit affect their migration and em- ployment decisions? We explore this question in the context of rural Ethiopia using panel data from 2010 and 2014. We estimate a household fixed effects model and ex- ploit exogenous variation in the timing of land redistributions to overcome endogenous household decisions about how much land to bequeath to descendants. We find that larger expected land inheritances significantly lower the likelihood of long-distance permanent migration and of permanent migration to urban areas during this time. Inheriting more land is also associated with a significantly higher likelihood of em- ployment in agriculture and a lower likelihood of employment in the non-agricultural sector. Conversely, the decision to study is unaffected. These results are most heavily driven by males and by the older half of our youth sample. We also find that several mediating factors matter. Land inheritance plays a much more pronounced role in pre- dicting rural-to-urban permanent migration and non-agricultural sector employment in areas with less-vibrant land markets and in relatively remote areas (far from major urban centers). Overall, the results suggest that inheritance strongly influences the spatial location and strategic employment decisions of youth.

Keywords: Agriculture, employment, land inheritance, migration, youth

It's the youth bulge that stands to put greater pressure on the global economy, sow political unrest, spur mass migration and have profound consequences for everything from marriage to Internet access to the growth of cities (Sengupta, 2015).

PAPER

1. Introduction

How does the amount of land youth expect to inherit affect their migration and employ- ment decisions? In rural Africa, youth typically rely on inheritance (or on small land rental markets) to access parcels under usufruct land rights systems[1]. However, popula- tion pressures—including a youth bulge in many developing countries—are reducing land availability (Jayne et al., 2010; Muyanga and Jayne, 2014) and potentially opportunities for youth to work in agriculture. Further, as farms intensify agricultural production to overcome land constraints (Ali and Deininger, 2015; Barrett et al., 2010; Bellemare, 2013; Carletto et al., 2013; Headey et al., 2014; Larson et al., 2014; Sheahan and Barrett, 2014), labor saving technologies may consequentially substitute youth farm labor (Bustos et al.,

2016). Pessimistic views on inheritance prospects may push some youth to delay entering the labor force by seeking a secondary or tertiary education. Alternatively, youth may be en- couraged to transition from low-return agricultural to high-return non-agricultural activities (Bezu and Barrett, 2012; Nagler and Naude, 2014). Understanding how land inheritance size impacts youths' subsequent migration and employment decisions is thus critical for understanding the likely impacts of these artifacts of development.

Our main objective is to examine if perceptions of land inheritance prospects (as a proxy for individual land access) affect youth migration and employment decisions in the context of rural Ethiopia. We use a unique dataset on all descendants (children and other close relatives, living in or out of the home, who might stand to inherit land) of household heads and their spouses in 27 woredas (districts) of the Amhara and Oromia regions of Ethiopia.

Our analysis utilizes a measure of individual expected land inheritance based on detailed information provided by household heads on inheritances granted and expected to be granted to each of their descendants. As in Bezu and Holden (2014), we analyze multiple youth employment outcomes simultaneously (permanent migration, long-distance permanent migration, rural- to-urban permanent migration, agricultural employment, non-agricultural employment, and propensity to seek education)

[1] We adopt the World Bank definition of youth employment, encompassing individuals between ages 15 and 34 (Filmer et al., 2014).

to understand whether land constraints drive human capital investment and transitions into potentially high-return occupations. We consider how these relationships vary with gender and youth age. Lastly, we examine the role of mediating factors, to inform policy: the quality of land rental markets and travel time to a major urban center. Such factors may influence the costs of migration, opportunity costs, and barriers into non-agricultural labor.

One of the main empirical challenges confronting analysis of this question is the endo- geneity of individual land inheritance. The size of youth land inheritances is likely shaped by numerous factors unobservable to the econometrician yet correlated with individual labor activities. We estimate a household fixed effects model and appeal to historical land reforms in Ethiopia to develop an instrumental variable for expected individual land inheritance. Specifically, since the installation of Ethiopia's current government in 1991 following the col- lapse of the communist "Derg" dictatorship, 20 of our 27 sample woredas have experienced a large-scale land redistribution. Under such redistributions, the local government allocates land to households based on household size at the time (with particular attention to adult males), with variation over space and time. Using a complete list of descendants of the head and their spouse, provided by the head, and using kebele (or sub-district) official surveys to identify the most recent year of redistribution, we construct an instrumental variable for individual expected inheritance. This instrument is the share of an individual's male co-descendants that were at least 18 years old at the time of the redistribution, interacted with a dummy for having more than one male descendant immediately below one's self in the birth order. This interaction flexibly allows the impact of having a greater share of male descendants be over age 18 at the time of the redistribution to vary according to whether or not the head will face pressures to provide multiple male inheritances immediately after providing an inheritance to a given descendant. Allowing for this is important given that males in our dataset tend to receive larger inheritances than do females (about 60 percent larger, at the median)[2]. Any given youth has a greater likelihood of inheriting land if he has a higher proportion of his male co-descendants aged 18 or higher prior to the redistribution, but the impact should be especially large for youth faced with an acute threat to the size of their inheritance: multiple males immediately following them in the birth order. We show that this instrument is strong, and in a placebo analysis we demonstrate that its strength quickly deteriorates if we use any year other than the actual year of redistribution.

We find that larger expected land inheritances significantly lower the likelihood of long- distance permanent migration and of rural-to-urban permanent migration during this time, despite overall null impacts on permanent migration. Inheriting more land does not signif- icantly reduce permanent migration, but it leads permanent migrants to form households nearby rather than in other districts or urban areas. Inheriting more land is also associated with a significantly higher likelihood of employment in agriculture and a lower likelihood of employment in the non-agricultural sector. Conversely, the decision to study is not robustly impacted by one's expected land inheritance.

These effects are largely driven by men; inheriting more land does not significantly im- pact the migration of women. Further, while inheriting more land predicts significantly greater employment in agriculture and lower employment in the non-agricultural sector for men, the impacts are significantly smaller in magnitude and—in the case of non-agricultural employment—statistically insignificant for women. Impacts on long-distance permanent mi- gration and employment in the non-agricultural sector are also significantly larger for youth aged 20–34 (above median for the sample) than for those in the 15–19 age range, reflecting that it is somewhat older youth whose migration and employment decisions are most heavily influenced by the size of their land inheritance. This may be driven by older youth being closer to the time of inheritance, or, for men in particular, closer to the timing of establishing financial independence and marital arrangements (Honwana, 2012). Land inheritance plays a much more pronounced role in predicting rural-to-urban permanent migration and non- agricultural sector employment in areas with less-vibrant land markets than in areas with more vibrant markets. Similarly, it is in relatively remote places (far from a major urban center) that the amount of land inheritance is most important for migration and employment decisions. This suggests the importance of context in studying the effects of inheritance.

Overall, the results suggest that inheritance strongly influences the spatial location and strategic employment decisions of youth. Youth have a strong tendency to remain in the agricultural sector if given the opportunity to access land, and they pursue non-agricultural labor opportunities in large part as a response to land shortages.

The paper is organized as follows. Section 2 presents our overarching conceptual frame- work, reviewing existing literature and the knowledge gaps that our paper seeks to address. Section 3 outlines access to land in Ethiopia, the norms that governance inheritance of land in Ethiopia, and the current state—and related drivers—of migration and youth employ- ment in rural Ethiopia. Section 4 outlines our primary data source and how we measure inheritance, migration, and employment outcomes. Section 5 outlines our empirical strategy, including our main econometric specification and identification strategy. Section 6 presents our main results as well as result by gender, age, depth of

[2] This is despite legal provisions in our study regions stating that women have equal rights as men to access, use, and manage land (ANRS, 2006, 2007; ONRS, 2007).

land rental markets, and proximity to a major urban center. Finally, Section 7 concludes.

2. Conceptual Framework

There are two formative complementary or substitutionary relationships between factor in- puts (labor, land capital, and non-land capital) in agricultural production that influence the demand for youth labor. The first is the complementarity between land and family labor.

These relationships can be quite complex in sub-Saharan Africa (SSA), depending on land and labor constraints (Headey et al., 2014). Consider the case where land is constrained as in Ethiopia, but labor and land are perfect complements. If the household has excess labor, then the demand for youth farm employment will be relatively low. However, the relationship between labor and non-land capital is another integral determinant of labor demand in this case. The adoption of labor-intensive technologies would shift upward the demand for youth labor. This is what one might expect to occur in SSA, given smallholder farmers' intensification of fertilizer use, high yield varieties, and other input-intensive prac- tices to increase production (Barrett et al., 2010; Headey et al., 2014; Headey and Jayne, 2014; Larson et al., 2014; Muyanga and Jayne, 2014; Sheahan and Barrett, 2014). Else- where, farmers have shifted their adoption toward labor saving technologies, causing an exodus of labor from the agricultural sector (Bustos et al., 2016).

Of course, the presence of local non-agricultural employment and income opportuni- ties may draw youth out of agriculture (de Brauw and Mueller, 2012). Opportunity costs of working on the family farm put pressure on youth employment decisions. Recent work suggests the opportunity costs posed by the agricultural wage (Dillon and Barrett, 2014) and non-agricultural self-employment sectors may be low (Bezu and Barrett, 2012; Nagler and Naude, 2014), the latter being driven by high barriers to youth starting their own non-agricultural enterprises. Thus, among households with rudimentary production technologies or excess labor, youth may be pushed to take advantage of the monetary re- turns to migration, traveling to destinations with higher wages (de Brauw et al., 2013a).

Existing literature has not come to firm conclusions about the impacts of land access on subsequent youth migration and employment decisions. An important recent study links individual access to land with youth aspirations of exiting the agricultural sector in southern Ethiopia (Bezu and Holden, 2014). The authors find robust negative relationships between farm size per child and off-farm employment, with weaker evidence on migration. But esti- mated effects of land access on migration and off-farm employment may be attenuated by at least two factors. First, using the ratio between farm size and children of the household head may result in a biased measure of individual inheritance. Eligible candidates for inherited land include migrant children of the head and spouse, as well as extended family members (Holden and Bezabih, 2008). Second, even a measure of lagged household farm size may fail to account for land transfers that occurred prior to the initial interview. If an individual's expectation of additional land inheritance in the future is negatively correlated with what they received prior to the initial interview, and pre-initial interview transfers increase migra- tion and non-agricultural employment, then estimates of the impacts of expected individual inheritance in the future on migration and employment may be downward biased. This mo- tivates our analysis of the impacts of land access that takes into account the full history of descendants of the household head or their spouse—regardless of whether or not they still live at home—and which further takes into account all inheritances already granted as well as those expected to be granted in the future.

We also account for how recent developments in migrant labor and land rental markets might influence youth employment-land relationships. First, we examine how expected land inheritance differentially predicts employment decisions depending on whether the individual is in close proximity of a major urban center. The expected returns to migrant labor will be higher if moving costs are lower—either due to proximity or due to knowledge of the local language increasing the probability of securing employment at destination (Sjaastad, 1962). Yet, the wage gap between one's origin and destination may be much smaller in areas close to cities, reducing youth migration (Harris and Todaro, 1970). A less pronounced inverse relationship between access to land and youth migration (push factor) may thus be observed in areas closer to towns due to these countervailing effects. This is an empirical question meriting analysis. Second, we consider whether the presence of more robust local land rental markets reduces youth tendencies to migrate or work in the non-agricultural sector. Local rental markets provide youth opportunities to establish their own farms outside of inheritance. For this reason, youth are one of the most prominent groups engaging in these markets in SSA (Deininger et al., 2015). In areas with robust rental markets, youth migration and employment decisions may be less responsive to expectations on inherited land. Although rental markets provide youth access to land, we do not expect the presence of rental markets to perfectly offset responses we might observe between expected land inheritance and employment; there is likely a premium to having ownership or longer-term usage rights to the land youth cultivate. This premium may be due in part to inheritance conferring more secure property rights than does rental.

3. Background and Context

3.1 Access to land in Ethiopia

Ethiopia has long faced severe problems of land scarcity. Population density is growing rapidly, leading average household farm sizes to dwindle. In 2011–12, more than half of the rural farm households in Ethiopia cultivated less than one hectare of land (CSA, 2012). Further, a youth bulge in Africa[3] promises to intensify these problems for youth in partic- ular (CSA, 2015). In such land-constrained countries under usufruct land rights systems, like Ethiopia, youth rely on periodic land redistributions, inheritance, and/or small rental markets for any access to land.

The communist "Derg" dictatorship ruled Ethiopia from 1974–1987; land was formally owned by the government, which aimed to maintain social equity by ensuring at least some degree of equality in household access to land. The current regime has been in place since 1991, following the collapse of the Derg dictatorship. Land continues to be formally owned by the government, with formal land markets (sales) outlawed. However, several land redis- tributions have occurred since 1991, usually based on household size at the time (with extra weight placed on adult males). In our study regions of Amhara and Oromia, 20 of our 27 sample woredas experienced such a land redistribution, though there is substantial variation in the timing of the redistributions, as shown in Table 1[4]. The median year of redistribution is 2003, but these range in time from 1992 to 2013. Post-Derg era land redistributions have mostly involved land which had been previously utilized by state farms (Bruce et al., 1994)[5].

Individual land users in our study regions have the legal right to transfer their land use rights to their children or other family members (ANRS, 2006, 2007; ONRS, 2007). Individuals also have the right to rent their land use rights to any person—with some region- specific restrictions on size and duration of the land transactions[6]. Land inheritances in Ethiopia are not uniform across descendants of the head—both due to cultural factors like norms associated with gender and age and due to restrictions on land fragmentation[7].

3.2 Norms of Inheritance

Although statutory land tenure and inheritance laws in Ethiopia allow all rural citizens wishing to engage in agriculture to access land, customary norms and practices tend to favor men (Fafchamps and Quisumbing, 2005)[8]. First, marriage is primarily patrilocal whereby the wife resides with or near the husband's parents. Second, sons (especially the first born) traditionally care for their parents in old age (Kumar and Quisumbing, 2012). Finally, cus- tomary beliefs limit the type of agricultural labor in which females can engage (plowing, sowing seeds and threshing are exclusively male activities), necessitating male labor partici- pation on any plot.

Existing research has explored sibling competition and its effects on parental and youth decision-making in a variety of contexts[9]. Fafchamps and Quisumbing (2005) suggest that a groom's number of brothers (but not sisters) has a strong negative effect on land inheritance at marriage. Gibson and Gurmu (2011) find that having a greater number of elder brothers decreases a sibling's agricultural productivity (younger male siblings receive less productive land) and diminishes marriage opportunities (via less assets brought to the marriage).

Finally, previous research contends that not only older brothers, but also younger sib- lings may affect a youth's decision to seek an alternative livelihood outside of agriculture. Gibson and Gurmu (2012) analyzed sibling out-migration in a district of Ethiopia close to the capital of Addis Ababa (in Oromia region) and found that the birth of a younger sibling doubled the odds of out-migration over time. The primary reason for migration was to seek high school education or non-agricultural employment opportunities.

3.3 Migration and employment in rural Ethiopia

Recent analysis of migration in Ethiopia suggests that migrants are predominantly 'pushed' from their homes rather than attracted by an urban 'pull' of higher returns on human capital investments. For example, the Ethiopian Urban Migration Study (World Bank, 2010) reports that more than 42 percent

---

[3] As of 2015, 37 percent of the population of Ethiopia was between the ages of 15 and 34 (CSA, 2015).

[4] In the survey, we asked about the latest redistribution so as to ensure that respondents recall the period of redistribution post-Derg dictatorship.

[5] While communal grazing land and woodland continues to be distributed to new claimants as need arises, such reallocations are not nearly at the scale of the land redistributions that occurred during the post-Derg era (Demeke, 1999).

[6] For example, while the restrictions are more relaxed in Amhara, the Oromia land proclamation decrees that individuals have the right to rent out only up to half of their total land holding, limiting the duration of the land rental to a maximum of 3 years for those who employ traditional farming and 15 years for modern/mechanized farming (ONRS, 2007).

[7] Farm fragmentation is a key challenge in Ethiopia—partly induced by intra-household land transfers over the last 20–25 years. In response, many regions (including our study regions) have introduced restrictive regulations regarding the size of a plot. Oromia land law sets a floor size per plot of 0.5 hectares for annual crops and 0.25 hectares for perennial crops (ONRS, 2007), while the minimum plot size in Amhara is 0.25 and 0.11 hectares for plots under rain-fed agriculture and irrigation, respectively (ANRS, 2006, 2007).

[8] For further discussion of customary law and inheritance, see North (1990), Fafchamps and Quisumbing (2002), and Mekonnen and Worku (2011).

[9] See, for example, research on sibling composition and rivalry on: health outcomes (Kumar and Quisumbing, 2012; Mekonnen and Worku, 2011; Kushnick, 2010; Garg and Morduch, 1998; Morduch, 2000), education outcomes (Congdon Fors et al., 2015; Gibson and Sear, 2010; Lloyd et al., 2009; Butcher and Case, 1994), and inheritable wealth (Grawe, 2010; Keister, 2003).

of migrants stated that they would not have migrated if they would have been able to make a living in their original home. Zeleke et al. (2008) reports that young men are the most likely to migrate in Amhara region and respondents cite a lack of sufficient means of subsistence, shortage of land, and shortage of employment opportunities in the rural areas as primary reasons for migrating. Likewise, Dorosh et al. (2012) find that households with less agricultural land were more likely to send out migrants, as were poorer households and households afflicted by a community-wide drought shock. Similar relationships between migration and land are reported in de Brauw (2014) and Lee and Mueller (2016).

According to the National Labor Force Survey in 2013 (NLFS), rural-rural and rural- urban migration shares are almost equivalent at 35 and 33 percent respectively of total migrants (authors' calculations using NLFS, 2013). Of course, there is substantial regional variation in these numbers, with greater rural-rural migration in Amhara, Oromiya and SNNP regions than in Tigray, for example[10].

Although migration in Ethiopia occurs for a variety of reasons (education, risk insurance, employment diversification), research on non-agricultural labor activities suggests that there are few opportunities for rural laborers to obtain employment outside of agriculture. Among rural-urban migrants aged 15–65, only 35.5 percent are motivated to migrate in search of work (Mueller et al., 2015). Education is the strongest determinant of rural-urban migration (de Brauw et al., 2013b; Mueller et al., 2015), following large national education investments during the last decade of about 4 percent of GDP (World Bank, 2016).

Schmidt and Bekele (2016) use the NLFS 2013 to show that only 23 percent of the economically active population identifies their primary occupation as being in the non- agricultural sector. Among non-agricultural sector workers, the largest share (30 percent) is engaged in sales work, of which street vendors and local market sales comprise 42 percent. Informal alcohol vendors make up another 20 percent of sales work, while formal shopkeepers comprise 22 percent. The majority of the remaining non-agricultural laborers are divided among construction and mining (11 percent), food processing and craftwork (8 percent), teaching (6 percent), and a variety of other jobs such as refuse and personal service work- ers. These are by and large low-skilled occupations with limited labor demand, possibly explaining why youth are often pushed rather than pulled into them.

Both employment diversification (via non-agricultural employment and/or migration) and the pursuit of educational opportunities represent potential strategies of risk diversifica- tion. A variety of factors including sibling competition for inheritable assets like agricultural plots, agricultural shocks (e.g., droughts or floods), and declining agricultural productivity may lead youth to pursue these strategies. Given that agricultural land in Ethiopia is predominantly accessed via inheritance or share-cropping[11], we hypothesize that access to land (via inheritance) affects youth decisions to stay in agriculture or seek other livelihood opportunities. We explore this hypothesis using a unique panel dataset that collects data over a variety of agro-ecological zones and farming systems.

4. Data

Ethiopia provides an ideal environment in which to examine how access to land affects individuals' decisions to diversify out of agriculture for several reasons. First, it is a pri- marily agrarian economy where land is accordingly central to livelihoods—as in much of the developing world. Second, geographic and topographic characteristics, as well as farm- ing systems and the value of farming, differ significantly over short distances—providing useful variation in our explanatory variables. Finally, land tenure policies and inheritance customs, described in Section 3, provide a natural experiment for understanding the effects of sibling (and co-descendant) configuration on land inheritance perceptions and ultimately employment diversification choices.

We take advantage of a panel survey conducted in 2010 (round 1) and 2014 (round 2)[12]. Round 2 was purposefully designed to address the research questions outlined above; it collects detailed information on not only household members (that live in the household and comprise the household roster), but also direct descendants of the household head or their spouse that are non-resident. This permits us to analyze the expected inheritances as well as the migration and employment decisions of all descendants.

The round 1 survey encompassed 1,810 households and was completed in July 2010 in order to evaluate the impact of the Sustainable Land Management Program (SLMP) in Amhara and Oromia regions. The sample was drawn from a list of kebeles (sub-districts) within the Blue Nile Basin in Amhara and Oromia[13]. The final sample consisted of 27 kebeles located in 9 woredas, with approximately 200

[10] de Brauw and Mueller (2012) also note differences in regional migration trends, findings that greater land transferability is associated with decreased migration.

[11] Although sharecropping provides access to agricultural land, tenuous contracts require sharecroppers to continuously change contracts and work different agricultural plots (see Deininger et al. (2003, 2011)).

[12] Both rounds were conducted by the International Food Policy Research Institute (IFPRI) in collaboration with the Ethiopian Development Research Institute (EDRI).

[13] Based on the list of SLMP kebeles in Amhara and Oromia, a random sample of woredas (districts) were selected whereby a woreda must contain one SLMP kebele.

households surveyed per woreda[14]. In round 2, 1,748 of the households interviewed in round 1 were located and interviewed again, representing a household attrition rate of 3.4 percent over 4 years.

Our analysis uses a cross-sectional dataset. We include in our estimation sample all direct descendants of the household head[15] or their spouse who lived in the household in round 1. Our dataset records whether or not they left the household (permanently migrated) by round 2, and their sector of employment in round 2. We describe our specific measures in Section 4.1. Our controls are from round 1 to reduce concerns of reverse causality.

4.1 Variable Measurement

We measure youths' expected land inheritance by asking heads about each of their direct descendants: how much land they have already received[16] and how much land they expect to provide in the future. Summing the two gives the total expected inheritance. This is a meaningful quantity as heads are generally the prime decision-maker over inheritances. In the text, we refer to individuals' expected land inheritance; in all cases this should be understood as the sum of what they have inherited and what the head expects to provide.

We measure migration in three ways. First, we code a dummy variable for permanent migration that takes on a value of 1 for any youth who was a household member in 2010 but is no longer a household member by 2014. For this definition of permanent migration, individuals may have migrated anywhere in Ethiopia or elsewhere. However, they cannot simply be temporarily absent; they must no longer be considered a household member. Second, we code a dummy variable for long-distance permanent migration, which takes on a value of 1 provided that the individual permanently migrated since 2010 and by 2014 lives outside of the woreda (district) in which they resided in 2010. Finally, we code a dummy variable for permanent migration to an urban area, which takes on a value of 1 provided that the individual permanently migrated since 2010 and by 2014 lives in an urban area.

We are predominately interested in whether individuals work in the agricultural or in the non-agricultural sector. We accordingly consider two employment outcomes: agriculture is the individual's primary occupation, and the non-agricultural sector is the individual's primary occupation. We further examine whether or not the individual is currently studying as their primary occupation—indicating the choice to acquire human capital[17].

4.2 Descriptive statistics

Table 2 summarizes the outcomes, land access measures, and individual and household characteristics for the full sample as well as for the sub-sample of those who expect to inherit land (71 percent of the full sample). We focus most of the analysis on those who expect to inherit land; this encompasses the vast majority of all individuals, and is also the estimation sample driving our slope coefficients when we consider the logged value of land inheritance as our key explanatory variable. We apply a natural logarithmic transformation to reduce the tendency for extreme outliers to drive inferences in our regression analysis.

Panel A summarizes the outcomes of interest. Nearly half of individuals (45 percent) permanently migrated between survey rounds. Of those permanent migrations, nearly half were to locations outside of the woreda in which they lived in 2010 and 62 percent were to an urban area[18][19]. The primary occupation is most often in agriculture (37 percent) or in school (29 percent); but 16 percent work in the non-agricultural sector and 13 percent do domestic work. Only 4 percent of the sample reports being unemployed. The average individual expects to inherit 0.34 hectares of land (Panel B).

Panel C shows that the sample is tilted towards males (67 percent). The descendants' average age in round 1 is about 20 years, most (98 percent) are children of the head[20], 68 percent have finished the first education cycle (grades 1-4), and few (5 percent) are married. A quarter of the descendants have more than one male descendant directly following them in birth order. On average, descendants have 1.4 older male descendants and 1.2 older female descendants; 17 percent were at least 18 years old at the time of the last land redistribution. Household characteristics[21] are summarized in Panel D. While about two-thirds of households have a metal roof, only 3 percent have an improved floor. The

[14] For more information on sample selection and site location, see Schmidt and Tadesse (2014).

[15] We use the round 2 household head since data on the complete list of descendants of the head and their spouse—as well as inheritance amounts—was completed in round 2.

[16] We ask how much land they have received from either the household or the peasant association (PA).

[17] There are two other possibilities for primary occupation: domestic employee and unemployed. These are summarized in Table 2, alongside our main employment outcomes of interest.

[18] These numbers come from the following calculations: 0.21/0.45 = 0.47 and 0.28/0.45 = 0.62. Note that moving out of woreda and moving to an urban area are not mutually exclusive.

[19] Our sample implies an annual out-of-woreda (district) migration rate of 5 percent. This is slightly larger than the rate computed using 2007 Census data, 1.1 percent (Mueller et al., 2015), perhaps due to the focus on youth who have greater rates of mobility (Lee and Mueller, 2016) and increasing migration trends.

[20] The sample is restricted to direct descendants of the head or their spouse, but this can include stepchildren or grandchildren (though it rarely does).

[21] Household characteristics are not included because they are collinear with household fixed effects.

household head was, on average, 53 years old, male (83 percent) and had no education (58 percent). 71 percent were Orthodox Christians and 25 percent were Protestant.

5. Empirical Strategy

We investigate the effect of land inheritance on youths' migration and sector of primary employment decisions. If all variation in youths' expected land inheritance were exogenous to employment and migration decisions, we could recover causal estimates of the impact of expected inheritance by estimating the following linear probability model:

$$E_i = \beta_0 + \beta_1 L_i + \gamma \mathbf{X}_i + \alpha_j + \epsilon_i \quad (1)$$

where i indexes individuals. We denote by E_i migration and employment outcomes, by L_i expected land inheritance, by $\mathbf{X}_i$ a vector of control variables, described below, and by α_j household fixed effects. Standard errors are clustered at the kebele level, the relevant administrative unit in which land redistribution policies are executed.

5.1 Identification

A concern of our analysis is that the anticipated amount of land inheritance is likely to be endogenous to migration, employment, and educational decisions. There are several possible sources of omitted variable bias likely to bias ordinary least squares (OLS) estimates of β_1.

First, in a model without household fixed effects, one would worry that a household's land endowment, wealth, and income levels would heavily influence both migration and employment decisions and expected inheritance. Migration is costly and requires the payment of up-front costs to finance it (Carrington et al., 1996). Further, employment in agriculture is more likely in a family with ample experience in this sector due to their own larger land en- dowments and knowledge (Bezu and Barrett, 2012). Indeed, this source of omitted variable bias is a compelling reason to include household fixed effects in all regressions; through their inclusion, our regression results use within-household variation in expected land inheritances to explain within-household variation in migration and sector of employment decisions.

Second, within a household, parents may select descendants with particular characteristics—such as a physical aptitude for, or a keen interest in, agriculture—for larger inheritances. This would be problematic for identification if such physical and mental traits also drive employment and migration decisions. Similarly, within a household, parents may prioritize children with good marriage prospects in the village (Fafchamps and Quisumbing, 2005). As such children face lower search costs in finding a partner, they may find higher- quality partners and marry at an earlier age, thus reducing the likelihood of long-distance and rural-to-urban permanent migration. Parents could also prioritize children most likely to help them in old age (Bernheim et al., 1985). Such children may be more or less likely to migrate or to work in agriculture; helpful children may be those who are helpful due to superior physical and mental endowments, but they may also be those who are helpful due to inferior endowments and thus greater willingness to stay behind and serve parents. As these different potential sources of omitted variable bias may skew OLS estimates in different directions, it is not possible to sign the direction of bias.

We address such sources of omitted variable bias in two main ways. First, we control for a number of factors that may influence the land allocations that youth receive and which are also likely to influence migration, employment, and educational opportunities and decisions. All of our specifications include household fixed effects to capture all characteristics of a community (kebele) and a household that may influence youths' decisions. These include the availability of land (community wide as well as within the household), laws and regulations, customs and traditions, the full history of community land redistribution, as well as access to agricultural and non-agricultural employment opportunities and educational institutions.

We additionally allow kebeles to have different impacts on individuals according to their gender, age, and marital status by including interactions of kebele fixed effects with a dummy for being male, with fixed effects for the descendant's age, and with a dummy for being married at baseline. This could capture the fact that, for example, different local governments may preferentially treat males, youth at critical stages such as those just reaching marriage- able age, or the married when redistributing land to individuals.

Our household fixed effects control for the total amount of land available to the house- hold. However, within households, there is a great deal of variation in expected inheritance across descendants. Some of this may be explained by a number of individual characteristics for which we control: being male, being the oldest male, age, marital status, whether the individual is a child of the head, whether they have completed the first cycle of primary school (grade 4), and whether they were themselves at least age 18 at the time of the last land redistribution. The set of older descendants a youth has is also likely to influence both the youth's decision-making and his access to land since older descendants are a) likely to inherit land and other assets before him and b) may provide information or support in identifying and obtaining employment or educational opportunities. Following Vogl (2013), we include fixed effects for the exact permutation of older descendants (mostly comprised of siblings, but also including a small number of grandchildren or step-children of the head) that the youth has above them in the birth order (e.g., no older descendants, Boy (B)-Girl (G)-Boy (B), GB, BG, BBBB, G, etc)[22]. We additionally control for having more than one male descendant immediately below (younger than) one's self in the birth order. Males in Ethiopia generally receive larger land inheritances than do females, and any individual's land inheritance tends to be smaller when they are immediately followed by multiple males.

Second, we implement an instrumental variables (IV) strategy. Specifically, we leverage a unique feature of Ethiopia: given its authoritarian regime, land access in Ethiopia is influ- enced by government efforts to redistribute land. There is significant geographic variation in such redistributions; the median year is 2003, but these range in time from 1992 to 2013[23].

Our in-depth interviews with kebele officials suggest that males over age 18 receive priority at the time of redistribution. This suggests that households with a greater share of their male descendants being over age 18 at the time of the most recent land redistribution should have relatively more land allocated to these descendants. While our fixed effects capture the average impacts of these redistributions (as well as their gender-, age-, and marital status- specific impacts), their impacts may vary in other ways within a household. Specifically, we would expect "marginal" individuals at high risk of receiving a small inheritance to benefit most from having a greater share of their male co-descendants be over age 18 at the time of the land redistribution. Our data reveal one such vulnerable group: those with more than one male descendant immediately below them in the birth order, for whom their household's head will very soon after them have two or more boys reaching the age of inheritance. In our dataset, the median male land inheritance (in terms of land area) is 60 percent greater than that of the median female. As such, brothers pose a larger threat to inheriting land.

We use a single interaction term as an instrumental variable for expected land inheritance: the share of male descendants in the household who were over age 18 at the time of the land redistribution interacted with a dummy for having more than one male descendant immediately follow them in birth order. As we have one excluded instrument (an interaction term) and one endogenous variable, our model is exactly identified. The instrumental variable is summarized in Table 2; its mean is 0.03.

Our first stage equation states that an individual's expected land inheritance, measured as L_i, is a function of the product of the share of male descendants in the household who were over age 18 at the time of the most recent land redistribution, r_i and a dummy for having more than one male descendant immediately follow one's self, m_i:

$$L_i = \delta_0 + \delta_1 r_i \times m_i + \delta_2 m_i + \theta \mathbf{X}_i + \pi_j + \eta_i \tag{2}$$

where π_j are household fixed effects.[24]

The validity of this instrument rests on a single identifying assumption: The difference in the effect of having a larger share of male descendants in the household be over age 18 at the time of land redistribution on those with versus without more than one male descendant immediately below them in birth order only affects migration and employment decisions through its effect on expected land inheritance. Importantly, the individual components of the excluded instrument, m_i and r_i, are included in our main specification of Equation 1 (the latter through our use of household fixed effects). That is, we explicitly allow both of them to directly impact our migration and employment outcomes. We do not claim that either of them only affects such outcomes through their effect on the size of an individual's inheritance. Thus, we need only believe that their interaction is a valid instrument—not that either of the two variables in level form is a valid instrument.

In Table 3, we show that this instrument satisfies the inclusion restriction: it is a strong predictor of the size of individual i's land inheritance. In our baseline specification with our full control set (column 2), a standard deviation (0.11 unit) increase in the excluded instrument makes one's land inheritance 1.3 times greater[25]. The F statistic on the excluded instrument is 26.6, suggesting no problems of

[22] As in Vogl (2013), with this control set, we anticipate that the gender of the next sibling after a descendant, conditional on having such a sibling, can be taken as if random.

[23] In 20 kebeles, a land redistribution occurred after 1991 (in the post-Derg regime era). In 7 kebeles, no such redistribution occurred. In those kebeles in which no redistribution occurred, we code that the share of descendants over 18 at the time of the most recent land redistribution was 0, to reflect that none of the descendants in the household helped the household obtain more land by virtue of their age.

[24] r_i does not appear in the regression in its level form as it is collinear with our household fixed effects.

[25] This comes from taking exp(2.478 × 0.11) = 1.3.

weak instruments[26]. We argue that the exclu- sion restriction holds since the precise timing of land redistributions in a community—and specifically, the difference between its effect on those with versus without multiple male descendants immediately below them in the birth order—should be exogenous to the within- household selection mechanism determining the size of individual land inheritances.

A potential concern with our IV strategy is that kebeles with relatively early (or late) land redistributions may simply be on different time trends with respect to how having younger brothers influences within-household allocations of land. If this were the case, then it might not be the land redistribution itself that explains the strength of our first stage, but rather just the order in which kebeles experienced such a redistribution (with that order potentially being endogenous to factors influencing youth employment and migration decisions)[27]. Our first stage would be just as strong if we were to instead pretend that each kebele's land redistribution occurred in year t + k rather than year t, for k E (−∞, ∞). We carry out this placebo analysis in Figure 1, for integer values of k E (−15, 15), plotting k on the x- axis and the F statistic on the excluded instrument in our main specification (column 2 of Table 3) on the y-axis. We see that the F Statistic is maximized when k = 0 (i.e. when we use for each kebele the actual year, t in which land redistribution occurred). Further, it quickly deteriorates as we move away from k = 0. Indeed, among the 30 years to which we try perturbing the actual year of redistribution, for 26 we obtain an F Statistic indicating problems of weak instruments[28][29]. Overall, these findings are encouraging; they suggest that it is the extra land being made available by redistributions, and not different trends across kebeles with early versus late redistributions, that is driving our strong first stage results.

6. Results

6.1 OLS Estimates

Table 4, Panel A provides ordinary least squares (OLS) results from regressions of permanent migration (columns 1–2), long-distance permanent migration (columns 3–4), and permanent migration to an urban area (columns 5–6) on a youth's logged amount of expected land in- heritance, in hectares. We present specifications with (even-numbered columns) and without (odd-numbered) our full control set; all specifications include household fixed effects.

In our preferred specification with our full set of controls, a 10 percent increase in a youth's land inheritance is associated with a 1.6 percentage point decrease in the incidence of permanent migration[30]. This represents a 3.0 percent decrease relative to the mean rate of permanent migration. Inheriting land is also associated with a lower incidence of long- distance permanent migration, and less permanent migration to urban areas in particular. These findings are present regardless of whether we include our full control set. A 10 per- cent increase in land inheritance is associated with a 2.4 percentage point decrease in the incidence of long-distance permanent migration, and a 2.7 percentage point decrease in the incidence of permanent migration to urban areas. Relative to the means of each of these outcome variables, these indicate an 8.9 percent and a 7.9 percent reduction in long-distance permanent and rural-to-urban permanent migration, respectively. This suggests that receiving a land inheritance is associated with less migration, but that the magnitude of its impacts are particularly large for long-distance and rural-to-urban migration.

Table 4, Panel B presents OLS results from regressions of one's primary sector of employ- ment being agriculture (columns 1–2), non-agriculture (columns 3–4), and being a student (columns 5–6) on a youth's logged amount of expected land inheritance, in hectares. The likelihood of one's primary sector of employment being agriculture is significantly larger for those who have inherited or expect to inherit land, regardless of whether we include our full control set. In our preferred specification with our full set of controls, increasing a youth's land inheritance by 10 percent is associated with a 2.5 percentage point increase in the incidence of one's primary sector of employment being agriculture, which is a 7.8 percent increase relative to the mean incidence of employment in agriculture. The amount of land inheritance is also correlated with a lower incidence of employment in the non-agricultural sector, although this effect is not statistically significant at conventional levels (p-value = 0.16). While land inheritance is negatively correlated with whether or not an individual's primary occupation is being a student, the correlation is not robust to the inclusion of our full control set[31].

[26] If we instead compute the excluded instrument using the share of total descendants that was over age 18 at the time of the land redistribution, rather than the share of male descendants, we obtain a slightly smaller F statistic of 26.2.

[27] Table 1 shows this order, with Tulugura kebele experiencing the first redistribution, followed by Fundisa and Arjo a year later, and Shemagile Giyorigis experiencing the latest land redistribution.

[28] In our main specification, the Stock-Yogo critical value for 10 percent maximal IV size for a Cragg-Donald F Statistic is 16.38.

[29] Further, the four other "sufficiently high" F Statistics occur at t − 5, t − 4, t − 3, and t − 2; this may be due to redistribution policies in some kebeles favoring not those over age 18, but rather those over age 23 (or age 22, or age 21, or age 20)—that is, youths slightly older than 18.

[30] Given our level–log model, here and elsewhere, the effect of a 10 percent increase in land inheritance is obtained by taking the coefficient on expected land inheritance × ln(1.1).

[31] We obtain similar results (available upon request)—for both our migration and employment outcomes—when we instead measure land access using a dummy for whether or not an individual has inherited or expects to inherit land.

6.2 IV Estimates

The OLS estimates presented thus far may fail to account for important, within-household variation in factors that influence both land inheritance as well as migration and employment decisions. To address this endogeneity problem, we next turn to IV estimates. Section 5.1 outlined our IV identification strategy and described our excluded instrument: the share of male descendants in the household who were over age 18 at the time of the most recent land redistribution interacted with a dummy for having more than one male descendant immediately follow one's self.

Table 5, Panel A compares our earlier OLS estimates of the impacts of the size of land inheritance on migration outcomes (columns 1–3) with IV estimates that account for the endogeneity of land inheritance to migration (columns 4–6). Compared to the OLS estimates, the IV estimates are larger—though, for the case of permanent migration to any area, the effect is no longer statistically significant. However, we still find strong impacts on long-distance permanent migration and rural-to-urban permanent migration. A 10 percent increase in a youth's land inheritance is associated with an 8.1 percentage point decrease in the incidence of long-distance permanent migration and a 4.8 percentage point decrease in the incidence of rural-to-urban permanent migration. Relative to the means of each of these outcome variables, these indicate a 30.0 percent, and a 14.1 percent reduction in long- distance permanent migration and rural-to-urban migration, respectively.

In Panel B of Table 5, we compare OLS estimates of the impacts of the size of land inheritance on employment outcomes (columns 1–3) with IV estimates (columns 4–6). The significant, positive impact of inheriting more land on employment in agriculture is now even larger in magnitude and more statistically significant; the IV results show that a 10 percent increase in expected land inheritance increases the incidence of employment in agriculture by 6.2 percentage points, which is a 19.4 percent increase relative to the mean incidence of employment in agriculture (significant at the 0.01 level). The impact of the amount of land inherited on employment in the non-agricultural sector is also larger in the IV results, and also significant at the 0.01 level; a 10 percent increase in land inherited leads to a 4.1 percentage point increase in employment in the non-agricultural sector, which is a 21.6 percent increase relative to the variable's mean. As in the OLS results, however, we find no impact of receiving a larger land inheritance on the probability of being a student. Inheriting land seems to powerfully impact one's sector of employment, but not one's choice of whether or not to study.

6.3 Impacts by Gender and Age

While we have thus far identified average impacts of the size of land inheritance on youth migration and employment outcomes, we have not examined how these impacts differ across youth with different characteristics. However, from a policy perspective, it is important to understand which individuals in our sample are most driving these results. Of special importance are the differential impacts on men versus women, and on youth at different ages— specifically, above versus below median for our sample, which involves separately considering 15–19 year olds and 20-34 year olds. Given cultural and social norms that often disfavor women in land inheritance (Fafchamps and Quisumbing, 2002) and in educational and employment opportunities (Croppenstedt et al., 2013), one might expect land inheritance to have a significantly different impact on young women than on their male co-descendants. In addition, a lack of financial independence can delay other social and political milestones in youths' lives (Honwana, 2012). Thus, the very young may not be poised to take large migration and employment decisions in response to an inheritance, while older youth may be at critical junctures in which land strongly influences decision-making.

Table 6, Panel A estimates a model in which we interact our full set of individual-level controls with gender; this allows us to compare how well land inheritance predicts migration and employment outcomes for men versus women, and to test for any statistically significant differences. Given problems of weak instruments for this interacted model, we estimate by OLS[32]. This is less of a concern given the consistent story—in terms of sign and statistical significance—told by our OLS and IV results for our key outcomes. Also, to the extent that the bias in our OLS estimates is uncorrelated with gender, the relative size of the coefficients on land inheritance for men versus for women is informative.

What is immediately apparent is that men are driving our results for migration. Land inheritance is not a significant predictor of permanent migration by women, but it predicts a significantly lower likelihood of long distance permanent migration and rural-to-urban permanent migration for men. Further, these differences are both significant at the 0.01 level. We also find that larger inheritances predict a greater likelihood of working in the agricultural sector for both genders, though this finding is statistically significantly larger in magnitude for men than it is for women. That is, increasing a man's inheritance increases his likelihood of working in agriculture more than it increases a woman's chances. While inheriting more land predicts a lower probability of working in the non-agricultural sector for both genders, this finding is only statistically significant for men. A small land inheritance may drive men

[32] Due to degrees of freedom considerations in these analyses by gender and youth age group, we estimate a slightly modified specification that uses gender, marital status, and age fixed effects instead of fixed effects for kebele × gender, kebele × marital status, and kebele × age fixed effects.

to the non-agricultural sector, but women do not take up these non-farm opportunities—possibly due to the above-hypothesized higher barriers to entry that they face. This difference between the findings for men and women is statistically significant at the 0.05 level. Finally, inheriting more land does not predict a higher probability of being a student for either gender.

In Panel B of Table 6, we estimate a model in which we interact our full set of individual- level controls with a dummy for being 20 years old or older—the median age in our sample, allowing us to compare how well land inheritance predicts migration and employment out- comes for each group. Once again, we estimate using OLS in response to problems of weak instruments. We see that our migration results are mostly driven by those aged 20–34 (older youth), as are reductions in employment in the non-agricultural sector. This is consistent with older youth being those most vulnerable to having decisions impacted by land inher- itance, while the relatively young are not yet taking major life decisions in response to an expected inheritance. However, land inheritance predicts similar increases in employment in agriculture for both groups. As for men and women individually, neither below-median nor above-median aged youth are more likely to be students as a result of inheriting more land. Overall, it seems that land inheritance does not matter much for whether or not one studies—either in the aggregate, or for a particular gender or age group. This is consistent with the overall low prioritization of education among rural households in Ethiopia relative to other countries (Dillon and Barrett, 2014).

6.4 Impacts by Rental Markets and Proximity to Urban Center

It is also critical to examine the role of mediating factors that may heavily influence youths' costs of migration, opportunity costs, and barriers to entry into non-farm labor. We consider two such mediating factors: the quality of land rental markets and travel time to a major urban center. We differentiate kebeles with relatively low land rental activity from those with relatively high land rental activity by examining if a kebele is below- or above-median in terms of the share of households renting out land. We distinguish kebeles that are relatively close and relatively far from a major urban center by again dividing our sample kebeles into those that are below- and above-median in terms of travel times, respectively. Following the Ethiopia Central Statistical Agency, we define major urban centers as all regional capitals plus any other cities with a population of 100,000 or more in 2007 (CSA, 2014). The 26 cities range in size from 20,824 to 3,156,057, and have a median population of 110,086; they are listed in Appendix Table A1. Once again, we estimate a model by OLS in which we interact our full set of individual-level controls with one of these two dummies—either a dummy for having below-median land rental market activity, or a dummy for having an above-median travel time to a major urban center[33].

As shown in Table 7, the size of land inheritance is a more powerful predictor of spatial and sectoral location decisions in areas with more vibrant land rental markets and those close to major urban centers. Where land rental market activity is low (below median), a reduction in one's land inheritance predicts a significantly greater tendency to migrate to an urban area and be employed in the non-agricultural sector than we see in areas with richer rental markets. Rental may be a viable alternative to inheritance, but where such markets are weak, youth not inheriting land will tend to migrate and enter the non-agricultural sector in higher numbers. This provides evidence of the partial substitutability of land access via inheritance versus land rental markets. Similarly, travel time to a major urban center matters as well; for those far away (above median travel time), a reduction in one's land inheritance is a significantly greater predictor of long-distance and rural-to-urban permanent migration, and of employment in the non-agricultural sector, then it is for those nearby. When an urban center is nearby, youth employment in the non-agricultural sector is largely unaffected by the size of land inheritance, and we see little impact on long-distance or rural-to-urban migration, reflecting greater off-farm employment opportunities close to home.

7. Discussion

We find strong relationships between expected land inheritance and youths' (ages 15–34) likelihoods of engaging in long-distance permanent migration, rural-to-urban permanent mi- gration, and non-agricultural sector employment in rural Ethiopia. Our empirical model— which exploits exogenous variation in the timing of land redistributions to overcome the endogeneity of the size of land inheritance—predicts that a 10 percent increase in inheri- tance size reduces rural-to-urban migration and employment in the non-agricultural sector by 4.8 and 4.1 percentage points, respectively. These findings are largely driven by the male and 20-34 year old sub-populations. The period of 20 to 34 years of age is crucial because it is the stage of the life cycle where individuals typically form new households. The fact that the employment decisions of older youth are most susceptible to expected land inheritance evokes a common trend, the African concept of waithood (Honwana, 2012), whereby older youth postpone major employment decisions until they attain financial independence.

We examine two prominent features of land and labor markets to measure the extent to which youth

[33] These regressions further include fixed effects for kebele × gender, kebele × marital status, and kebele × age fixed effects, as well as their interactions with one the two dummies (for rental market activity or for travel time to a major urban center).

employment decisions are constrained by land inheritance. First, we consider the role of access to land rental markets, which could provide an alternative to inherited land and facilitate youth self-employment in agriculture. The relationship between land inheritance and rural-urban migration appears to weaken, and that between land inheritance and non- agricultural employment is entirely eliminated, in areas of high rental market activity. This reaffirms the notion that push factors dominate pull factors in dictating migratory decisions in Ethiopia (World Bank, 2010). Our results highlight youth preferences to use migration or non-agricultural employment as a last resort after exhausting all means of access to land (such as temporary arrangements via land rental markets). It also supports the notion that rural inhabitants tend to diversify sectorally (Schmidt and Bekele, 2016), particularly in areas constrained by land availability, rather than exit agriculture altogether.

Second, we assess whether a reduction in either moving costs or search costs, captured by being closer to an urban area, mediates the effect expected inheritance has on employ-ment and relocation. There is no apparent relationship between land inheritance and either migration or non-agricultural sector employment in areas closest to urban areas (those with below-median travel times). The wage gap between rural and urban areas is likely negli- gible in such settings, disincentivizing migration. Moreover, employment in places close to urban areas is likely driven by labor demand. In contrast, in remote areas, youth are most likely pushed to diversify through non-agricultural sector employment or migration when subject to liquidity constraints, as under periods of income variability (Gray and Mueller, 2012) or land scarcity (Bezu and Holden, 2014; Deininger et al., 2007). We show that by relaxing youth constraints on land in remote areas, the proclivity to engage in long-distance migration or rural non-farm employment is greatly reduced.

Our findings have broader implications for the development strategies available to Ethiopia. Absent government intervention, the decline in arable land over time may increase youth unemployment and urbanization. In this regard, relaxing policy-induced frictions in the land rental market in the country (Holden and Ghebru, 2016), or otherwise freeing up land for individual use, can result in far-reaching impacts in reducing youth unemployment. Educational campaigns, starting at a young age, in conjunction with investments in the ser- vice and manufacturing sectors will be crucial to absorb the fraction of youth with limited opportunities for landownership. The government has signaled its commitment to the latter under its 5-year Growth and Transformation Plan (2015/16-2019/20) (Schmidt and Bekele, 2016). Finally, there is growing need to initiate a modernization in the agricultural sector, by increasing access to extension and encouraging widespread adoption of agricultural tech- nologies. Agricultural growth will increase rural household welfare, generating the demand for auxiliary services and goods which landless rural youth can provide

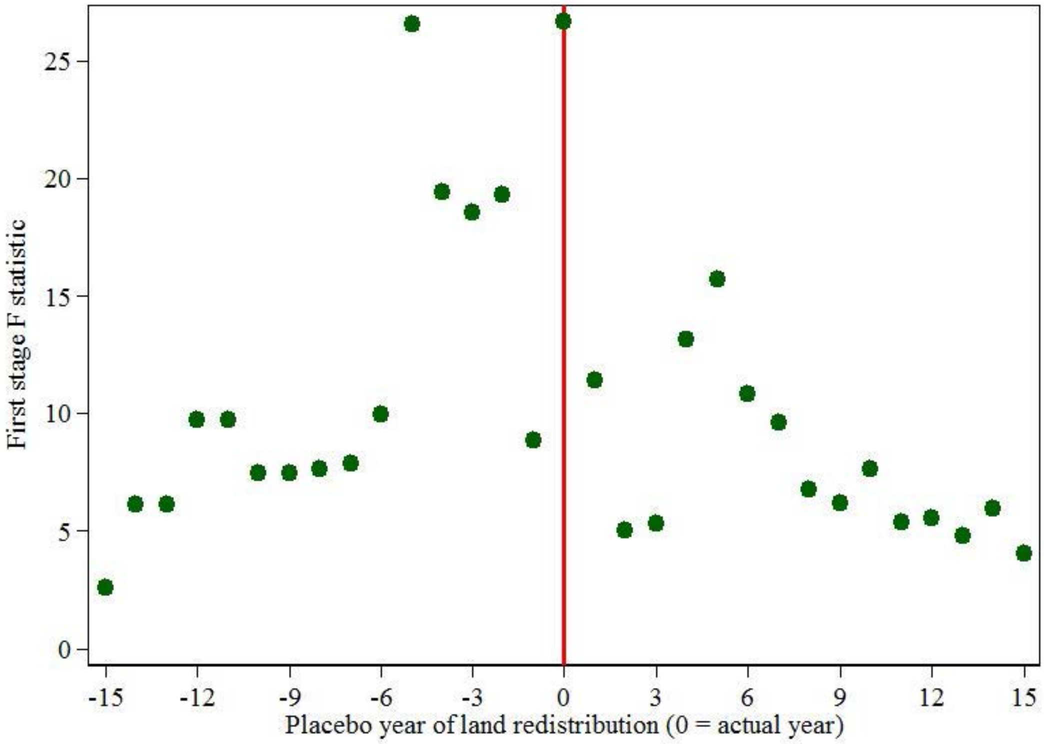
Figure 1 – Placebo analysis: First Stage F statistics if land redistribution is assumed to occur before or after the actual year



Source: Authors' calculations based on IFPRI's Watershed Surveys of 2010 and 2014
Notes: The x-axis indicates the number of years after the actual year of land redistribution that we assume land redistribution occurred; positive numbers indicate that we pretend it occurred in later years than the actual, while negative numbers indicate that we pretend it occurred in earlier years. The y-axis displays the First Stage F Statistic on our excluded instrument (from estimating column 3 of Table ??). The vertical line at x = 0 highlights the value of the F Statistic when we use the actual year of land redistribution

Table 1 – Observations by years of last land redistribution

Panel A: Year of Most Recent Post-Derg Era Land Redistribution

Kebele	Year
Tulugura	1992
Fundisa	1993
Arjo	1993

Panel E: Instrument						
Excluded instrument*	0.03	0.11	1717	0.02	0.1	1170

Source: Authors' calculations based on IFPRI's Watershed Surveys of 2010 and 2014

Notes: *The share of male descendants who were over age 18 at the time of the redistribution interacted with a dummy for having more than one male descendant immediately follow one's self. Land redistribution always refers to the most recent redistribution.With land refers to those who either have already inheritted land or expect to inherit land. Improved floor refers to being made from concrete, stone, cement, tile, bricks, or wood (not made from earth or cow dung). Households without a descendant in the sample are not included in household characteristics descriptive statistics. Religions are those of the household head

Notes: Migrated is defined as living in the household during round 1, and living elsewhere in round 2. We calculate the share of households in each kebele with at least one parcel of land either rented, sharecropped, or temporarily loaned. The median share across the kebeles is 22.5%. Low and high activity refers to being below and above the median share of households, respectively. Close and far refer to a household being below or above (respectively) the median travel time (107 minutes) to a major urban center (regional capital or cities with a population of 100,000 or more in 2007). Estimates are from completely interacted models where rental market activity and distance dummies are interacted with all controls. All specifications include dummies for being a child of the head of household, for being at least 18 years at the time of the kebele's last land redistribution, for completing cycle 1 of primary school (grades 1-4), for being the oldest direct descendant and being male, and for having multiple male descendants immediately following in the birth order. Also included are fixed effects for exact permutation of older sibling sex, for kebele × age fixed effects, for kebele × marital status, and for kebele × gender. P-value of difference refers to the p-value for the interacted log land inheritance variable. Standard errors are in parentheses and clustered at the kebele level

Socioeconomic dynamics resulting from structural transformation and agriculture transition in Ghana

DOI: 10.1481/icasVII.2016.a03d

ABSTRACT

Since 1990 Ghana's economy has accelerated sharply and the level of overall poverty experienced a significant decrease. Agriculture is still playing an important role but is gradually replaced by the progressive expansion of the non-agricultural economy, in particular the services sector. Using nationally representative data from the Ghana Living Standards Surveys by the World Bank for 1991, 1998 and 2005, we examine recent trends in the reallocation of labour across sectors, agriculture production, input adoption and socio-economic characteristics of the households, both at national and regional levels. We attempt to advance the analysis of structural transformation in Ghana by investigating the determinants of household labour allocation via a micro-econometric approach based on synthetic panels (Dercon, 1985). This analysis shows that structural transformation is occurring at different speeds across the country leading to the development of a "north-south dualism". While northern regions' economies are still relying on low productive agriculture, the "Services revolution" is gradually shaping the southern regions economy. Regression-based results suggest that factors such as households' demographic composition, level of education, poverty status, migration flows, access of infrastructure and financial services are all factors contributing to labourers' occupation choices.

PAPER

1. Introduction

The debate on Sub-Saharan Africa's economic growth and poverty alleviation has recently seen a resurgence of interest by policy makers and the academic world on the role of structural transformation (AfDB, 2013, ACET, 2014). The structural transformation process that consists in the reallocation of labour from traditional agriculture sectors to industry and services[2], started in Europe with the industrial revolution (Kim, 2007, Allen, 2009) before spreading out in Africa, Asia and Latin America, where countries started a quicker and more mixed transition with respect to the rest of the world. This process evolved differently throughout the developing countries: while Asian economies rapidly evolved "from flying geese into leading dragons" (Lin, 2012) the African shape of structural transformation was radically different. Many countries experienced substantial amounts of labor reallocation across sectors and the sectoral composition of their economies generally shifted from mostly agrarian to a combination of agriculture, industry and services. A great movement of farmers away from rural areas led to a drop in the agricultural value added and employment since the 1960s. Industries lost ground since the mid-1970s and globalization did not realize the promise of growth. Inter-sectoral mobility of labour went in the wrong direction, shifting from more productive to less productive sectors, with services instead of manufacturing becoming the primary recipient of labour exiting from agriculture. Not much recovery seemed to take place, with African countries remaining under-industrialized at all levels of income (McMillan et al., 2012, Rodrik, 2014).

Since Fisher (1939) and Kuznets (1966), who included structural transformation as one of the six most relevant stylized facts of development, a vast macroeconomic literature stressed this topic in several ways. A useful review of this literature is provided by Herrendorf et al. (2011) who highlighted the importance of multi-sector models to control for the complexities and the two-way causality relationship between economic growth and structural change. Recent literature examined the relationship between structural transformation and productivity gaps (Caselli, 2005; Duarte and Restuccia, 2010), urbanization (Michaels, 2012; Gollin et al. 2013, Christiansen et al., 2013), demographic transitions (Beegle, Weerdt, and Dercon, 2011; de Brauw et al., 2014), land institutions (Deininger et al., 2014), farming systems (Jayne et al, 2014) and environmental externalities (Antoci et al. 2009, 2012). Despite the huge potential for structural change due to the high share of the labour force in agriculture in most

[2] See Lewis, 1954, Kuznets, 1966, Maddison, 1980 and Chenery et al., 1986 among others.

of Sub-Saharan Africa (SSA), literature on structural transformation in Africa has been not investigated much. Only recently, contributions on this topic experienced an important improvement. Authors like de Brauw et al. (2014), Christiansen and Todo (2014), McMillan et al. (2014a) and De Vries et al. (2015)[3] started to fill this gap by analysing gains/losses and consequences for economic growth and poverty reduction objectives[4] of structural transformation in Africa.

Experiences from developing countries achieving such targets usually indicate that the drivers of growth and development differ not only between countries, but also within the same country. Labour reallocation itself changes, depending on cultural and environmental factors, often not modeled within macro-level analysis but yet representing the assumption on which these are based. It is thus hard to give a precise insight of the drivers affecting structural transformation and labour movements across sectors without controlling for the host of heterogeneity arising from differences at regional level or - better - at household level (Foster and Rosenzweig, 2007; Fox and Sohnesen, 2012). In this sense, the microeconomic perspective is quite relevant, since it better reflects individuals' occupational choices by looking specifically at their local heterogeneity. The availability of questionnaires on individuals' employment sector, time use, income, wage and other relevant labour-related indicators helps makes the construction of productivity measures easier. These, once paired with other relevant covariates can improve the understanding of labour allocation decisions.

At the moment, research at micro-level on structural transformation is scant, in particular if considering its microeconomic dimensions in a context of labour reallocation. To the best of our knowledge only recently authors like Christiansen and Kaminski (2015) and McCullough (2015) focused on micro-level empirical research on structural transformation. The first looked deeply into the distribution of productivity levels within sectors by proposing a micro-level decomposition approach of consumption growth and poverty reduction in Uganda. The second provided a descriptive overview of the key features of structural transformation in four different African economies.

Country level studies on Ghana's structural transformation (Breisinger et al. 2009; Kolavalli 2010, Jedwab 2011, Jedwab and Osei, 2012) often concentrate on the evolution of demographic, employment and productivity indicators at the national level, leaving very little space for micro-level scale considerations. The contribution of this study lies in filling this gap by providing, on the one hand, a descriptive review of changes in the structure of the workforce and the evolution of agricultural and socio-economic characteristics of households living in rural areas over a period of 20 years; on the other hand, a micro-level empirical assessment using Weighted Least Squares to identify the determinants and the key correlates that can explain the likelihood of households changing the distribution of labour across the different occupational sectors. Ghana is of particular relevance to our purposes for two reasons. The first is related to its enormous structural transformation potential: its average GDP growth rates increased in the last decades, the number of poor reduced, and – most importantly – according to WDI (2014) the number of people employed in agriculture decreased by 18% in the last 20 years, with the sector still employing 44% (in 2013) of the economically active population. The second is the availability of data over a 25 year time span, which is long enough to capture structural variation in the country's economy. We base our analysis on the Ghana Living Standards Surveys from 1991/92, 1998/99 and 2005/06 designed by The World Bank. The GLSS data include detailed information on households' social and economic characteristics, as well as a detailed section on agriculture activity. From this we have drawn variables related to farm activity, agriculture inputs and farming equipment and livestock. However, in both developed and developing countries, long-running panel datasets are rare, whereas cross sectional household surveys are often conducted on a regular basis. Although such surveys do not allow following individuals over time, to overcome the unavailability of panel data, groups of people may be tracked from one wave to another by the use of cohort clusters (Deaton, 1985) rather than observations at the individual or household level in a "pseudo-panel" framework.

The rest of the paper is organized in two parts. The first part begins with section 2 by providing some stylized facts of Ghana's economic growth, poverty reduction and structural transformation, and ends up with a descriptive analysis of the process of structural transformation both at national and regional scales. The second part of the paper focuses on the econometric analysis: section 4 describes the econometric model and section 5 provides the econometric results. A final section concludes.

2. Economic growth and structural transformation in Ghana: aggregate stylized facts

By African standards, Ghana has done reasonably well in recent years, representing a success story of noteworthy poverty reduction and significant economic growth. In relation to poverty reduction, the level of overall poverty among the Ghanaian population fell from 52% in 1991/92 to 29% in 2005/06, and lingered at 24% in 2012/13. The Ghana is one of the few African countries to achieve the first MDG target of halving poverty[5], although four out of its ten regions are lagging behind with people still living in extreme poverty. Regarding economic growth, since 1990 the country's economy expanded, with average GDP growth rates

[3] Among others, we do not report all the literature.
[4] See, for instance, McMillan and Headey (2014) for a comprehensive review in a World Development special issue.
[5] In Africa and Eastern Asia, only 63 countries have reached the MDG-1 hunger target between 1990 and 2015 (FAO, 2014).

ranging between 4% to 5% during the 90s and early 2000s and thereafter increasing to 8% on average (WDI, 2014). This impressive growth performance – which reached a peak of +14% in 2011 – is quite unusual at world level. In fact, in the last 20 years only a few developed and developing countries achieved these levels over such a period.

In the last decades, agriculture has been the backbone of Ghana's economy contributing between 40 and 50% of total GDP between 1965 and 1975 and rising up to 60% in the 80s. Even though it experienced a constant decline, agriculture still plays an important role in ensuring food security by representing the 22% of the GDP in 2014 (Figure 1) with 44% of the economically active population employed in the sector in 2013 (down from 62% in 1992).

During the 80s, the Ghanaian economy underwent an important change with the implementation of the Structural Adjustment Program (SAP)[6]. Since the launch of the SAP, which that rescued Ghana from the economic collapse, the country experienced strong improvements in the industrial sector, whose contribution to total GDP increased to 27% in about 20 years. The same happened to the manufacturing sector, which grew by seven percentage points right after the SAP implementation, but its value added never went beyond the 10% of the total GDP. Looking at Figure 1, between 1981 and 2005 the service sector became increasingly relevant for the entire Ghanaian economy, reaching an average value of about one-third of the total GDP. The "regime switch" registered in 2006 (-10% agriculture, -6% industry, +1% manufacturing, +16% services) is mainly due to the rebasing of the series[7], with the number of subsectors under services being increased from six to eleven in the new series. The reorganization of the services sector led the way accounting for almost half of Ghanaian GDP, overtaking the agricultural sector as the most prominent sector of Ghanaian economy.

3. The Process of Economic and Social Development in Ghana

3.1 The dataset

In the present study we provide a descriptive analysis of change in households' characteristics, the structure of the workforce among agricultural and non-agricultural households and an analytic assessment of the determinants of time allocation using three waves from the Ghana Living Standards Surveys (GLSS), a comprehensive dataset modeled after the Living Standards Measurement Surveys (LSMS) and designed by The World Bank. The surveys were conducted in 1991/92, 1998/99 and 2005/06 (i.e., GLSS3, GLSS4 and GLSS5), adopting almost identical questionnaires with positive synergies in the analysis of economic transformation, agricultural transition and its contribution to poverty and hunger alleviation.

Among the variables included in the sample, we consider household demographic variables, variables related to participation in labor activities, land owning, annual household income and consumption, as well as durables owned by the household and information on access to credit. The entire sample includes 4,523 observations from GLSS3, 5,998 from GLSS4, and 8,688 from GLSS5, representing respectively 3.3, 4.2, and 5.5 millions of households at national level. Furthermore, we define a subgroup of agricultural households as households operating land and earning income from crop sales. For each round, we estimate an amount of agricultural households of around 60% percent out of the total sample. In particular, the sample sizes of agricultural households are 2,958, 3,698, and 4,755, for 1991, 1998 and 2005 respectively. Finally, we define three geographic groups according to the geographic location of the different regions. We group the ten regions in three different clusters, the northern macro-region, characterized by a semi-arid tropical climate (rural savannah), the central macro-region and the southern one, the coastal area[8].

The three clusters consist of 2782, 6098 and 2528 observations respectively. We report the evolution of the different variables over time at national and regional scales for the overall sample and the agricultural households.

3.2 National level

Table 1 in the Appendix reports summary statistics of main variables for the overall sample at national level. Education seems to have expanded during the 1990s in the country, which has resulted in a rise in the average years of school, from 2.7 in 1991/92, to 4.0 in 1998/99, to 5.3 in 2005/06, and an increase in the highest years of education in the household from 4.7 to 8.2 over the whole period. Figures show a decline in the share of household heads employed in agriculture from 53% in 1991 to 45% in 2005 although the agriculture sector is the major source of income in Ghana, whereas the share of household

[6] As reported by Konadu-Agyemang (2000) the most relevant measures behind the SAP implementation (1983) consisted in cuts in social services, devaluation of the cedi, abolishing the domestic price control, broadening the tax base, strengthening the tax administration, divesting state owned enterprises and encouragement of cocoa and other traditional exports.

[7] The rebasing exercise has been performed by the Ghana Statistical service using the International Standard Industrial Classification (ISIC). More information available at: http://www.statsghana.gov.gh/docfiles/news/gdp_newsletter_rebased_gdp_nov_2010.pdf.

[8] North includes: "Northern", "Upper East" and "Upper West" regions; Center includes "Volta", "Eastern", "Ashanti", "Brong Ahafo" regions and finally South includes "Western", "Central", "Gt Accra".

heads employed in transport, storage and communication increases over the whole period. On the other hand, the employment shares in manufacturing, and wholesale and retail trade increase from 1991 to 1998 (i.e., from 7.7 to 8.9 for the former, and from 11.4 to 13 for the latter), and slightly decrease from 1998 to 2006 (i.e., from 8.9 to 8.7 for the former, and from 13 to 12.7 for the latter).

Figures on annual consumption describe an increasing trend over the whole period both for food and non-food expenditure per adult equivalent expressed in 2005 Ghanaian cedis and appropriately deflated for price variation. This kind of variable is commonly used in the literature as a welfare indicator in measuring poverty and inequality (Ravallion and van de Walle, 2008). Figure 2 depicts the distribution of log consumption per adult equivalent for the three rounds of the GLSS showing higher densities towards the right side of the graph for non-farm households, while farmers have more density towards the left side. Following the consumption path, total household income (in 2005 Ghanaian cedis), as well as its sources show an increase over time.

Descriptive statistics show a limited access to credit in the country with higher shares of informal sources with respect to formal ones, and loans mainly allocated for agricultural activities, as well as for business purposes. Some studies highlight that among others, age and gender of the household head and political affiliations are the main determinants of credit demand by farmers (Kimuyu and Omiti, 2000; Akudugu, 2012). On the other hand, other analyses reveal that extension services, education level and saving habits influence household access to formal credit (Dzadze et al., 2012; Hananu et al., 2015), with loans mostly used for agricultural and non-agricultural production, and consumption purposes.

Table 2 (see Appendix 1) provides summary statistics for the subsample of agricultural households only. Descriptive statistics show that among others, the household size, the gender of the head and the level of education are also important components also for the restricted sample of agricultural households. The share of female-headed households as well as the household size decrease (from 26 to 23% in the former and from 4.9 to 4.7% in the latter) in 14 years, whereas the average years of education in the household increase from 2.2 in 1991/92, to 3.1 in 1998/99, to 3.9 in 2005/06.

Figure 3 shows the distribution of the amount of land operated for the three waves of the survey. Operated land is defined as the sum of the agricultural land owned-and-operated by the household plus the difference between the amount of land rented/sharecropped in and rented/sharecropped out. The majority of the distribution falls below two hectares of land, and more than 75% of farmers operating operate less than the average farm size each year. The resulting figures show an expansion from the 1990s with a rise in the average farm size, from 2.3 hectares in 1991/92, to 2.5 in 1998/99, to 3.3 in 2005/06[9]. The increase may also be seen also for land owned, that includes operated land, land sharecropped out and rented out by agricultural households; that grows from 3.1 hectares in GLSS3 to 3.9 hectares in GLSS5. In this regard, Figure 4 presents basic information on land ownership by land size for agricultural households. It is interesting to note that the percentage of households owning less than 0.5 hectares of land shrank by 9% between the first and the last wave. This reduction has been partly compensated by the growth (+6%) of the large landowners (→4 ha). Furthermore, the share of farmers owning land with deed exponentially increases over time from 5.9% in 1991/92, to 16.6% in 2005/06.

Moving towards the variables related to farm activity, Figure 5 depicts the use of agricultural inputs by classes of land endowment per year. Overall, the purchase of seeds and seedlings is the most important agricultural input, with the exception of households owning more than two hectares of land in 2005/06. We find evidence of a negative variation in the share of seeds and an increase of the amount of fertilizer and pesticides adopted over time for all classes of land endowment. Smaller farmers tend to use more seeds rather than other agricultural inputs, whereas households cultivating more than two hectares of land purchase pesticides and fertilizer more frequently, especially in the 2005/06 round.

In this context, among agriculture inputs, it is worth taking into consideration the labour variable, revealing a decreasing but still high share of rural households (namely, 66% in 1991, 73% in 1998, and 57% in 2005) hiring workers during land preparation, weeding and harvest. On the other hand, the value of agricultural assets decreases over time, from 336 Ghanaian cedis in 1991/92, to 149 in 2005/06, with very low shares of households owning different assets, such as tractor, plough, cart, and sprayer.

3.3 Regional dynamics

Development economics literature largely documented the process of structural transformation over time at national level. However, responsiveness to change at national level is the result of different changes at local level. Factors like tradition, different levels of development or environmental and geopolitical acute disparities largely influence households' decision making processes. This is why, in order to assess the phenomenon of structural transformation in Ghana it is also crucial to thoroughly understand the patterns of change also at sub-national level. We proceed by clustering the ten regions in three macro-regions according to their geographic position, namely North, Centre and South, which represent respectively the rural savannah, the centre and the coastal area. For each group we analyse

[9] It is worth noting that these values do not include landholders not selling crops.

the evolution of society, economy, agriculture and technology in a descriptive framework. We place particular emphasis on the reallocation of labour across the different sectors by focusing on the ten regions separately through the adoption of choropleth maps.

Table 3 in the appendix compares the full sample and the agricultural households, featuring their most relevant socio-economic characteristics. Looking at the full sample, the first line shows the share of farmers over the total. Farmers are predominantly located in the northern area, which is less urbanised and where agricultural households are almost the double with respect to the southern macro-region. It is worth noting that the share of agricultural households decreases in all the three macro-regions (-10% in the north, -15% in the centre, -13% in the south). This reduction coincides with a migration from rural to urban areas. In fact, figures on the share of rural households over the total clearly show an important drain out towards urban areas in the centre (-12%) and coastal regions (-7%), while in the rural savannah it is pretty much constant over time.

In northern regions, households are on average slightly bigger and much less educated with respect to the rest of the country. Indeed, if we look at the dynamics, the average number of years of education almost doubles over time in both the centre and southern areas, while in the north it decreases. Even though in some areas education level seems to experience an upward trend, education inequality remains an issue in the north where it is strongly differentiated by gender. Female members' education with respect to the other household members is lower than in the other macro- regions. They benefit less from education with respect to men, particularly in the rural savannah areas, where the percentage of female headed households in 2005 was 13%, approximately one-fifth of the other two regions. Figures from the agricultural households' subsample confirm this trend.

The following rows provide information on the households' participation in labour activities. The first set of indicators represent the percentage rate of households' members of working age declaring to be employed, unemployed, inactive (see Table 3). Figures are in line with the findings at national level. There is a very low spatial diversity across regions with about three out of four adults employed in any working activity, with 1 to 3% of unemployed adults (with higher rates in the coastal area) and an average of 15% of adults declaring to be inactive. No definite pattern can be associated to these dynamics, neither in the full sample, nor for the agricultural households. Labour is the prevailing source of income in Ghana, and is mainly employed in agriculture and services segments because of the endemic characteristics of these sectors, which are both labour intensive. What is really striking is the evolution in the share of labourers, which takes different shapes across sectors and over the years. To get a better idea of the changing patterns in the reallocation of labour within the country we plot in Figure 6 a set of bar charts constructed for the full sample at regional level and reflecting the employment rate in each of the three different segments where households' heads are employed: agriculture, manufacturing and services (wholesale and retail trade, transport, storage and communication and community, social and personal services). It is evident that agriculture still plays a central role in the economy of the northern provinces - the poorest ones. Basically, in 1991 the agriculture sector absorbed the 80% of households' heads residing in the northern region, 60% in the centre and 41% in the south, evidencing a great spatial variability of the labour markets. The more we move towards the coastal regions the less important agriculture is for the local economy. Greater Accra region is a worthwhile example, showing the lowest share of households employed in this sector. Looking at the dynamics, although there are remarkable differences across the regions, we show a general declining pattern for the agriculture sector in all the areas studied, including the ones that rely more on agriculture. Conversely, the manufacturing sector (mainly constituted by electronics, automotive and light manufacturing, food processing, aluminium smelting and cement) is much more concentrated in the south. Looking at the map, the capital city's region shows the highest share of households (around 15%) employed in the sector, driving the difference between the centre and southern macro regions. We have to bear in mind that Greater Accra and the whole south benefited more by the SAP with respect to the northern and central regions, even though in the long run its effect fades out. In fact, by looking at the coastal area regions, the employment rate of household heads in the manufacturing sector is slightly shrinking (-2%), reducing its absorption of household heads from 15% to 12%. In the south the development process seems to run faster than in the north which is experiencing the industrial phase with a decade of delay (+3% of household heads employed). The same conclusions can be drawn for services, which is the second major segment contributing to the country's gross domestic product. Services include wholesale and retail trade, transport storage and communication, community, social and personal services. Figure 6 depicts disaggregated statistics across regions and over time for the services sector's sub-groups. If we look at the 2005/06 values, we see that in the northern area household heads employed in services are around 6%, 12% in the centre and 17% in the south. We do not find sharp improvements in any of the sectors between the first and the last round, meaning that at the time of the first wave the contribution of each services' segment on the overall regional economy was already stabilized. However, there are small movements that are important to consider to give insights to each region's structural transformation shape. The most interesting patterns are registered within the full sample, whilst for the sub-sample of agricultural households the share of household heads employed in each services' sub-sector does not fluctuate over time. The wholesale, retail and trade sector is the only sector among services representing a larger share of workers. It shows an upward trend in all the three macro-regions, with a major incidence in the coastal one (+3.7% between the first and the last wave). This is the result of the running globalization process that is pushing to invest in services to manage the growth of tourism and a bulky demand of food and manufacturing imports. Demand for labourers in the sector of "Transport, storage and communications" is slightly increasing over time, even though this segment is the one among services that contributes less to the labour supply. In northern areas transport is almost absent, whilst it is particularly relevant in the Greater Accra region. This sector is likely to further grow further from 2005 onwards with the beginning of the digital era. Finally, the share of household heads working for "Community, social and personal services" has almost the same breadth of trade services but has a decreasing trend over time in all the three macro-regions. Once again, the capital region represents the hub also for this sector.

Given the distribution of labour reported above, as well as the nature and characteristics of the households located in the northern area, we expect that the highest share of income in the rural savannah would be dominated by agricultural output sales. Our findings confirm this expectation, but it is intriguing to note that income from self-employment related activities capture an important share of the overall income distribution within the households (see Table 4 in the Appendix). In the agricultural households' sub-sample, income from crops represents the major source of revenue for all households across all macro-regions, while income from self-employment is ranked right after. Self-employment is becoming increasingly important in the northern region (+2%) and this share seems to contribute to the gradual replacement of income from livestock sales (-10%). The analysis of the three surveys reveals a similar pattern for the full sample. In Figure 7 we report maps with pie charts quantifying the share of each source of income over the total per year. The relative importance of each sector varies across regions, confirming the importance of self-employment and non-agricultural wages in the southern macro-region (Central region, Greater Accra, Eastern region among all). Income of households living in the Greater Accra region comes mainly from non- agricultural wages and self-employment forms of labour. This greater concentration of non- agricultural jobs is larger where there has been an increase of services sectors. On the other side, the contraction of income from livestock sales is also confirmed at a more disaggregated level, while it is interesting to note that in regions such as Volta and Western region, there is an improvement in the profitability of crop sales. Agricultural markets are thus changing over time and differently across regions as a result of the slow process of structural transformation gradually occurring in the agricultural sector; this is characterized by a growing importance of agribusiness, with high-value agricultural products and cash crops[10] grown as a form of business. The evolution of cash crop cultures overtime is conspicuous, in particular between the second and third round of the survey (see Figure 8). In the northern macro-region, both food and cash crop values of production are increasing. Moving towards the central part of the country, Northern Region and Brong-Ahafo did not show any significant change in their production systems, which remain balanced between cash and food crops production. Although the cash crops expansion of the early 2000s occurred almost everywhere, there are important spatial differences to be noted in terms of value of production, particularly in the central and southern regions. The Ashanti region, which today is one of the largest world's cocoa suppliers, registers a great expansion in the cash crop value of production, in particular between the second and third wave. This is the most prominent case of specialization we find across the regions. A plausible explanation could be that this variation in the value of production is the consequence of an improvement in both human capital and in a change in the technological means of production, which are the expression of an increased productivity. It is not surprising that northern regions, which are the less educated ones, are lagging behind the rest of the country where a transition from an equilibrium of "subsistence" and "business" agriculture to a "business-based" one is in place

In Table 4 we report figures for the expenditure on agricultural inputs and their intensity of use. We disentangle the intensity of use from macro-regions to a regional scale and we plot in Figure 9 the regional averages of the most relevant figures. In the northern regions this shift towards a modern, and more commercial agriculture, is hindered by the chronic constraints affecting their livelihoods such as the absence of adequate infrastructures, the insufficient access to technology, agricultural inputs, and other facilities. The bar charts regarding the intensity of input use reported in Figure 9 clearly reflect this issue. However, if we look at the trend, there is a slow but increasing variation in all the regions for both pesticides and inorganic fertilizers. Inorganic fertilizers expenditure rose consistently between the second and third wave in almost all the regions apart from Volta, while northern macro- regions are still behind in terms of intensity of use of pesticides, seeds and hired labour.

It must be noted that since the figures reported above do not track the same people over time, it is hard to know whether and how this process of structural transformation can be strongly/weakly associated with households' demographic characteristics, residential choices, access to land, infrastructure and facilities or spatial transformation. In order to provide direct insights into the determinants of such a change, we move to a slightly more complex analysis by taking advantage of the pseudo-panel framework.

4. Empirical methodology

In this section we discuss the econometric models estimated and some econometric issues encountered in analysing patterns and determinants of structural transformation. According to the existing literature three different categories of indicators are usually employed to measure structural transformation. The first one is the change in production structure and it is generally defined by the share of income coming from each activity.

[10] Cocoa, among others.

The second one is a measure of productivity of labour, typically GDP per worker or GDP per hour (Herrendorf, 2013), while the last one is the employment share, which in literature is calculated using either the number of workers or the hours worked by sector (Duarte and Restuccia, 2010). Each dimension explores different aspects of structural transformation; we concentrate on the last one to investigate the determinants of change in time spent working in agriculture, services, industry and manufacturing sectors through time. In theory, when structural transformation occurs, people devote less time working in low productivity sectors (generally agriculture in poor countries), and increase time spent moving towards high productivity ones. Of particular interest here is the potential effect of some key correlates such as demographic shifts, land use, agricultural and non-agricultural wealth, technology adoption and mechanization, access to infrastructure and facilities, credit and migration.

In order to evaluate how structural transformation and agriculture transition may be affected by households' socio-economic characteristics, the best source would be a long-running panel dataset that allows tracking the same households over time. However, in both developed and developing countries, long-running panel datasets are rare, whereas cross sectional household surveys are often conducted on a regular basis, Ghana being no exception. Although such surveys do not allow following individuals over time, to overcome the unavailability of panel data, groups of people may be tracked from one wave to another on the basis of their common observable time-invariant characteristics, like for example date of birth, geographic location, poverty status, quality and size of operated land.

Consequent empirical economic analyses make use of cohort clusters rather than observations at the individual or household level. "Pseudo-panels" based on age cohort have been widely used in the literature, in particular after the seminal work of Deaton (1985), who suggested that cohorts constructed from repeated cross section data can be used to estimate a fixed effects model (e.g., Deaton and Paxson, 1994; Banks, Blundell and Brugiavini, 2001). The idea behind these synthetic panels is that on average the behavior of a group of households is well approximated by the behavior of other households belonging to the same cohort at another point in time. Technically, this approach is formally similar to instrumental variables technique, where the group indicators are used as instruments (Verbeek, 2008).

4.1 Model setup

Let's define i households, and s sectors, representing the four main segments of the Ghanaian economy (i.e. agriculture, services, industry, manufacturing). We define the share of worked hours $Sh_{is,t}$ for household i in sector s at time t as equal to $Sh_{is,t} = \frac{HW_{is,t}}{THW_{i,t}}$, with $HW_{is,t}$ and $THW_{i,t}$ being respectively the number of hours worked per week in sector s and the total number of hours worked in all sectors at time t by household i[11]. We assume that the share of hours worked in each sector can be expressed as a function of a set of controls:

$$Sh^*_{is,t} = f(D_{it}, L_{it}, W_{it}, I_{it}, F_{it}, G_{it}) \quad (1)$$

where $D_{is,t}$, are the demographic characteristics which include the household composition in terms of size and female members (by age), the dependency ratio and the average years of education of adults in working age; $L_{cs,t}$ and $W_{cs,t}$ represent farm-related variables (i.e. size of land (ha) operated, inequality in land distribution and annual expenditure in agricultural labour force) and wealth-related variables (i.e. total Tropical Livestock Units, dwelling ownership and poverty status), respectively. $I_{is,t}$ and $F_{is,t}$ are the access to infrastructure/facilities' variables (i.e. participation in Agricultural Cooperatives, access to electricity, distances from health facility, nearest road and banks[12]). Finally, $G_{is,t}$ is a vector of geographic variables (i.e. belonging to different agro-ecological zones and rural/urban).

We start by examining the linear functional relationship resulting from (1), which is represented as follows:

[11] Information on labour time allocation is reported within the questionnaire for primary, secondary and – eventually - tertiary activities at the individual level. The time span considered is represented by the hours spent working in the last seven days. Data on hours worked were purged from outliers to make sure they would not exceed the cap of 40 weekly hours (per worker) across activities. Values exceeding the maximum were then replaced by a proportional amount of hours in a way that their sum across occupations was equal to 40..

[12] All variables apart from electricity are computed at community level.

$$Sh_{it} = \delta_{it} + \beta_0 + D'_{it}\beta_1 + L'_{it}\beta_2 + W'_{it}\beta_3 + I'_{it}\beta_4 + F'_{it}\beta_5 + G'_{it}\beta_6 + \eta_t + u_{it}, \tag{2}$$

where i indexes households $(i = 1, \ldots, N)$ and t indexes the time span $(t = 1, \ldots, T)$. Then δ_{it} captures the households' unmeasurable and unobserved skills and abilities, η_t the time trend and finally u_{it} the disturbance. Even though this model assumes that the error term u_{it} is not correlated with the predictors and δ_{it}, it must be recognized that δ_{it} might be correlated with any of the demographic controls D'_{it}. Similarly to Ackah and Aryeetey (2012) a pooled analysis of the data based on an equation like Eqn. (2) generates a number of issues regarding individual heterogeneity, "in part because such analysis cannot control for unobservables, and in part because it assumes that repeated observations on each household are independent" (Ackah and Aryeetey, 2012, p. 85).

4.2 Construction of the Pseudo-Panel

Following Deaton (1985) we solve this issue constructing a pseudo-panel by the use of a set of C cohorts $(c = 1, \ldots, C)$, that by definition represent groups of households that share a vector of common characteristics that are constant over time. These are constructed according to a joint set of multiple characteristics, namely the (i) household head's age category, (ii) the head's sex and (ii) his/her residing region for a total of 114 groups followed over time[13]. By tracking the cohorts, we are able to average Eqn. (2) over the cohort members to obtain a new equation (3) expressed in terms of cohort means, that represent the observation units in the new pseudo-panel framework. This procedure, which allows the clearing out of the heterogeneity across households yields the following structural form

$$\overline{Sh}_{cs,t} = \overline{\mathbf{X}'_{ct}}\beta + \overline{\delta_{ct}} + \overline{u_{ct}} + \eta_t, \quad c = 1, \ldots, C; t = 1, \ldots, T \tag{3}$$

In Eqn. (3), $\overline{Sh}_{cs,t}$ and $\overline{\mathbf{X}'_{ct}}$ represent respectively the average values of the share of hours worked in each sector and the vector including all the explanatory variables for all observed households at time t in cohort c. $\overline{\delta_{ct}}$ is defined as the average of the fixed effects for all the households belonging to cohort c in year t, and can be treated as the unobserved cohort fixed effect if the sample size in each cohort is sufficiently large (Warunsiri and McNown, 2010). All error components in (2) that are correlated with the control variables have been purged from the error term, in this way the estimation of equation (3) with cohort fixed effects yields unbiased and consistent results. However, since the number of observations per cell varies substantially, the error term $\overline{u_{ct}}$ is heteroskedastic, leading to biased standard errors. We follow Dargay (2007) and Warunsiri and McNown (2010) and correct this heteroskedasticity using Weighted Least Squares (WLS) estimation by weighting each cohort with the square root of the number of observations contained in each cell.

However, while from one side WLS estimator helps in addressing the heteroskedasticity issue, on the other it may produce inflated R^2. This issue is quite common in the literature, in fact, as reported by Willet and Singer, the goodness-of-fit obtained under WLS regression "is frequently much larger than the value obtained under the corresponding OLS fit. […] This increment reflects, in part, the success of the weighting in solving the problem of heteroscedasticity" (Willet and Singer, 1998, p. 237).

To check for possible biases in the measurement of the coefficients arising from the adoption of the WLS estimator, we supplement the estimates from the WLS with results obtained from the Fixed Effects specification[14].

5. Results and discussion

Before discussing the econometric results, we looked at the mean values of the hours worked in each sector per year and by the seven age-cohort groups. Summaries are reported in table 5 and Figure 10. Overall, comparing the allocation of time in each sector, we see that the average amount of time devoted to agriculture decreases over time (~-6%), with services (~+3%), industry (~+1%) and manufacturing

[13] See Annex A for details about cohorts' construction

[14] A number of supplementary robustness checks will be included at a later stage. These will include (i) results from samples disaggregated by demographic characteristics like gender, rural/urban residence or agricultural households/non-agricultural households; (ii) control of the measurement error problem by improving the size of cells from 6-years age bands to 10-years generation bands.

(~+2%) that conversely experience an upward trend. A more detailed picture is provided in Figure 10 where we plot the share of time disentangling the sample by ages' cohorts. Looking at the differential across years for each age cohort we note that the largest variation of time allocation occurs in particular among cohorts with younger head of households, namely the 15-21 and 22-28 age cohorts. In relation to the first case, the large decrease in time allocated to agricultural jobs (~-14%) is compensated by an improvement in the time devoted to both industry (~+10%) and services (~+5%). Looking at the other cohort, we register a similar pattern; this time all sectors contribute to compensate the shrinkage in time allocation to agriculture: time spent in industry increases by ~+2%, in manufacturing by ~+5% and in services by ~+4%. Smaller movements are registered for the other cohorts.

5.1 WLS estimates

From now on we will discuss the econometric results, focusing on the estimates for equation (3). The estimates from the regressions with FE and WLS are reported in Table 6 and Table 7 in odd and even columns. Both tables present the share of hours worked per week in all the sectors aforementioned. In Table 6, columns (i) and (ii) show the results for hours worked in agriculture, whilst columns (iii) and (iv) concern the services sector. Results for industry (columns (i) and (ii)) and manufacturing (columns (iii) and (iv)) are reported in Table 7. All regressions are conducted on households' demographic, wealth, productivity and facilities' characteristics. Cohorts fixed effects (not shown) are included in order to expunge the dependence between the regressors and the error term evidenced in equation (3). Results are consistent across the two specifications for most of the variables. In order to provide a complete picture of the results we will comment on the two tables jointly. We start by looking at the effect of households' gender composition on the hours worked in each sector. Household composition in terms of share of females in different ages does not really affect the time allocation across occupations. Looking at Table 6 and Table 7 we only find consistent results for time spent in industry, which decreases consistently for young females (15-19) with respect to males. Even though only significant in the FE specification, we find that households with a large share of females aged 20-34 experience a decrease in the share of hours devoted to agriculture. Time spent working in agriculture also decreases as the dependency ratio (or consumer-producer ratio) increases. It is interesting to see that the higher the consumer-producer ratio the greater the work effort (time) allocated to services. Households with a higher than average education for people in working age tend to leave agriculture and enter into services. The average number of years of education significantly and negatively influence the number of hours worked per week in agriculture, and significantly and positively affect the time spent on services. Turning to the vector $L_{cs,t}$, farm related variables are not significant (when correcting for heteroskedasticity) apart from the variable on annual expenditure on agricultural labour, which results in a negative response for services. Operated land has a positive but non-statistically significant coefficient for agriculture, however, both the t-statistics at the border (-1.49) and the significance in the FE specification can provide weak evidence that the higher the land, the more the time spent in agricultural jobs might be economically viable. Interesting, but sometimes counterintuitive results arise when moving to wealth-related variables. For instance, the number of total tropical livestock units is negatively related with time spent in agriculture, and positively related with time spent in services sectors. A counterintuitive result arises when controlling for the percentage of households owning a dwelling, which results in a positive correlation with the time spent in agriculture. When looking for the poverty status, we find negative and statistically significant coefficients for time spent in agriculture and positive and statistically significant coefficients for that which relates to manufacturing. On average, richer households reduce the time spent working in agriculture and increase the time devoted to manufacturing. Regarding infrastructural attributes, of note is the overall effect of the electricity ownership, which we employ as a proxy to control for access to infrastructures: the coefficients for time spent in agriculture have the expected sign (negative), even though weakly significant, while we register an increase in time spent in services and industry sectors. Among the other variables included within the vector of access to infrastructure, only the distance from the nearest motorable road appears to be significant. This variable, which is often used in empirical research as a proxy for household market access is significant for agriculture, whilst in relation to services we can draw some conclusions based only for the FE specification. A longer distance from motorable roads may present a problem for farmers to reach urbanized centres to sell the agricultural products; this may form an incentive to reduce the time spent in agriculture in favour of other sectors. We use the distance to the nearest bank as a proxy for the distance to the nearest city, assuming that banks are located mainly in urbanized centres. Distance to the nearest bank is positively and significantly related to hours spent in agriculture, suggesting that the farther away the town, the more hours people will work in agricultural jobs, since they would face problems moving back and forth from the town easily. This result confirms the finding of Magai et al (2015). However, distance from the nearest bank can also be interpreted as an indicator of financial inclusion, in particular as a measure of access to credit and use of bank services. When access to financial services is not hampered by constraints such as the distance to financial institutions, the time spent for agricultural activities increases. The amount of credit borrowed by households, which is further introduced, confirms the signs of the distance to banks, although not significant. As shown until now, the reasons why people move in/out from agriculture and the other sectors are several and complex. The variability in the households' occupational portfolio, and thus in the sectoral composition of GDP, are often related to spatial changes. Thus, it is crucial to also control for the relevance of migration and how it acts in Ghanaian context. We use in-migration as a proxy for spatial transformation, defining it as the percentage of households within the cohort moving to the village in the previous five years. The resulting coefficient is negatively related to time spent working in agriculture, and positively related to time spent working in manufacturing. The striking finding is that on average in Ghana, people deciding to move away from the original position look to jobs in fields different than agriculture.

6. Final remarks

In Sub-Saharan Africa, the structural transformation process has not been as growth-enhancing as in Asia, but it is characterized by a vivid expansion of the low productive sectors, in particular services. In order to trace an exhaustive picture of the evolution of economy, society and productivity in Ghana we first provide a descriptive analysis of the factors involved in agricultural and economic transition, both at national and regional scale, and afterwards we try to assess which are the determinants influencing workers' time allocation in each sector.

Our findings show that in Ghana structural transformation is occurring slowly, not in every region, and not at the same speed. Overall, the different magnitude of changes is not enough to rapidly transform local economies in the same way. A remarkable dualism emerges between south and north, but more specifically between the coastal area and the rest of the country. This is particularly evident when looking at the reallocation of labour across sectors, at the agricultural production and technology adoption. Northern areas still rely a great deal on low productive agriculture and the economy's transition to high-productive agriculture or other sectors appears to be slow at the moment. The agricultural sector's draining is not compensated by a quick reallocation of labour to services or industry. On the other hand, in southern regions while agricultural employment did decrease, the labour that was released was absorbed mostly by low-productivity sectors, with a presumable low impact on economy wide-productivity. This might be due to the weak and inadequate transformation of the agricultural sector itself, which did not experience an increase in the agricultural productivity that could lead in turn to the development of other spin off industries.

Plausible explanations for that are related to factors such as the level of education, adoption of technologies and as reported in the literature, also by migration flows. In order to investigate the incidence of such correlates on time allocation, we have proposed a pseudo-panel estimation technique based on cohorts clustered at age, sex and region of residence of the household head's level. Controlling for a large set of variables that affect time spent in each sector, our models deal particularly well with agriculture and services related time shares.

One of the most striking findings regards the education of individuals, which is one of the main determinants of households' occupational choices across sectors. Results are robust in particular regarding agriculture and services. Mobility of labour is likely to occur in particular for households with higher educated individuals, who reduce time spent working in agriculture and increase time devoted to services related jobs. Moreover, we show that addressing structural constraints remains crucial for agriculture capacity to generate employment opportunities. Poor connectivity, which accounts for the lack of Green Revolution, leads to limited competition, market fragmentation and undermines households' possibility to shift their production systems towards more sustainable ones. Infrastructure constraints should be lifted in order to promote, first of all, development of agricultural sector, since isolation of Ghanaian households from main infrastructures contributes to trap them in agricultural jobs. Structural transformation in Ghana is associated also with North-South migration and as in most developing countries with a rural-urban mobility (Osei and Jedwab, 2013): this is reflected in an exit from agriculture and in a growth in time spent into manufacturing sector.

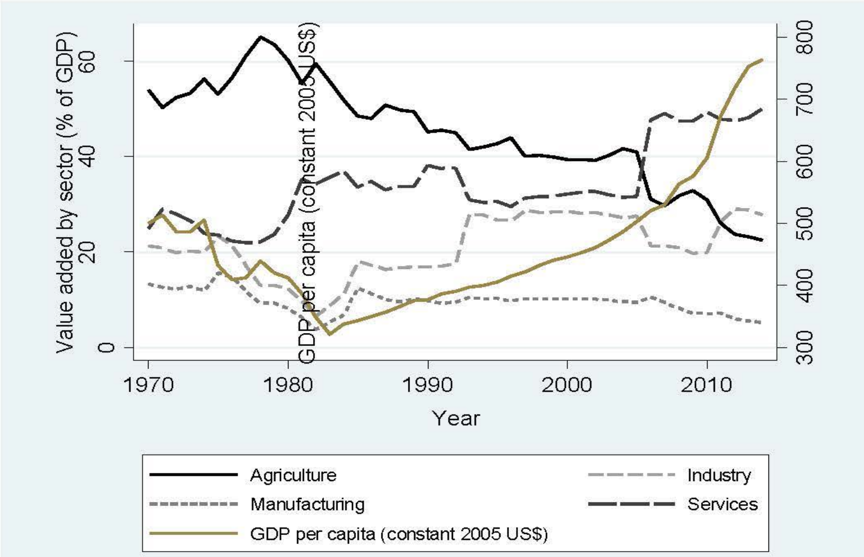
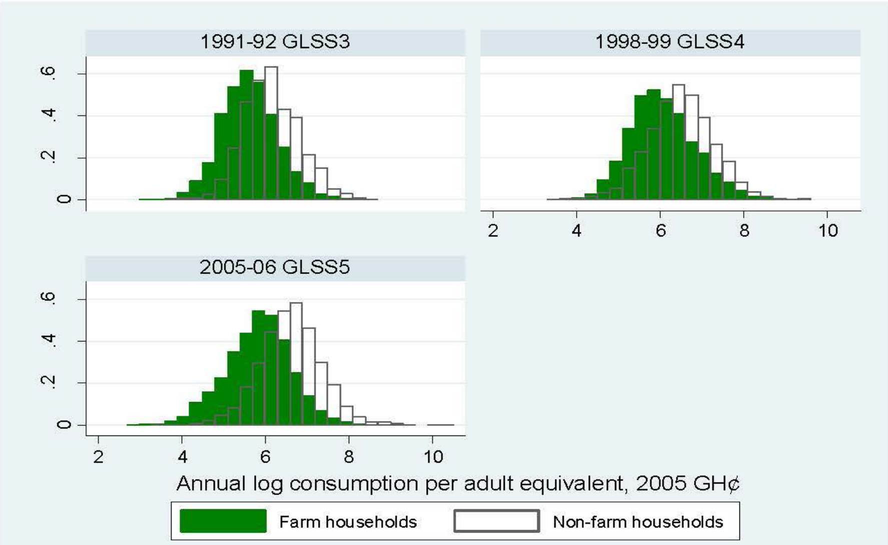
APPENDIX 2 – List of Figures

Figure 1. Value Added by sector (% of GDP), 1965- 2014



Source: The World Bank, World Databank, Development Indicators, 2016.

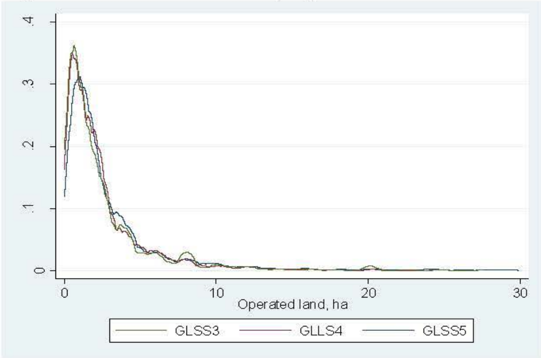
Figure 2. Frequency distribution of consumption for GLSS3, GLSS4, and GLSS5



Source: Authors' computation based on 1991-92, 1998-9, 2005-06 Ghana Living Standards Survey (GLSS).

Note: We perform a t-test for the comparison of means between the agricultural/non-agricultural households for each year ($H_0: \mu_0 = \mu_1$). The two-tailed p-value confirms that in all cases the difference in means is statistically significantly different from 0.

Figure 3. Distribution of operated land sizes: kernel density functions by GLSS waves, ha



Note: Kernel density functions for each wave use the Epanechnikov kernel and optimal bandwidth.

Figure 4. Landholding sizes: pie chart by year

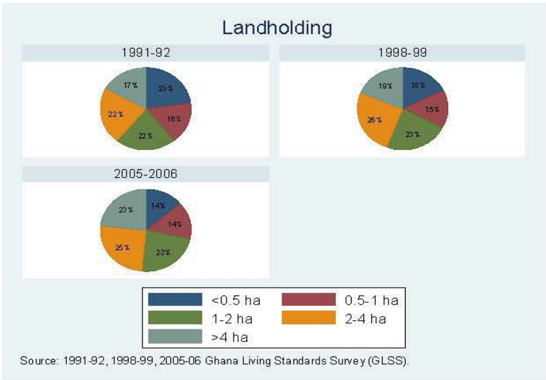


Figure 5. Use of agricultural inputs by land endowment

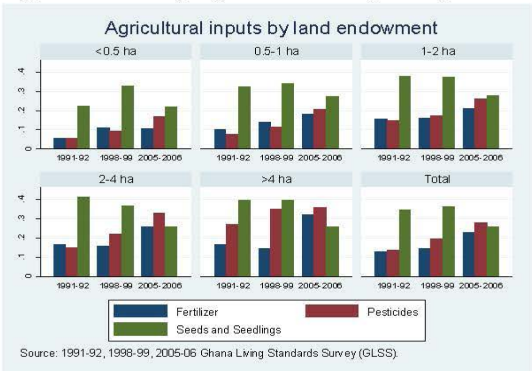

Figure 6. Share of household heads employed in agriculture, manufacturing and services, trend across regions.

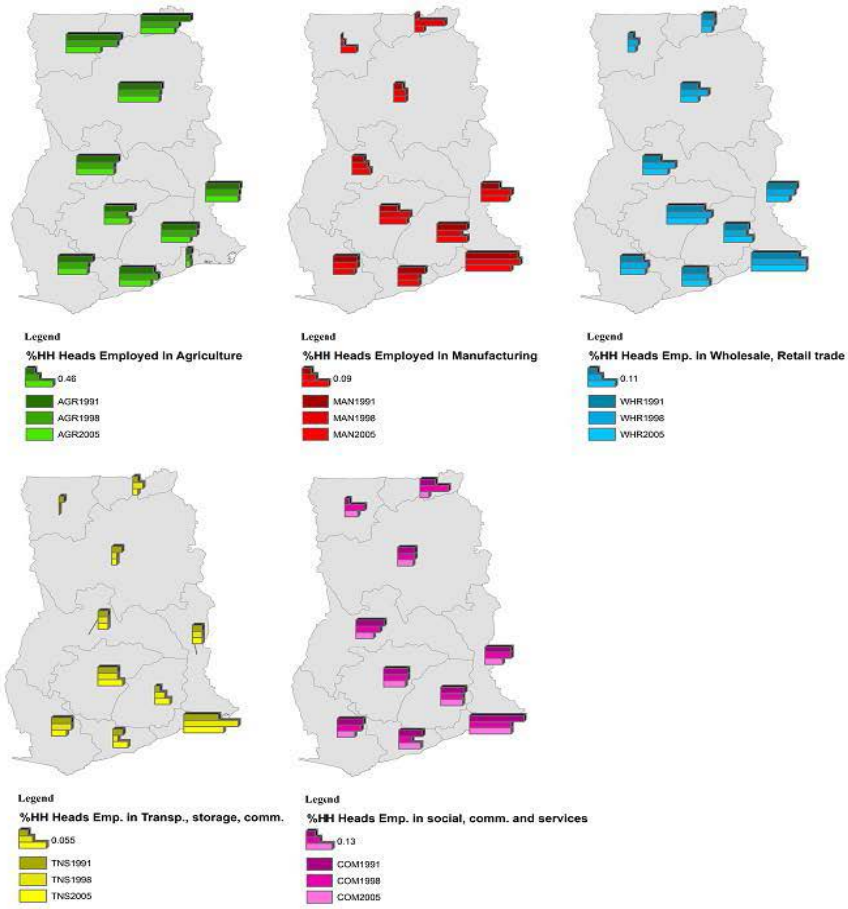

Figure 7. Share of income by sources, across regions in 1991, 1998, 2005.

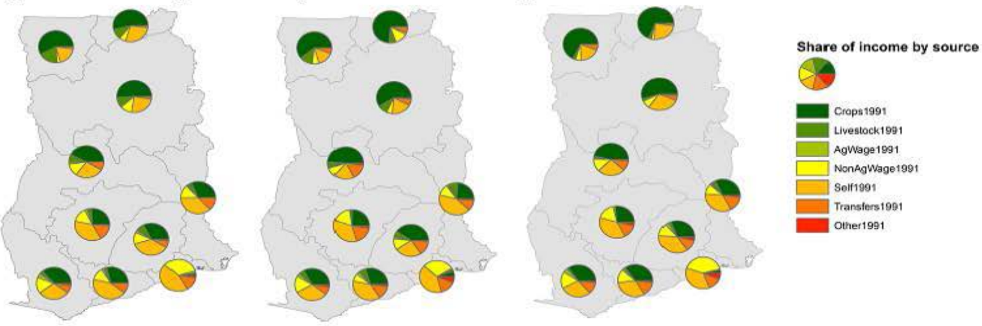

Figure 8. Total value of production of cash crops and food crops, trend across regions

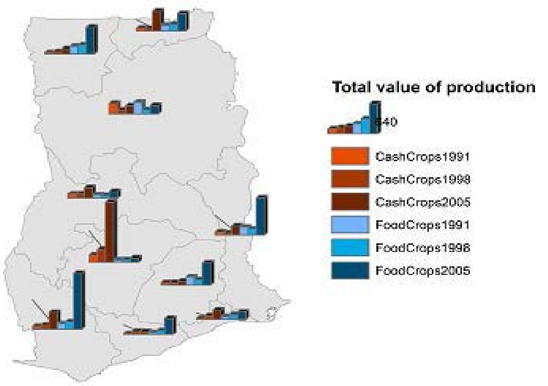

Figure 9. Input expenditure per Ha, trend across regions

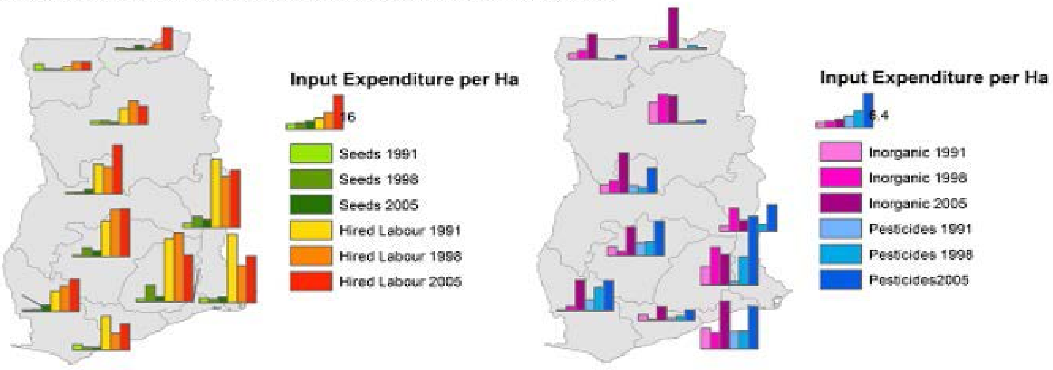

Figure 10. Share of hours/week worked in agriculture, industry and services, by age of head's cohorts, over time.

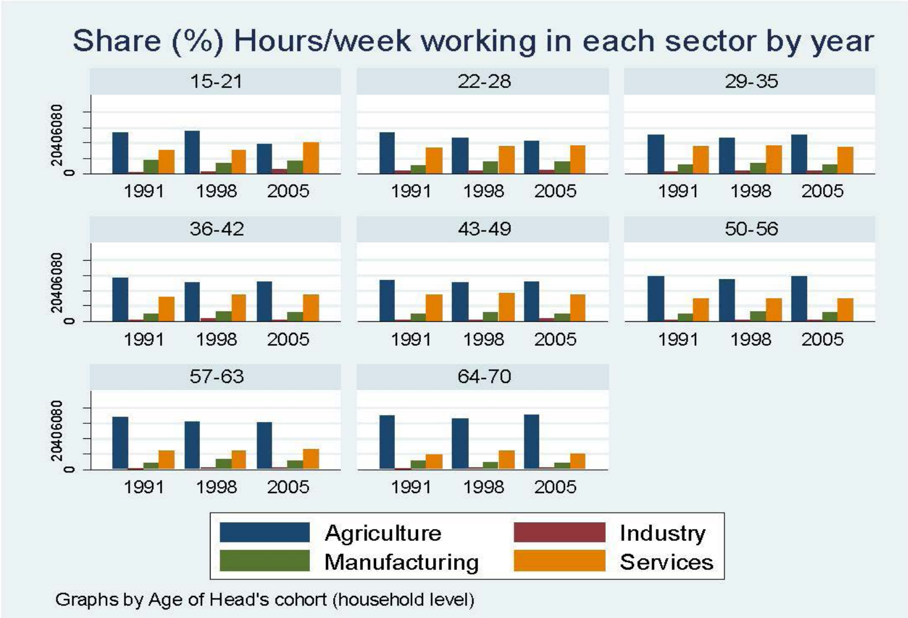

ANNEX A – Cohorts construction

A.1 Cohorts construction

Cohorts can be defined in terms of single or multiple characteristics. Using a multidimensional grouping system would help increase ing the number of cohort-groups. Hence, we construct our pseudo-panel by grouping households into cohorts according to a joint set of multiple characteristics, namely the household head's age category, his/her sex and residing region.

Since we also want to also analyze the sector of economic activity of the head, we restrict the sample to households with heads aged 15 to 64. More specifically, since the three cross sections fall seven years apart from each other, we reduce the first sample (1991/92) to households whose heads are 15 to 50 years old, the second (1998/99) to households with heads between 22 and 57 y. o. and the third round (2005/06) to household heads with ages ranging between 29 and 64. Similarly to Ackah et al. (2012) we allow households to "age" over time by tracking the same groups across the years.

For each variable included into the analysis, averages within each cohort are treated as individual observations within the pseudo-panel. Following Verbeek and Nijman (1993) we construct the cohorts ensuring that the number of observations per group would be as large as possible to reduce biases in the estimates. On the other hand, since we have only three cross- sections, if the cohorts include a large number of households, the number of cohort-groups generated will be too small, affecting the overall cross-sectional dimension of the panel. We use seven-years bands to define the generational cohorts, which result in eight age classes (15-21, 22-28, 29-35, 36-42, 43-49, 50-56, 57-63 and 64 to 70) generated for each region in each survey year. Our pseudo- panel finally results from the interaction of 7-years generation bands with the ten regions of domicile and a gender variable (male/female) for the household's head, for a total of 114 (out of 160) cohorts tracked over time15[15].

Households whose heads are of these ages and are found in the relevant cross-sections are pooled to form the pseudo cohorts. Even though the households interviewed will change in each round, they will still be fully representative of the cohort designed according to the characteristics of the population.

[15] Most authors include the birth region or more often year of birth intervals (Propper, Rees and Green, 2001), which are both time invariant variables. In a cohorts' framework, each household belongs to the same group for the whole period.

ANNEX B – Unemployment

To check the robustness of our estimates, we also include among the time allocation the time spent not working, accounting for the time declared by people in working age as not working/inactive. We consider as non-working time: (i) when job is not declared and registered time is missing, (ii) the difference between the total amount of workable hours per week – which we set as 40 (8 hours/day per 5 working days) – and the real time worked. Similarly to the procedure applied for $Sh_{is,t}$ variable, we winsorize all values exceeding 40. Differently from $Sh_{is,t}$ the share of hours worked is computed over 40 as follows: $Sh^{40}_{is,t} = \frac{HW_{is,t}}{40}$.

$$Sh^{40}_{unemp,it} = 1 - \sum_{s=1}^{4} \frac{HW_{is,t}}{40}$$

which will be 0 in case of full employment (all individuals within the same household i work 40 hours per week), and 1 in case of full unemployment.

Hereafter we report the descriptive statistics of the share of hours/week worked in the different fields, overall and divided by cohorts. We have to bear in mind that data refers to the last week before the interview. Share of time spent not working is quite high. First of all, this may be due to sensitivity of responses to the agricultural business cycle; in addition the date of the interview reflects possible seasonal movements across months. Secondly, respondents can be reticent or underreport the time spent working. Third, data does not consider time spent in domestic chores, which will presumably capture a great share of time in particular for women.

Table B.1. Share (%) Hours/week working in agriculture, services, industry, manufacturing, not working, by year

THEMATIC SET

A4 MEASURING THE SOCIAL DIMENSION OF AGRICULTURE

Session Organizer
B. Davis | FAO | Rome | Italy

ABSTRACT

Within the context of the development of the SDGs and the most recent generation of integrated household surveys, the importance and relevance of the interconnectedness of the social and economic dimensions of agricultural households is gaining prominence. While a recognition of the role in influencing behavior of the inseparability of the agricultural household in the context of market failure is well established in the literature, more generalized collection of the necessary broad types of data is more recent. This session will focus on the measurement and analysis of social topics within the context of agricultural households and the particular environment and constraints in which they live. Papers can focus on such diverse topics as the multi-dimensional nature of resilience, the implications of social protection for agriculture, the role of human capital in agricultural productivity, the role of agriculture in youth un- and under employment, etc. Papers can focus on an application to a specific topic in a given country, or focus on methodological issues.

ABSTRACT

Livestock are estimated to contribute to the livelihoods of about 60 percent of rural households in developing countries, including the poor. Measuring the extent of such contribution has been traditionally challenging because of data gaps. This paper presents an attempt to assess the contribution of livestock to household livelihoods, measuring both tradable and non-tradable or marginally tradable outputs. It builds on the National Panel Surveys of Uganda and Tanzania, that presents a comprehensive livestock module, as well as on ad hoc surveys implemented by the Ministries responsible for livestock in both countries to fill some NPS information gaps. Results suggest that non-tradable and marginally traded livestock outputs represent about half of the contribution of livestock to household livelihoods.

Keywords: LSMS, livestock, non-tradable outputs, social capital

PAPER

1. Introduction

Livestock are estimated to contribute to the livelihoods of about 60 percent of rural households in developing countries. Measuring the extent of such contribution has been traditionally challenging because of because of data gaps. In recent yearsa number of African countries have released Living Standards Measurement Studies (LSMS) datasets with a specific focus on agriculture. These datasets provide an unparalleled opportunity to measure with statistical accuracy the contribution of agricultureto household livelihoods,including specifically that of livestock.

This paper relies upon the Tanzania 2012/13 National Panel Survey (TZNPS) and the Uganda 2011/12 National Panel Survey (UNPS) to quantify the contribution of livestock to household livelihoods. The National Panel Surveys of both countries currently represent one of the largest sets of livestock data at household level throughout Africa. They include information on livestock ownership and husbandry and production practices, such as on labour, feed and health inputs, and both tradable and non-tradable or marginally tradable outputs, such as manure and animal power. The NPSs, however, also present some data gaps if the objective is to measure the contribution of livestock to household livelihoods, as they include neither questions on the quantities and unit prices of non-tradable livestock outputs nor questions specifically aimed at measuring social capital. To fill these gaps, the Ministries responsible for livestock in Tanzania and Uganda undertook two ad hoc surveys with local expertson "measuring the non-measured contribution of livestock to household livelihoods. By combining data from the NPSs and the Ministries'surveys, the paper develops and applies a methodology to estimate the full contribution of livestock to household livelihoods. This involves measuring net the income stream from sales of meat, milk, eggs and other livestock products, such as hides and skins; quantifying the value of manure, transport services and draught power rendered by animals; assessing the value of live animals as savings and insurance; and estimating the contribution of live animals to social capital. Results indicate that non-tradable outputs represent about half of the total contribution of livestock to household livelihoods. The remainder of the paper proceeds as follows. Section 2 illustrates the data and reports summary statistics. Section 3 discusses the methodology. Section 4 reports the results. Section 5 draws conclusions.

2. Data and Summary Statistics

2.1 The datasets

This paper uses data on livestock collected by the Tanzania National Bureau of Statistics (NBS) and the Uganda Bureau of Statistics (UBOS) as part of the implementation of the Tanzania and Uganda National Panel Surveys respectively (TZNPSs and UNPSs)[1]. For Tanzania, data are available for the 2008/09, 2010/11 and 2012/13 TZNPS,for Uganda for the 2009/10, 2010/11 and 2011/12 UNPS.

[1] These surveys have been implemented in the context of the Living Standard Measurement Studies – Integrated Surveys on Agriculture (LSMS-ISA) Project of the World Bank.

The 2012/13 TZNPS and the 2011/12 UNPS include an expanded livestock module, with between 80 and 100 questions. The NPS surveys collect information on livestock ownership and herd dynamics due to different reasons (e.g. sales; thefts; gifts; etc.), breeds, differentiated by local/indigenous and improved/exotic; use of inputs, including feed, water, labour, vaccines and drugs; production of livestock products, including not only meat, milk and eggs, but also dung and other services provide by livestock, such as transport; consumption and self-consumption of animal source foods.These surveysrepresent one of the largest sources of household-level livestock data throughout Africa[2]. As a way of comparison, traditional LSMS surveys include between 5 and 20 questions on livestock.

Although the livestock module in the NPSs is particularly comprehensive, it does not collect quantity and price parameters on some important non-marketable or marginally traded livestock outputssuch as dung, draft power and transport. In addition, the surveys do not explicitly target the measurement of social capital,which is often considered as a major value of livestock In order to address these gaps, the Ministry of Agriculture, Livestock and Fisheries in Tanzania and the Ministry of Agriculture, Animal Industry and Fisheries in Uganda implemented two on line surveys with local experts. The two surveys were completed by a total of 145 experts, 61 from Tanzania and 84 from Uganda, and collected

Table 1: Livestock ownership in Tanzania and Uganda

Variables		Mean	Standard deviation	Observations
Livestock owners (% of all households)	Tanzania	0.56	0.50	12,190
	Tanzania Rural	0.70	0.46	7,908
	Uganda	0.57	0.49	8,514

[2] The information collected through these newly added questions has been systematically reviewed and validated by experts from the Ministries responsible for livestock in both countries through a series of workshops within the project "Livestock in Africa: improving data for better policies" joint with the FAO and the countries' statistical institutes.

information on dung production per day by animal species; unit price of dung by animal species; frequency of use of cattle and equines for transporting goods and persons and for draft power; unit cost of animal hiring; on the relative contribution of different representative herds to cash, food, animal power, insurance and savings and social capital.

2.2 Livestock ownership

Table 1 reports summary statistics of livestock ownership in Tanzania and Uganda over the 3 survey rounds. The data indicate that 56%of all Tanzanian households and 57% of all Uganda households own livestock, with these percentages being 70% and 66% in rural areas respectively.In Tanzania, 87% of livestock owners have poultry, 43% have small ruminants and 32% have large ruminants. The ranking is the same in Uganda where 71% of livestock keepers have poultry, 63% have small ruminant and 44% have large ruminants. Pigs are more common in Uganda (23%) than in Tanzania (11%).

The average herd/flock size in the two countries is reported both in terms Tropical Livestock Units (TLUs) and number of animals owned by species One TLU is equivalent to 250 kg of live weight. The conversion factors used for this paper are 0.5 for large ruminants, 0.1 for small ruminants, 0.2 for pigs and 0.01 for poultry. The average herd/flock size in Tanzania is larger than in Uganda: they measure 2.39 and 1.65 TLUs, respectively. Tanzanian livestock owners seems to have more of all types of animals but the largest difference can be found for small ruminants where the average herd size in Tanzania is 9.88 and in Uganda is only 3.15.

2.3 Household income

Table 2 presents details on the different sources of household income, including income from livestock, as calculated using the Rural Income Generating Activities (RIGA) methodology developed by the FAO.Household income derives from 6 main sources including wages, self-employment, crop production, livestock production, transfers, and other sources; it only includes regular income, and excludes investments, windfall gains, and purchase and sale of durable goods (Carletto et al., 2007). The advantage of this methodology is that it is developed specifically for LSMS data, with the purpose to generate figures comparable across countries. In both Tanzania and Uganda, the major source of household income in is crop agriculture, averaging 50% for rural households. Self-employment in non-farm activities comes second in both countries. The contribution of livestock to household income is estimated at8.7% and 8.5% for all Tanzanian and Ugandan households respectively, at 11.2% and 8.3 in rural areas.These estimates provide a lower bound of the overall contribution of livestock to household livelihoods as they not take into account outputs that are non-tradable or marginally tradable and the value of livestock as social capital.

Table 2: Components of household income (%) – RIGA methodology

Income components	Tanzania		Uganda	
	Rural	Total	Rural	Total
Agricultural wages	6.37	5.09	5.96	5.11
Non-agricultural wages	9.25	18.11	9.04	12.17

Livestock income	11.23	8.73	9.34	8.05
Self-employment	14.71	22.30	16.96	19.53
Transfers	8.36	7.46	7.66	9.38
Other sources	0.15	0.12	0.99	1.54
Total Income	100	100	100	100
Observations	7,836	12,003	6,393	8,205

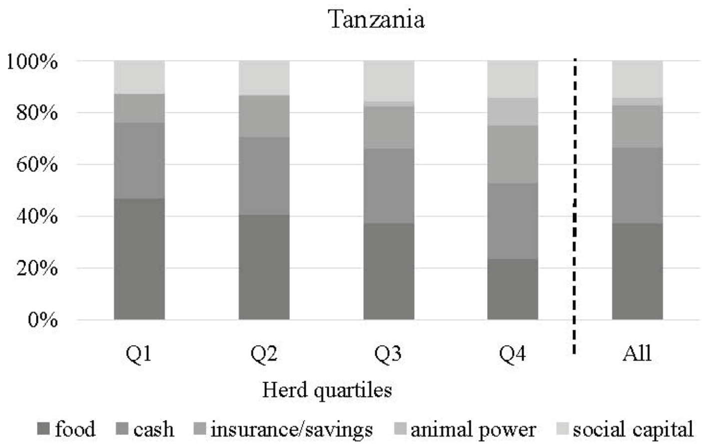
Source: RIGA project WB based TNPS waves 2008/09, 2010/11 & 2012/13 and UNPS waves 2009/10, 2010/11 &2011/12

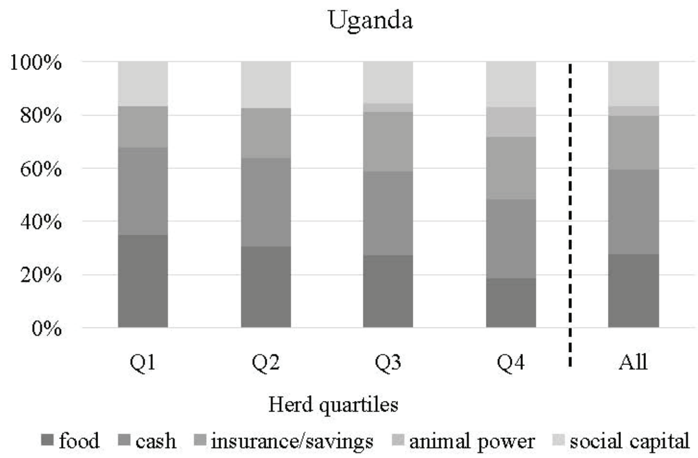
2.4 Tradable and non-tradable livestock outputs

Figure 1 displays the relative contribution of livestock to food, cash, insurance and savings, animal power and social capital. These are presented for herds quartile (Q) of the TLU distribution. In Tanzania the bottom herd quartileis composed by 7 chickens; the second by 1 goat and 13 chickens; the third by 1 cattle, 4 goats, 1 pig and 11 chickens; and the top quartile by 18 cattle, 16 goats, 1 pig and 15 chickens. In Uganda, the bottom herd quartile comprises a flock of 5 chickens; the second herd quartile includes 2 goats and 5 chickens; the third 1 cattle, 3 goats, 1 pig and6 chickens; and the top quantile includes 10 cattle, 7 goats, 1 pig and 12 chickens.

The figure indicates that while tradable livestock outputs, including self-consumption of animal protein and cash from the sale of animal products and live animals represent the main channel through which livestock contribute to household livelihoods, as they make up 67% and 59% of the total value of livestock "outputs" in Tanzania and Uganda respectively. Their relative contribution

Figure 1 - Contribution of livestock to household livelihoods by livelihood dimension





Source: own elaboration based on data collected by the Tanzania and Uganda Ministries responsible for livestock

of tradable outputsto livelihoods decreases with herd / flock size as only households that keep a relatively large herd, comprising at least one cattle in the sample,significantly benefitfrom other livelihood services provided by livestock and most notably insurance, savings and animal power. As the figure presents relative value, note that in all cases households in the upper herd quartiles derive more benefits in absolute terms from both tradable and non-tradable outputs.

3. Measuring tradable and non-tradable livestock outputs

This section presents a methodology to compute the contribution of livestock household livelihoods taking into account non-tradable and marginally tradable livestock outputs.The starting point is livestock income as calculated applying the RIGA methodology, to which we add measures of the benefits obtained from non-tradable outputs: savings andinsurance; and self-consumption of marginally traded outputs, including animal power and dung. In particular, we slightly modified the RIGA methodology to assure comparability of the results between the two countries and computed livestock income as the sum of income from sale of live animals and livestock products and by–products, minus recurrent expenses and purchase of live animals. Equation 1illustrates the calculation.

$$\begin{aligned} \text{Livestock income} = \; & + \text{sale of livestock} \\ & + \text{sale of livestock byproducts (milk, eggs, dung, draught power, etc.)} \\ & + \text{value of self consumption of livestock food products} \\ & - \text{expenses for feed, water and hired labour} \\ & - \text{expenses for veterinary services} \\ & - \text{purchase of livestock} \end{aligned} \quad (1)$$

We consider sale and purchases as income and expenditure rather than investment and disinvestment for the reasons both that purchase and sales of animals is common, particularly pf small ruminants and poultry, and that in many cases animals are not necessarily sold when they are no longer productive. Since the price data are noisy we use the median sale and purchase price for the region of reference to calculate the value of animals sold and purchased. As animal dung is mainly used by the household as manure, we calculate its value by using the data provided in the crop production sections of the survey.In particular, the data provide information on the use of organic fertilizer and the quantity purchased, which allow us to compute the value of self-consumption of organic fertilizer. As for transport, insurance and savings and social capital, we usedthe data collected by the Ministries responsible for livestock described in section 2.1. For each quartile of livestock ownership distribution, we have data on the contribution of livestock to household livelihoods from food, cash, savings/insurance, animal power and social capital. We use this information to impute the value of each of these outputs as a share the household's cash and food livestock income, which we calculate from the NPS data.

4. Results

Table 3 reports the decomposition of livestock income into its components as obtained from the modified RIGA methodology computation illustrated by equation 1. The table relies only on the 2012/2013 Tanzania NPS and the 2011/12 Uganda NPS, which include the expanded module of livestock with detailed information on production and husbandry practices. The relative importance of the different components is similar in the two countries. Households derive most of their livestock income from the self-consumption of animal products, which contribute 48% and 51% of the gross revenue from livestock (60% and 68% of the net livestock income). The sale of live animals come second, representing 42% and 35% of the gross livestock revenue, followed by the sale of meat, milk and eggs which account for 10% and 14%.

Table 3: Livestock contributionto household income (rural livestock keepers only)

Income components	Tanzania		Uganda	
	TZS	% livst income	UGS	% livst income
Sale of livestock	201,740	52.27	87,496	47.07
Sale of livestock by-products	47,250	12.24	27547	15.63
Sale of dung	19	0.01	42	0.02
Sale of animal power	N/A	N/A	6600	3.74
Food self-consumption	229,654	59.50	126,327	67.95
Expenditure (feed, water, labor)	-23,018	-5.96	-18,691	-10.05
Vet services	-14,809	-3.84	-14,827	-7.98
Purchase of livestock	-54,867	-14.22	-38,212	-20.55
Livestock income	385,970	100	176,282	100
Observations	1,780		1,585	

Source: own elaboration based on TNPS 2012/13 and UNPS 2011/12. Livestock by-products include milk, meat and eggs. Sale of animal power includes draught power and hauling services, this information was not collected for Tanzania

Table 4 reports the calculation of the total contribution of livestock to household livelihoodsbut also includes non-tradable or marginally-tradable outputs.The data indicate, first of all, that the contribution of livestock to household livelihoods is highly underestimated if only tradable outputs are measured: the benchmark measure of livestock income (table 3) accounts for less than 43% of the total contribution of livestock to livelihoods in Tanzania and for about 36% for Uganda. In particular, the results show that 45% and 43% of the livestock gross revenuecomes from non-tradables, including use of dung, animal power, insurance and savings and social capital. Dung account for 6% and 10%. The other half comes revenue from the sale of live animals, meat, milk and eggs.

Table 4: Contribution of livestock to household livelihoods (livestock keepers only)

Income components	Tanzania		Uganda	
	TZS	% tot contribution	UGS	% tot contribution
Cash(sales of livestock and by-products)	257,230	28.36	131,304	26.97

5. Conclusion

This paper presents an attempt to assess the contribution of livestock to household livelihoods, measuring both tradable and non-tradable or marginally tradable outputs. It builds on the National Panel Surveys of Uganda and Tanzania, that presents a comprehensive livestock module, as well as on ad hoc surveys implemented by the Ministries responsible for livestock in both countries to fill some NPS information gaps. The results suggest that non-tradable and marginally traded livestock outputs play an important role for household livelihoods In particular, savings/insurance, social capital and animal power are estimated to account for as much as 50% of the total contribution of livestock to household livelihoods Standard methods to estimate livestock income, therefore, significantly underestimate the contribution of livestock to livelihoods.

While these findings need to be certainly substantiated with additional and more detailed analyses, they suggest that statistics offices should attempt to better measure the non-tradable dimensions on livestock in selected surveys and that policy makers should be caution when designing market-based policies to promote the development of livestock, as the market-related contribution of animals to household livelihoods is limited.

ABSTRACT

The concept of resilienceis increasingly gaining traction in the international development literature as a way to profile, rank and predict the response capacity of households to shocks and stressors to livelihoods, particularly those that threaten to food security.The objective is to provide a more rigorous framework and a single reference indicator for the design and implementation of sustainable long-term development initiatives that minimize the need for perennial mobilization for humanitarian and emergency assistance. While there are still debates about the construct and measurement, there is general consensus that a household's resilience encompasses aspects of household income generating capacity and diversification, ownership of agricultural and non-agricultural assets, access to social safety nets and basic services, as well as household stability and adaptive capacity to shocks.

By providing a steady and predictable source of income, particularly one that is unconditional, the SCTP is hypothesized to impact positively on the productive capacity of households and asset ownership without negatively affecting pre-existing social safety nets and access to basic services. The net effect of this should be improved food security and more resilient households able to respond to shocks and stressor with more positive coping strategies that are not detrimental to long term development prospects. This report accordingly examined the impacts of the SCTP on the dimensions of resilience and overall resilience score. We further examine the validity of the resilience index in predicting future food security.We find significant positive impacts of the SCTP on agricultural and non-agricultural asset ownership, crop production, livestock ownership and household debt situation. We find no ‗crowding out' effects of the SCTP on access to private and public social safety nets, and no signs of reduced labour hours although there is some reduction in the hours spent on casual labour. We also find significant positive impacts of about MWK 13,000 on overall per capita consumption as well as a MWK 7900 on per capita food consumption. In addition, we find significant positive effect on household food security, meal frequency, meal quality and dietary diversity. Our estimate of household resilience, using the FAO RIMA II model, also shows significant improvement in the household resilience index for the T households.

Using the information on actual household coping responses to shocks over the last 12 months, we assess the ‗reliability' of the resilience score be examining its predictive power on the coping strategies adopted by households in response to shocks. We find a strong positive association between the resilience index and the share of positive coping responses to shocks. While 37 per cent of households in the lowest quintile of the resilience score are able to adopt positive coping strategies to shocks, the corresponding figure for households in the highest quintile is 71 per cent, with noticeable difference between T and C households. We also examine the predictive power of the resilience score to food security using only the sample of C households in order to exclude the effect of the SCTP. The results of this analysis also show that high resilience score at baseline was reasonably predictive of food security at endline among the C households, indicating a reasonable level of reliability of the resilience score.

While the SCTP had no explicit objective on resilience, the overwhelming evidence of increased resilience and the association thereof with actual positive coping strategies to shocks experienced by the households suggests that households that benefit from unconditional cash transfer programs are able to make the right decisions that contribute to building household resilience in the many dimensions it is construed.

PAPER

1. Background

The concept ofResilience is becoming increasingly popular within the international development community as aframework for profiling and ranking households in terms of their response capacity to shocks and stressors to livelihoods, particularly those that threaten food security. The objective is to providea single reference indicator for summarizing multidimensional aspects of household livelihoods in order to better inform development and humanitarian interventions and also summarize program impacts. The term has a long history of use in mental health studies where resilience is defined as "the ability to withstand and rebound from disruptive life challenges" In the development literature, resilience is discussed in relation to threats to livelihoods, often occasioned by shocks that can be natural or man-made, exogenous or endogenous, seasonal or recurrent, short or protracted (D'Errico et al. 2013; FAO II 2014). The definition of resilience in the development literatureis still a matter of some discussiondue to the multidimensional nature of the term, and contemporary definitions differ mainly in terms of scope and emphasis on the types of threats to livelihoods that have to be taken into consideration. The Resilience Alliance defines the resilience as "The capacity of a system to absorb disturbance and reorganise while undergoing change." DFID defines it as "..the ability of countries, communities and households to manage change, by maintaining or transforming living standards in the face of shocks or stresses—such as earthquakes, drought or violent conflict—without compromising their long-term prospects," while the FAO's Resilience Measurement Technical Working Group defines it as "...the capacity that ensures adverse stressors and shocks do not have long-lasting adverse development consequences." (Resilience Alliance, 2002) . Barrett and Constas (2014) define development resilience as "the capacity over time of a person, household or other aggregate unit to avoid poverty in the face of various stressors and in the wake of myriad shocks. If and only if that capacity is and remains high over time, then the unit is resilient" The common thread through these and other definitions is the notion that resiliency reflects an ability to successfully avoid poverty and food insecurity even in the event of negative shocks or stressors to an established pattern of livelihood.The relevance of this concept cannot be overemphasized due to the increasing disruption in food supplies and agricultural productivity caused by climate change, as well as the frequent outbreaks of civil unrest and armed conflict. Conceptually, a more resilient household is one that is better able to anticipate and manage its exposure to negative shocks to livelihood, and when preventive measures fail, be able to withstand with more positive coping strategies. For example, households that make use of irrigation or other soil management techniques in farming are generally better positioned to avert the full effect of droughts, and also more likely to have higher productivity that minimizes the risk of food insecurity. Efforts to measure resilience are still very much debated both theoretically and empirically. However, there seems to be general consensus that a household's resilience encompasses aspects of household income generating capacity and diversification, ownership of agricultural and non-agricultural assets, access to social safety nets and basic services, as well as household stability and adaptive capacity to shocks. By providing a steady and predictable source of income, particularly one that is unconditional, the SCTP is hypothesised to positively impact on household income generation capacity, ownership of assets and household human capital such as health and education. We also hypothesise that the SCTP would not negatively impact on pre-existing access to social safety nets and basic services, or household demographic composition. The net effect of these effects should result in improved food security, lower exposure to the effects of perennial or seasonal shocks, and strengthened households' ability to cope with negative shocks with more positive coping strategies that do not undermine long term development objectives.

This expected outcome is not automatic or guaranteed. The use to which households put the SCTP money determines how much they can improve on their livelihood and ability to manage shocks and stressors to livelihoods. The choice of investments can also be constrained by the household's pre-existing conditions as households with tighter food consumption budget constraints may not be able to make medium to long term productive investments or asset accumulation to improve their resilience. This report examines the impacts of the SCTP on household resilience and provide some validity test of the resilience score by analysing the relationship between the resilience score and the use of positive coping strategies in response to shocks. We also examine the predictive power of the resilience score for use as a ranking tool by examining the relationship between endline food security and baseline resilience for the control households who had no exposure to the SCTP treatment. The next section of provides an overview of the SCTP programme followed by a description of the broader impact evaluation design and the data source for the analysis. Section four provides the broad intent-to-treat (ITT) impact estimates on the various dimensions of resilience. Section five provides a description and estimation of household resilience capacity index using the FAO RIMA II model, and analysis the program impacts and the validity tests described above. Section six provides a summary and conclusion.

2. Overview of the Malawi SCTP Programme

The Malawi Social Cash Transfer Programme (SCTP) is one of the several cash transfer programs currently being implemented by governments and development partners acrossAfrica. Locally known as the Mtukula Pakhomo, the SCTP is an unconditional cash transfer programme targeted to ultra-poor, labour-constrained households. The programme began as a pilot in Mchinji district in 2006 and is run by the Government of Malawi (GoM). Since 2009, the programme has expanded to reach 18 out of 28 districts in Malawi. The programme has experienced impressive growth beginning in 2012, and most notably in the last two years. By December 2015, the SCTP had reached over 163,000 beneficiary households.

The objectives of the SCTP are to reduce poverty and hunger, and to increase school enrolment rates in these ultra-poor households. The first evaluation of the programme, the 2007-2008 impact evaluation of the pilot project in Mchinji, demonstrated that the Malawi SCT Pilot Scheme had a range of positive outcomes including increased food security, ownership of agricultural tools and curative care seeking[1]. Since that time, the programme has witnessed some changes in targeting and operations, and significant expansion. The expectation is that these improvements will lead to even stronger impacts for the larger target population. The SCTP is administered by the Ministry of Gender, Children, Disability and Social Welfare (MoGCDSW) with additional policy oversight provided by the Ministry of Finance, Economic Planning and Development (MoFEPD). UNICEF Malawi provides technical support and guidance. Funding for the programme from 2007-2012 was largely provided by the Global Fund to Fight AIDS, Tuberculosis and Malaria (GF). In 2011, the German Government (through Kreditanstalt für Wiederaufbau, or KfW) and the GoM signed an agreement to provide substantial funding for paying arrears in existing areas. In 2013, Irish Aid signed an agreement to expand into one new district, and in 2014, KfW and the European Union (EU) topped-up donor contributions to enable full coverage in the seven existing districts, as well as scale-up intoeight additional districts. Also in 2014, GoM launched a ǧgovernment-fundedč district (Thyolo) and the World Bank committed to providing resources to expand into two additional districts. The SCTP was launched in these 11 newly funded districts starting in mid-2014 through early 2015,bringing coverage to 18 districts.

Eligibility criteria are based on a household being ultra-poor (unable to meet the most basic urgent needs, including food and essential non-food items such as soap and clothing) and labour-constrained (defined as having no member ďfit to work' or having the ratio of čnot fit to work' to ďfit to work' of more than three). Household members are defined as ǔunfit to work' if they are below 19 or above 64 years of age, or if they are aged 19 to 64 but have a chronic illness or disability, or are otherwise unable to work[2]. Beneficiary selection is done through a community-based approach with oversight provided by the local District Commissioner's (DC's) Office and the District Social Welfare Office (DSWO). Community members are appointed to the Community Social Support Committee (CSSC), and the CSSC is responsible for identifying households that meet these criteria and creating a list. These lists are to include roughly 12 per cent of the households in each Village Cluster (VC), and after further screening, the list is narrowed in order to achieve a target coverage rate of 10 percent. The ultra-poor eligibility condition is implemented through a proxy means test (PMT). The transfer amount varies based on household size and there is a čschooling bonus' determined by the number of children in the household enrolled in primary and secondary school. Transfer amounts were updated just prior to the start of this evaluation in 2012. Due to inflation and decline of the value of the real transfer, transfer amounts were increased again in May 2015. The transfer amounts are shown in Table 2.1.1.

Table 2.1.1 – Structure and Level of Transfers (Current MWK)

	2013 to May 2015	After May 2015
1 Member	1,000	1,700
2 Members	1,500	2,200
3 Members	1,950	2,900
4+ Members	2,400	3,700
Each primary school child[1]	300	500
Each secondary school member[2]	600	1,000

[1]Provided for household residents age 21 or below in primary school. 2 Provided for household residents age 30 or below in secondary.

To put these amounts in perspective, Table 2.1.2 shows the average transfer payment and transfer as share of the household baseline consumption. On average, the total annual transfer amount received by households was MWK25,622 and the average monthly per capita of the transfer was MWK 559. We find that on average, the transfer represented 20 per cent of baseline consumption among all beneficiaries, but was higher at 27 per cent among the poorest 50 per cent of households at baseline.Additional details of the implementation and operational performance can be found in the main impact evaluation report (Handa et al, 2016). In particular, there was high adherence in terms of disbursement with up to 99 per cent of target beneficiaries receiving payments as expected. The quantum of money received was also generally consistent with the schedule in Table 2.1.1 except for lack of adjustment for rolling household size. There was little reference to corruption in terms of program officers demanding payments from recipients, and recipients were generally satisfied with the mode of payment. Although there were some misconceptions about eligibility for receiving the SCTP, perceived conditionalitiesregarding the expenditure of the SCTP money, how long into the future beneficiaries expect to receive the transfer, and delays encountered in going to receive the transfer, there is reason to believe that treatment has been very successful for which reason we would expect to see the theorized impacts.

3. Impact Evaluation Design

This section provides key highlights of the impact evaluation design and the analytical framework. Additional details can be found in main impact evaluation report (Handa et al, 2016).

Notes: Transfer values expressed in real August 2013 national prices, MWK. Small households contain four or fewer members. Descriptive statistics are corrected for multi-stage survey design.

3.1 Study Design

The impact evaluation for Malawi's SCTP uses a mixed method, longitudinal, experimental study design, combining quantitative surveys, qualitative interviews and group discussions, and simulation models to demonstrate wider community economic impacts[3]. The study districts, Salima and Mangochi, were selected for the study in order to integrate with GoM's SCTP expansion plans. The MoGCDSW had plans to conduct retargeting in existing programme areas, and to expand the SCTP to cover 18 districts, starting in 2012. The districts scheduled for scale-up in early 2013 were Salima and Mangochi, so the MoGCDSW took this opportunity to integrate an impact evaluation into the planned expansion activities. Subsequently, the research team worked with MoGCDSW, Ayala Consulting and development partners to randomly select two study Traditional Authorities (TAs) in each district (Maganga and Ndindi TAs in Salima, and Jalasi and M'bwana Nyambi TAs in Mangochi). The quantitative survey design consists of a cluster-randomized longitudinal study with baseline surveys (household, community and business) which began in July 2013 and two follow-up surveys (household and community) – the midline survey was conducted starting in November 2014 and the endline survey was conducted starting in October 2015. The qualitative survey is an embedded longitudinal study of 16 treatment households, which includes three main components: in-depth interviews (IDIs) with the caregiver and a young person (aged 13-19 at baseline) from each household at baseline and follow-up; key informant interviews (KIIs) with community members at follow-up; and focus group discussions (FGDs) in each study TA at baseline and follow-up. Insights from these qualitative interviews and discussions with community members provide complementary data to that obtained through the surveys and will allow us to examine certain topics in more depth, in particular, the role and evolution of social networks and the mechanisms and dynamics that shape outcomes related to the cash transfer programme.

Baseline data collection was conducted to allow the study team to accurately describe characteristics of beneficiary households before receiving any cash transfers. Midline and endline data has been compared to data collected at baseline using a difference-in-differences (DD) estimation approach to assess the full impacts of the SCTP. Data collected on the control group allows the researchers to

[3] The FAO, with direct funding from the Department for International Development-United Kingdom (DFID-UK), built a simulation model to predict the potential of the SCTP to generate local economy-wide effects. Those results are reported separately in: Thome, K., Taylor, J.E., Tsoka, M., Mvula, P., Davis, B. and Handa, S., Local Economy-wide Impact Evaluation (LEWIE) of Malawi's Social Cash Transfer (SCT) Programme, PtoP project report, FAO - March 2015.

identify which impacts over time are directly attributable to the cash transfer, controlling for outside influences. This is done by taking the overall changes experienced by beneficiaries and subtracting the changes also experienced by control households. The difference in these two are attributed to the programme and considered programme impacts.

3.2 Sampling and Data Collection

The sample for the quantitative longitudinal impact evaluation includes 3,531 SCTP-eligible households and 821 non-eligibles located in 29 VCs across the four TAs in the two districts at baseline. There are 14 VCs (1,678 households) in the treatment (T) group and 15 VCs (1,853 households) in the control (C) – or delayed-entry— group. Data on the non-eligible households were collected to enable FAO to build the local economy simulation model.6The study design uses both random selection (for the selection of study areas at the TA and VC level) and random assignment (to determine T and C VCs), the most rigorous approach available according to evaluation literature[4]. This randomization was done in cooperation with GoM, and was a transparent process open to the public, and the assignment to T-C status was public and attended by local community leaders. The baseline data was used to check for balance between T and C households in order to ǎassess' the performance of the randomization and the results showed that T and C households were balanced on more than 100 relevant variables that were examined. After treatment and control VCs were assigned, the qualitative sample of 16 households was selected from treatment VCs for IDIs of the caregiver and a young person. We used a stratified sampling approach to facilitate comparison across sex and orphan status, resulting in a sample that was half male and half orphaned. Geographically, our sample covers two districts, Salima and Mangochi, and four TAs (Salima – Maganga and Ndindi TAs; Mangochi – Jalasi and M'bwana Nyambi TAs). Four households were selected from each TA. We determined the sample size based on our previous experience, guidelines for longitudinal qualitative research, and feasibility. A prerequisite for selection of a household was that the household had to have at least one youth aged 13-19 years of age (at the time of baseline) who had completed the Young Person's Module in the quantitative survey. This allows for a richer analysis of the youth IDIs, as the qualitative interview could be linked to information on behaviour and attitudes of this same youth from the quantitative survey. These households were then sorted based on gender and age of caregiver and young person, and other characteristics of the young person. Sixteen households were selected on the basis of having a balance of characteristics among the youth respondents, including female/ male, orphan/ non-orphan, had sex/ never had sex and currently enrolled in school/ not currently enrolled in school. Alternate households with similar characteristics were selected to match each of the 16 selected, in case participants refused the IDI or were unavailable.

Focus group discussions (FGDs) at midline were held with two separate groups (beneficiaries and non-beneficiaries) in each of the four TAs, for a total of 10 FGDs[5]. The groups were divided into programme beneficiaries and community members not receiving the transfer in order to allow participants to speak freely, without stigma or judgement from the other group. FGD participants were community members aged 18 and above who have detailed knowledge of the community and were invited by the local village heads. The number of FGDs was determined by the fact that we wanted to cover each TA to account for general geographical and cultural differences that could affect the impacts, perceptions, and operations of the SCTP. The specific locations within the TAs were driven by the fact that, for logistical purposes, the FGDs were conducted during the same time period as the IDIs; therefore, FGDs were held in the same VCs where the IDIs were given.

The survey instruments used consists of six major components:

1. Household Survey administered to the main respondent for the household;

2. Young Person's Module for up to three youth ages 15-22 in the household (age at endline);

3. Anthropometric Measures for children ages 6 months to 71 months in the study households;

4. Community Survey given to a group of knowledgeable community members to gather information on community norms, resources, pricing and access to services;

5. IDIs for caregiver and one youth from 16 treatment households;

6. KIIs and FGDs with knowledgeable community members to discuss impacts, perceptions, and operations of the SCTP. Beneficiary and non-beneficiary FGDs were held separately.

Survey instruments were reviewed for ethical considerations and approved by the UNC Internal Review Board (IRB) and Malawi's National Commission for Science and Technology (NCST), National Committee for Research in Social Sciences and Humanities (UNC IRB Study No.14-1933; Malawi NCST Study No. RTT/2/20). Instruments are available online at: https://transfer.cpc.unc.edu/?page_id=196

[4] Shadish WR, Cook TD, Campbell DT. Experimental and Quasi-Experimental Designs for Generalized Causal Inference. Boston: Houghton-Mifflin. 2002.

[5] An additional set of FGDs was conducted in Mangochi since time permitted the team to do so.

3.3 Attrition

Attrition occurs when households from the baseline sample are missing in the follow-up surveys. There are different reasons for households not responding in subsequent survey waves. Migration, death, separation, or the dissolution of households can cause attrition and make it difficult to locate a household in the second or third wave of data collection. Attrition can cause problems for an evaluation because it not only decreases the sample size (leading to less precise estimates of programme impact), but it could also introduce bias into the analytic sample. If attrition is selective, it could lead to incorrect programme impact estimates, or it could change the characteristics of the sample and therefore, it could affect the representativeness of the impact results. There are two types of attrition: differential and overall. Differential attrition occurs when the treatment and control samples differ in the types of households or individuals who leave the sample. Differential attrition can create biased samples by reducing or eliminating the balance between the T and C groups achieved at baseline. Since we will conduct the analysis using the households present in all three waves of the survey, it is also important to examine for overall attrition, which is the total share of observations missing at the follow-up surveys from the original baseline sample. Overall attrition can change the characteristics of the remaining sample of analysis and render it non-representative of the population from which it was obtained. Overall attrition can affect the ability of the study's findings to be generalized to the population of interest. Ideally, both types of attrition should be null or small. We investigated attrition at endline for the quantitative sample by testing for similarities at baseline between (1) treatment and control groups for all households included in the panel of households, that is, for the households interviewed at baseline and in both follow-up surveys (differential attrition) and, (2) all households in the panel and the households who were missing in either the midline or the endline survey (overall attrition). Fortunately, we do not find evidence of differential attrition, meaning that we preserve the balance between the T and C groups found in the baseline survey. Summary attrition tables are given in Appendix A. However, there is evidence of overall attrition in the sample which we correct for by using modelled inverse probability weights. The attrition rates and effective sample sizes are shown in Table 3.3.1.

Table 3.3.1 – Household "In the Panel" and Attrition Rates by T - C Status and District

		In Panel Rate (Per cent)	Attrition Rate (Per cent)	N
Total sample		93.5	6.5	3,531
Treatment group		94.0	6.0	1,678
Control group		93.2	6.8	1,853
District	Status			
Salima	Treatment	95.1	4.9	800
Salima	Control	93.4	6.6	975
Mangochi	Treatment	92.9	7.1	878
Mangochi	Control	92.8	7.2	878

For the qualitative sample, the caregiver and one youth, aged 13-19 from 16 households were interviewed at baseline, for a total of 32 participants. At midline, three female youth had left their homes for marriage, and one went to live with relatives. One male youth left home to attend secondary school in another district. While these five youth were no longer in the SCTP households at follow-up, the research team was able to trace all of them for the follow-up interviews. One caregiver, a grandmother, had passed away shortly before midline interviews and the youth had gone to live at his aunt's house. Both the youth and the aunt were interviewed at midline. Therefore, at midline, 32 interviews were conducted, and 31 of those were with the same baseline participants, the only exception being the deceased participant. Our team had similar success with retention at endline; while six youth (three boys, three girls) were no longer living at the households where they were initially recruited, the interviewers were able to track and interview all of them. Of note, among the six who had left their households, all three females had married while all three males had left to study (two in secondary, one in madrasa). Three females who had married had returned home by endline and were interviewed in their original households. Overall, 32 interviews were conducted at endline with the same 32 respondents from midline.

4. Program Impact on Resilience Domains

This section presents the program impacts on the various domains of resilience. The domains include economic activities, asset ownership, access to credits and transfers, access to social safety nets, labour use, shocks and coping, consumption and food security. Impacts are estimated using DD regression and are reported as average treatment effects.

4.1 Impact on Economic Activities

One of the objectives of the SCTP is to reduce poverty and hunger among beneficiaries. Since household poverty and hunger are invariably the result of household production being in deficit of household demand, we recognize that increasing household production is the more sustainable way to reduce poverty and hunger in the long term. The SCTP cash is hypothesized to act as a catalyst for behavioural responses and necessary investments in household economic activities that will result in increased production. Our analysis shows an impact of 62kg in overall crop harvest, driven mainly by an impact of 60kg on the five main staple crops (maize, groundnut, rice, pigeon pea and pumpkin). There is also an impact of MWK 12,000 on the total value of crop harvest. On livestock production, the proportion of T householdsinvolved in livestock production at baseline more than doubled at endline (from 29 per cent to 59 per cent) and the impact on raising livestock was 22 pp. Livestock owned, measured in terms of the standard tropical livestock unit (TLU) equivalents also more than doubledamong T households from baseline to endline, and the impact on this indicator was about 5 pp. We also found significant positive impacts on livestock consumption, and expenditure on livestock purchases over the past 12 months. We generally do not find any impacts on the operation of non-farm household enterprises (NFE) or on enterprise profitability. Overall, we find an impact of 0.24 units in the number of economic activities that households are engaged in, an indicator of income source diversification and strengthening (Table 4.1.1).

Table 4.1.1 – Summary Impacts on Economic Activities

Dependent Variable	Endline Impact (1)	Midline Impact (2)	Impact Diff (EL-ML) (3)=(1)-(2)	Baseline Treated Mean (4)	Endline Treated Mean (5)

Number of economic activities	0.246***	0.079	0.167***	1.455	1.800
	(3.98)	(1.45)	(3.53)		
N	9,902	9,902		1,576	1,575

Notes: Estimations use difference-in-differences modelling among panel households. Binary outcomes are estimated using LPM. All estimations control for baseline head of household's characteristics (age in years, sex, indicator of any schooling, indicator of literacy, marital status), household demographic composition and size, indicators for new household members and household member outmigration, and a vector of contemporaneous cluster level prices. Robust t–statistics were obtained clustering at the different levels of the sampling design and are shown in parenthesis. * 10% significance ** 5% significance; *** 1% significance

The main impact evaluation report (Handa et. al, 2016) has extensive coverage on various aspects of these household economic activities including impacts inputs into crop production (fertilizer use, farm size, etc), crop sales, livestock consumption and sales, and the specific livestock types (goat/sheep, chicken, duck/geese). We also present some of the heterogeneous treatment effects on these indicators. In particular, we find similar effects, often with larger coefficient sizes, for the baseline bottom 50 per cent of households. Annex B of this report provides some of the activity specific and heterogeneous impact tables.

4.2 Impacts on Asset Ownership

We investigate the impacts of the SCTP on ownership and investments in agricultural and non-agricultural assets. At baseline, about 93 of households owned or cultivated land, and the inability to own basic farming tools often led to borrowing or renting of assets, taking away from already scarce household resources and reducing productivity. Ownership of basic durable goods is indicative of improved quality of life and also serves as a store of ‘wealth’ thatcan be sold or pawned to deal with 9 emergencies arising out of shocks or stressors to livelihood. Tables 4.2.1 and 4.2.2 provide a summary of the impacts on ownership of assets. Table 4.2.2 is based on cross-sectional differences for midline and endline since the information on asset ownership was not collected at baseline. In either case, we find significant positive impacts on a household ‘wealth’ index based on the first principal component for the ownership of the agricultural or non-agricultural assets. We also find significant impacts on asset purchases in the last twelve months as well as the monetary value of purchases. Details on the specific assets purchased and of the heterogeneous impacts are provided in main evaluation report by Handa et al, 2016.

Table 4.2.1 – Impacts on Ownership and Purchases of Agricultural Assets

Dependent Variable	Endline Impact (1)	Midline Impact (2)	Impact Diff (EL-ML) (3)=(1)-(2)	Baseline Treated Mean (4)	Endline Treated Mean (5)	Endline Control Mean (6)

.

4.3 Impacts on Access to Credit and Transfers

Access to credit and other transfers is another important dimension to household livelihood. Credits and transfers could be relied upon to smoothen consumption and other expenditure in times deficit. This could be during the lean agricultural season or illness of household members. Credits and transfers could also be necessary for occasional large expenses such as payment of school fees at the start of the school year, or investment in equipment for a non-farm business.Borrowing and purchases on credit could prove regressive especially if they come with high-interest payments and are used directly for consumption. By providing unconditional regular cash to the households, the SCTP is expected to ease the demand for credits, especially for consumption. At the same time, it is possible that being enrolled in the SCTP could extricate beneficiaries from networks of friends and relatives who would otherwise provide credit or other types of support. Additionally, beneficiaries may often be obligated by social norms to share their money with other friends and relatives through increased out-transfers. The net effect of all these dynamics can have profound effects on how the SCTP improves the livelihood of beneficiaries.

The survey instrument therefore elicited information on various aspects of credit and transfer activities and behaviour in all three waves. Questions were asked about outstanding debts that originated more than 12 months prior to each survey round, as well as loans and credit purchases in the 12 month period preceding each data collection. Our analysis shows a five pp impact reduction in the proportion of households with a debt on a loan that originated more than 12 months prior to the survey. We also find a nine pp impact reduction in purchases on credit and a further seven pp impact reduction on the proportion of credit purchases that have been fully repaid. We find no impacts on the taking a loan in the last 12 months or fully repaying the loan taken (Table 4.3.1). Putting it all together, a household was in debt if it had outstanding balances from more than 12 months ago, or had not fully repaid any loan or credit purchases (including any accruing interest) taken in the past 12 months. Overall, we find a 10 pp impact reduction on theproportion of households in debt, and a comparative decrease ofMWK 916 in the total debt in T households.

Notes: Estimations use difference-in-differences modelling among panel households. Binary outcomes are estimated using LPM. See Table 4.1.1 for additional explanatory notes on model specification, including a list of control variables utilized. * 10% significance ** 5% significance; *** 1% significance.

Further to the positive outlook on household debts, we investigate if this is caused by differential credit constraints. The results in Table 4.3.1 could be observed if T households were more likely to be refused loans or credits when in fact they needed it and actually applied for it. Additionally, if T households did not seek a loan or seek to purchase on credit because they were sure they would be refused, then we could still get the results in Table 4.3.1. There would be some concern if either of these reasons contributes significantly to the results in Table 4.3.1. There were question in the survey instrument to interrogate all these mechanisms, and our estimations show that T households were significantly less likely to have been refused a loan they applied for, or denied to buy on credit. We also find null effects on the baseline situation regarding access to sources of credit purchase and loans. Ouroverall indicator on credits is household credit constraint. A household is considered credit constrained if the household:

a. has a loan debt, but actually wanted more loan than it received at the same interest rate; or

b. would ask for a loan or purchase on credit if they were sure they could get it; or

c. has been refused a loan or denied a purchase on credit when they actually asked.

This does not control for whether they actually needed a loan or credit, but rather whether they had any barriers in case they needed it. We find no significant impact on this overall indicator (Table 4.3.2). In reconciling this with the result in Table 4.3.1, we can be quite sure that the positive outlook on credit among T households is not likely a result of differential credit constraints, but more likely a result of lack of need for credit. We also recognize that a credit is not necessarily a bad thing, especially if it can be put to productive use to generate multiplying effects. We accordingly examine impacts on the purpose for obtaining a loan or credit and find an eight pp impact decline in the share of household using credit for consumption. The impacts on use of credit or loan for health, education and productive investments are all null (Table 4.3.3).

Table 4.3.2 – Impacts on Credit Constraints

Notes: Estimations use difference-in-differences modelling among panel households. Binary outcomes are estimated using LPM. See Table 4.1.1 for additional explanatory notes on model specification, including a list of control variables utilized. * 10% significance ** 5% significance; *** 1% significance.

On transfers in and out of the household, we examine transfers of cash, food or labour. We find no impacts on any in- or out transfers, both at the intensive and extensive margins (Table 4.3.4). We also investigate the question of whether households could get any such support when they actually needed it, and also found no impacts (Table 4.3.5).It can thus be argued that the SCTP does not induce a č crowding outčof pre-existing sources of in-transfers or excess demand for out-transfers.

4.4 Impacts on Access to Social Safety Nets

Apart from individuals, the GoM and other non-governmental organizations also provide various social safety nets (SSN) to which poor households have access. It is also desirable that the SCTP will not have any čcrowding-outčeffect on the access to these social safety nets. To derive the most benefit from the SCTP, it is essential that the cash transfers act as a complement to these networks and social safety nets, not as a substitute. Table 4.4.1 shows the impacts of the SCTP on access to social safety nets. Overall, we do not find any impacts on benefiting from at least one SSN or on the number of SSNs households benefit from. We also do not find an impact on the value of the SSN benefits received, nor on benefits from the voucher for fertilizer program (FISP) – aflagship government program to boost

huge impact on the extensive margin (Table 4.4.2).

4.5 Impacts on Labour Use

The extent to which a household has available labour is likely to play a mediating role on how the SCTP impacts household economic activities and productivity. If labour is available and under-utilized due to liquidity or knowledge constraints, an increase in work participation would be expected for less labour-constrained households. This would increase household productivity and create a multiplying effect beyond the size of the SCTP amount. Conversely, households with tighter labour constraints may be less responsive in their work participation if members are not fit to work, and the SCTP cash would go directly into consumption. The more desirable outcome is that households are able to re-allocate labour from less productive activities to more productive ones, and to be able to move away from hazardous labour, particularly for children. Appropriatemodules in the surveys allow for analysis of these effects.

Notes: : Estimations use difference-in-differences modelling among panel households. Binary outcomes are estimated using LPM. See Table 4.1.1 for additional explanatory notes on model specification, including a list of control variables utilized. * 10% significance ** 5% significance; *** 1% significance

We first analyze the household labour constraint situation at baseline. A household is defined as severely labour constrained if it has no member fit to work (FTW). A person is considered fit to work if person is aged between 19 and 64 years, and has no chronic illness or disability, or is otherwise unable to work. If a household has at least one member FTW and the ratio of not fit to work (NFTW) members to FTW member is greater than or equal to 3, then the household is considered moderately labour constrained. A household is labour unconstrained only if the ratio of NFTW to FTW members is less three. The labour constraint classification is purely a function of the household's own demography, and it is important to add that this classification does not take into consideration the ability of the household to engage hired labour or rely on exchange labour. Additionally, there are less labour intensive income generating activities which household members with chronic conditions or disability, or who are older than 64 years of age could engage in. Accordingly, analysis of actual labor supply extends beyond labour supplied by those who are FTW. Table 4.5.1 shows the distribution of households and household members living in each of these household types at baseline. About 29 per cent of households were moderately labour constrained, but these accounted for 39 per cent of individuals. Severely labour constrained households made up 54 per cent of household count and contained 42 per cent of individuals. Overall, there is balance between treatment and control, and this is discussed in greater detail in the main report. Figure 4.5.1 shows the proportion of the sample FTW by age. As expected, the share of FTW decreases with age, and the distribution is essentially identical for T and C.

Next, we examine the impact of the SCTP on household labour constraint. There are a number of pathways through which the SCTP could influence how household labour constrain status would evolve. If SCTP households are able to ǎttract' new household members FTW, then this would improve the labour constrain status of the household. For example if a 65 year old single member is now able to attract a caregiver to live with because of the improved financial situation, then the labour constrain status changes immediately from severely constrained to unconstrained. Similarly SCTP households may be more able to avert the departure of household members when they are faced with a shock. The result of such effect on household welfare is ambiguous since there could be both negative and positive effects and the outcome depends on which of the effects dominates.

Table 4.5.1 – Baseline Labour Constraint Status at Household and Individual Levels

	Household			Individuals		
Status	C	T	Total	C	T	Total
Unconstrained	18.29	16.15	17.28	19.93	17.83	18.94
Moderately Constrained	29.52	28.49	29.03	39.34	39.00	39.18
Severely Constrained	52.19	55.36	53.70	40.74	43.17	41.88
Total	100.00	100.00	100.00	100.00	100.00	100.00

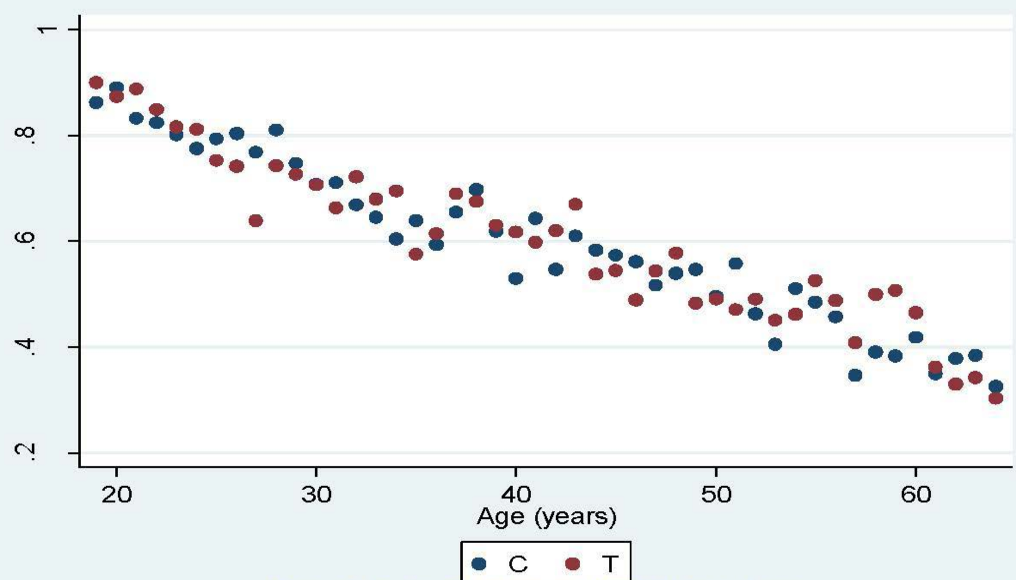

Fig. 4.5.1: Share of FTW by Age

Analysis shows that there were no impacts on the number of household members FTW, number of males FTW, share of households severely labour constrained and share of households labour constrained (moderately or severely). Impacts on the number of female members FTW and share of households moderately labour constrained were only marginally significant at the 10 per cent level (Table 4.5.2). Thus, it can be argued that changing labour constraint is not a plausible mechanism through which the SCTP could impact other outcomes.

Table 4.5.2 – Impacts on Labour Supply

We further examine the impacts on labour use for household chores and economic activities at the household level. Chores include time spent collecting water, time spent collecting firewood and time spent taking care of children, cooking or cleaning. We find no impacts on time spent on all household chores, own farm activities, fishing and then livestock activities. However, the number of hours in the last seven days spent on casual part time work reduces from 11 to 6 hours among T households with a significant impact of a four hour reduction. We also find a significant impact of three months decrease on the amount of time spent doing casual labour for others (ganyu work) in the last 12 months.We also find an impact of more than one hour increase in the amount of time spent on work outside of the household (excluding ganyu). Finding no impacts on the time spent on livestock production activities is quite surprising in view of the huge impacts on livestock production at both the extensive and intensive margins. This could be an indication of increasing returns to scale, particularly for households which raised livestock at baseline, or through the use of hired labour. To further explore the dynamics of labour use, we examine labour use for each of the main activities to try and see if there are any shifts that still keep the overall time use unchanged despite the significant increases in crop production. We also examine the possible role for the use of hired labour in this dynamic. Table 4.5.4 shows the impacts on household and hired labour use for the various farm activities: land preparation and planting, farm management (weeding, fertilizing, etc) and harvest. Here we find no impacts on household re-allocation of labour among the activities, but we find significant impacts on the use of hired labour at both the intensive and extensive margins. There is a three pp impact increase in the proportion of households using hired labour. We also find that hired labour is mostly utilized for land preparation and planting.

This is reasonable in view of the fact that land preparation and planting is mostly time bound and requires a lot of upfront input to set the stage for the rest of the season.

Finally, we examine labour allocation across the various activities by broad age-sex groups, namely males FTW, Females FTW, All Men (aged 18-64 years), Elderly (men and women aged 64 years or older) and children (males or females aged 6-17 years). Overall, the pattern of labour allocation is very similar

to the pattern in Table 4.5.3. There are no impacts on labour allocation for all household chores, farm activities, fishing and NFE activities. There is an impact on labour allocation to livestock activities by FTW males, but this is significant only at the 10 per cent level. We also do not find impacts on female withdrawal from casual part time activities, or intensification in work outside the household (excluding ganyu). There is a significant negative impact (positive outcome) in children participation in ganyu work.

4.6 Impacts on Shocks and Coping

Perhaps more directly related to the issue of resilience is the actual experience of shocks and how the households cope when they experience such shocks. Respondents were asked whether they were negatively affected by a series of shocks and their response to try and maintain their standard of livelihood. These shocks are categorized as covariate shocks (which typically affect the entire community – such as droughts, floods/landslides) and idiosyncraticshocks, which are more household specific (such as death of the main income earner in the household, sickness, theft of money, etc.). Coping to these shocks could usually include a mix of strategies some of which are negative (reducing consumption or sending children out to work), positive (relying on own savings/SCTP payment, receiving unconditional help from social networks), or ambiguous depending on the extent of the response (e.g. labour intensification could be positive or negative depending on the initial level and thresholds). In Table 4.6.1, we summarize the impacts of the SCTP on the experience of the aggregate shocks and the use of positive and negative coping strategies. We find no impacts of the SCTP on the experience of any negative shock, and on either covariate or idiosyncratic shocks. This is largely expected since the SCTP cannot per se avert the occurrence of many of the shocks listed. However, consistent with expectation, we find a significant 26 pp impact on the share of positive coping strategies and a significant negative impact of 23 pp on the share of negative coping strategies adopted. These two categories are not necessarily substitutes since households typically employ a mix of strategies. At the endline, we also enquired about whether households had experienced any positive shocks such as an inheritance, better

Notes: Estimations use difference-in-differences modelling among panel households. Binary outcomes are estimated using LPM. See Table 4.1.1 for additional explanatory notes on model specification, including a list of control variables utilized. * 10% significance ** 5% significance; *** 1% significance pay/job or death of a chronically ill household member (on whom the household had to make a lot of expenses). We find no cross-sectional difference in the experience of positive shocks between T and C households as well.

Table 4.6.2 gives the impacts on the specific shocks. We find no impacts on the proportion of households that experienced any of the specific shocks in the 12 month period preceding the surveys. Perhaps the one shock the SCTP could have affected is the death of a household income earner through improved health seeking behaviour, but the incidence of this is quite low and also likely to suffer from ceiling effects. The impacts on the specific coping strategies are given in Table 4.6.3. We find a significant

Table 4.6.3 – Impacts on Coping Strategies

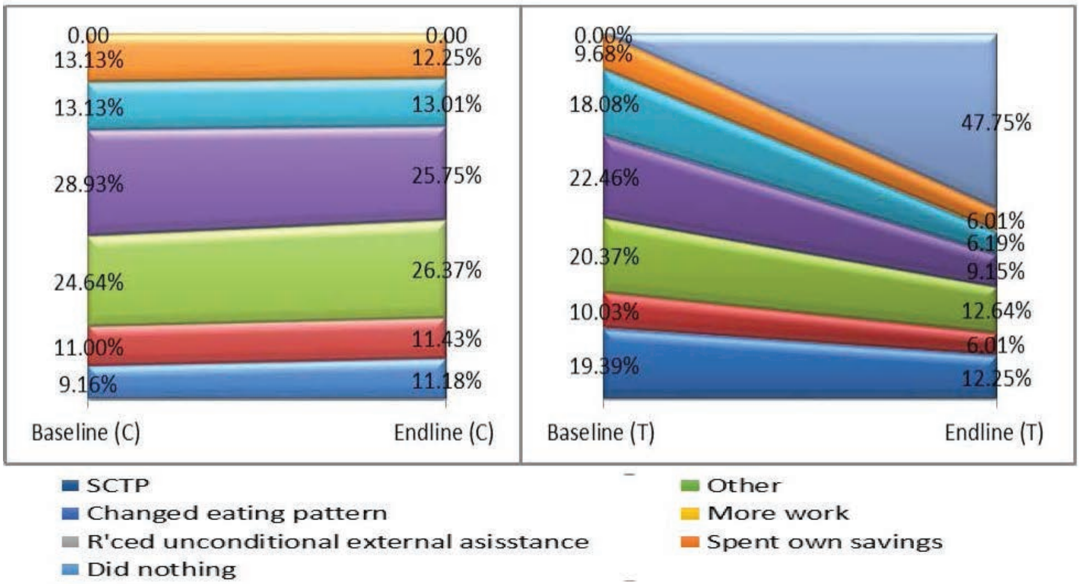
Figure 4.6.1 - Strategies for coping with negative shocks(aggregate shares)



negative impact of 20 pp on the proportion of households that had to cope by changing eating pattern (relying on less preferred food options, reducing food proportions or number of meals per day). We also find a five pp impact reduction on the use of borrowing as a coping strategy to shocks. The mix of coping strategies, including the role of SCTP is depicted in Fig. 4.6.1.

4.7 Impacts on Consumption and Food Security

The overarching objective of the SCTP is to mitigate the effects of poverty by ensuring food security and maintaining consumption. Adequate consumption and food security are not only essential for survival, but are also instrumental for wellbeing and particularly important for child growth and development. We estimate the impacts on consumption using total annual per capital consumption at the household level. Table 4.7.1 shows the impacts on household consumption expenditures. There is a MWK 10380 impact on overall per capita consumption and a MWK 7920 impact on food expenditures. Computations use the national poverty and ultra-poverty lines provided by the National Statistics Office (NSO). Details of the poverty lines and inflation factors to account for the timing of the surveys are found in the main impact evaluation report (Handa et al, 2016).

A breakdown of food consumption by the major food groups reveals a decrease in the share of expenditure on cereals and an increase in the share of the expenditure on meats and beverages. This shift may be an indication of a shift in preference, but also reflects a quality-for-quantity substitution that augurs well for household nutritional balance. A simple measure of dietary diversity – a count of the number of the broad categories a household meal typically comes from – shows significant increase

in dietary diversity (Table 4.7.2). We also find a significant positive impact on the food consumption score (FCS) – a composite score based on dietary diversity and the relative nutritional importance of different food groups. Finally, there is also a significant positive impact on the Simpson's Index of Dietary diversity – an index that takes into account not only the count of the food groups, but also the expenditure shares allocated to each group. The computations of the FCS and the Simpson's diversity index follows WFP and FAO methodology[6].

[6] See for example: Elliot Vhurumku: Food Security Indicators - Integrating Nutrition and Food Security Program-

Notes: Estimations use difference-in-differences modelling among panel households. Binary outcomes are estimated using LPM. See Table 4.1.1 for additional explanatory notes on model specification, including a list of control variables utilized. * 10% significance ** 5% significance; *** 1% significance

On food security, we were interested to know whether households were about having enough food, number of meals eaten per day, and whether household eat more than one meal per day. We find an impact of 20 pp reduction in the share of households worried about having enough to eat in the past 7 days, and a 14 pp impact on the share of households eating more than 1 meal per day (Table 4.7.3).

5. Household Resilience Capacity and Structure

This section of the report focuses on the estimation of household resilience capacity index and analysis of its structure and validity. The method for estimating the resilience index follows the FAO RIMA II model[7]. It must be stated that while the SCTP evaluation survey instruments were not explicitly designed with the RIMA II model in mind,we have enough variables that match all the RIMA II indicators and constructs quite closely. In addition, having actual data on shocks and coping strategies allows for some validity test which may be elusive for most studies. The panel data also allows for both contemporaneous and lagged analysis of the predictive power of the resilience capacity index for food security and responses to shocks.

5.1 The FAO RIMA II model, indicators and the SCTP instrument

The RIMA II model assumes resilience as a latent construct with multiple predictors and multiple outcomes. The predictors are grouped into four main categories called pillars. The pillars are namely access to basic services (ABS), ownership of assets (AST), social safety nets (SSN) and household

ming for Emergency response workshop, 25 to 17 February 2014.

[7] Resilience Index Measurement and Analysis – II. Food and Agricultural Organization of the United Nations. Rome 2016.

adaptive capacity (AC).Each pillar is a latent variable of itself determined by a number of household level indicators. The household is considered the unit of analysis because it is the unit of decision making for household production and consumption. The outcomes are per capita food consumption and the Simpson's Dietary Diversity Index. For the pillar of ABS, we do not have any direct measures to construct in index. However, since we are mostly concerned about resilience profiles for T and C households, it is reasonable to assume that, by design, C and T households are equally clustered in terms of this covariate dimension of resilience. For the other pillars, Table 5.1.1 shows the typical indicators that FAO considers for each pillar and the corresponding indicators that we have available from the SCTP instrument.

The outcome variables of per capita food expenditure and the Simpson's index are identical, so are the AST indicators of asset ownership (agricultural and non-agricultural) and livestock. For SSN, we have total in-kind transfers, credit constraint and perceived available support in times of need. Credit constraint and perceived available support captures a potential for support when shocks set in, and these are more relevant for measuring resilience. We recognize a potential downside to using the variable of in-kind assistance as a measure of resilience. Households that are better off by themselves may have little in-kind assistance, especially in ǒnormal' times, and so the indicator of whether support can be activated when needed is likely a more appropriate ex-ante measure. On AC, we have an indicator on number of income sources and the ratio of FTW to NFTW. Ideally, we would prefer to have the total income from each of these domains as a more direct measure of capacity and importance to household livelihood. We also have a binary variable of whether the household is crop production only household, or it does crop production with other income generating activities. Each measured variable is constructed to be positive that such more is better, and for binary variables, the better outcome is coded as 1.

Table 5.1.1 – RIMA Domain Indicators by FAO and SCTP Equivalents

Domain	FAO suggested indicators	SCTP Equivalents/Proxies
Outcome Indicators	Average per person daily income, Average per person daily expenditure, Food consumption score/other nutrition proxy, dietary diversity and food frequency score, dietary energy consumption	V1. Per capita food expenditure V2. Simpson's Diversity Index
AST	Agric assets, Non-Agric Assets, TLU, Land owned	V3. 'Wealth' index of agric assets, durable goods, housing& household characteristics V4. Per capita TLU owned V5. Per capita Total Land Cultivated
SSN	Amount of cash and in-kind assistance, Social Networks, Frequency of assistance, Formal/Informal Transfers	V6. Log of total in-kind transfers V7. Log of value of free maize V8. Credit Constraint, V9. Perceived available support in times of need
AC	Diversity of income sources, Educational level (household average), Employment ratio, Available coping strategies	V10. Number of income sources V11. Ratio of FTW to NFTW, V12. Not Crop production only household

5.2 Model Estimation and Summary Results

Empirically, the Resilience Capacity Index (RCI) is estimated using the Multiple Indicator and Multiple Outcome model (MIMIC) in a structural equation framework. The RIMA model is estimated using structural equation model based on the conceptual path diagram in Fig. 5.2.1. Each pillar is separately estimated using factor analysis of the variables that make up the dimension.The predicted value of each of the components is standardized to range from 0-100 and in-turn used to construct the RCI in the MIMIC model. In the MIMIC estimation, several approaches are used to estimate the weights as check for robustness and also try to eliminate any bias on the weights due to the treatment. Weights are generated using only the C households at baseline and endline, or only baseline data for T and C, or baseline for T and C and endline for C, and using all the data. The results are robust under all specifications and so we proceed with the model that uses all the data since this is recommended. Tables 5.2.1a, 5.2.1b and 5.2.1c give a summary of the MIMIC estimation. Table 5.2.1a gives the standardized coefficients of the pillars, the Z values and the significance. We find that each of the pillars is significant in the model at the one per cent level of significance. Table 5.2.1b gives the standardized coefficients to the reflective indicators. The coefficient of per capita consumption is standardized to one to make the coefficient of the Simpson's index interpretable. We find that a 1 unit increase in the RCI results in a 0.13 increase in the standard deviation of the Simpson's index.

The summary model fit statistics indicate that the chi-square value is significant at the 1 per cent level. The root mean square estimate of approximation is 0.0947 and the p-value indicates that there is greater than the

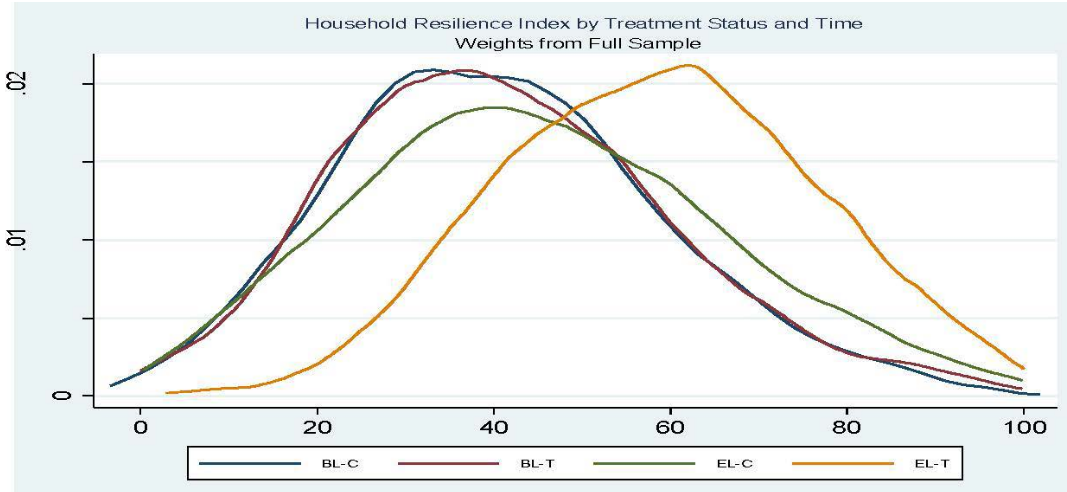
Figure 5.3 – RCI by treatment status and time



recommended threshold of 0.05. However, there is no universal agreement on these quality fit threshold. The CFI and the TLI are both appreciable high to indicate a good fit. Fig. 5.2.1 shows the diagrammatic representation of the model results. Fig. 5.2.2. gives a radar plot of the resilience structure matrix and correlation of pillars with RCI.

Table 5.2.2 gives a summary of the RCI scores for T and C groups at baseline and at endline, and this is depicted with the kernel density in Fig. 5.2.3. We find a clear increase in the distribution of the resilience scores for the T group at endline compared to the near identical resilience distribution of C and T at baseline. Table 5.2.3 gives the impact estimation results on resilience for the overall sample, baseline bottom 50 per cent of households, baseline small households, and baseline labour constrained households. We find that the impacts are significant for all groups.

5.3 Resilience Capacity and Coping with Shocks

To examine the predictive power of the resilience index, we further analyse the actual coping responses to shocks against the resilience index. The coping mechanism to shock was not an input to the determination of the resilience index and we would expect that more resilient households would tend to cope with positive responses as compared to less resilient households. Table 5.2.4 shows the distribution of the resilience and the share of positive coping responses to shocks at baseline and endline. The results show a high degree of agreement between the resilience scores and the share of positive responses to shocks that are adopted by households. At baseline, we find that the share of households adopting positive responses to shocks increases from 26 per cent for those in the lowest resiliency quintile to 59 percent for those in the highest resiliency quintile. This distribution is pretty much the same for C and T households. At endline, we find that the distribution of the share of households with positive coping responses to shocks stays essentially the same for C households as it was at baseline, but the share of households with positive coping responses to shocks is much higher

Table 5.2.4 – Share of Positive Coping Responses to Shocks by Resiliency Quintiles

Figure 5.4 – Lowess graph of positive coping and RCI

at all quintiles for the T group, increasing from 63 per cent for those in the lowest quintile to 77 per cent for those in the highest quintile. A lowess graph of the RCI and share of positive coping strategies to shocks is further depicted in Fig. 5.4 and clearly shows the concomitant agreement between the RCI and positive coping with shocks.

Table 5.2.5 – Baseline resilience and endline food security among C households

Baseline RCI quintiles among C households	Endline Food Security Indicators			
	Mean PC Food (MWK)	No food worry	Simpson's Index	Food Consumption Score
Lowest	19790.400	0.053	0.526	6.281
Second	25427.950	0.057	0.582	7.934
Middle	34004.360	0.071	0.595	8.873
Fourth	39047.250	0.140	0.620	9.342
Highest	54268.380	0.205	0.668	9.703

5.4 Baseline Resilience and Endline Food Security among C Households

Another examination of the validity of the RCI is its predictive power of food security, regardless of the treatment. This is done by examining the effect of baseline resilience and endline food security among C households. As shown in Table 5.2.5, we find that endline food security generally increases with increasing baseline RCI. This also shows that the RCI has reasonable validity for use in predicting future food security and as ranking tool for targeting of interventions.

6. Summary and Conclusions

This paper has examined the impacts of Malawi's SCTP program on the concept of resilience. We find that the SCTP has positively impacted household production, asset ownership, income diversification and strengthening as hypothesized. The SCTP has not led to a reduction in labour supply by beneficiary households has is often a concern for unconditional cash transfers. We also find that the SCTP has not produced any "crowding-out' effect on pre-existing social safety nets, both public and private. There is increased per capita food consumption, dietary diversity and food security. Using the FAO RIMA II model, we estimate the impact of these dynamics of household resilience and find that although the SCTP was not explicitly designed with increasing resilience in mind, nonetheless, the SCTP has positively impacted resilience. Thus, there is reason to believe that cash transfer, even one that is unconditional, can produce positive impacts on household resilience.

We examine the validity of the resilience index by analysing its correlation with positive coping to shocks and find that increasing resilience is associated with positive coping to shocks. Additionally, by analysing only the C sample, we find that baseline resilience is predictive of endline food consumption and food security. This implies that the RCI can be used as a profiling and ranking tool for interventions.

MEASURING AGRICULTURAL EMPLOYMENT, LABOR CONDITIONS, CHILD/FORCED LABOR, GREEN JOBS AND HUMAN CAPITAL MANAGEMENT

Session Organizer
M. Castillo | ILO | Geneva | Switzerland

ABSTRACT

Making progress towards sustainable development and poverty reduction will require a concerted effort to promote decent work in rural areas, particularly among developing countries. It will require analysis of targeted indicators on decent work in rural and urban areas that can be used to advance national development agendas. But what do we know about rural workers and their participation in the labour market or, more broadly, about decent work in rural areas as compared to urban areas? The internationally agreed decent work measurement framework and recently adopted standards by the International Conference of Labour Statisticians (ICLS) on measuring paid and unpaid forms of work are the starting point for the measurement and monitoring of decent work. However, currently there are different criteria applied by countries to define rural areas. The paper presents the case that the lack of a harmonized international statistical definition of rural and urban areas combined with a major data gap for even a basic set of decent work indicators in many countries limits the possibility of providing meaningful analysis on decent work in rural areas at the national, regional or global levels and presents recommendations on the way forward to address the challenges.

Green jobs and rural labour markets: gendered pathways for decent work

O. Muza[1] | Consultant | Harare | Zimbabwe

DOI: 10.1481/icasVII.2016.a05

ABSTRACT

Climate change will lead to structural changes resulting from adaptation and mitigation directly, and also in the process of change from old to new jobs. Not much is known about the transition prospects of rural men and women. The ability of rural workers to cope is a key emerging transition issue which requires immediate attention in the green transition discourse, policy and practice. Using secondary information, the study maps key livelihood and labour market challenges related to climate change impacts in key sectors found in rural areas, including agriculture, forestry, fisheries, artisanal mining and tourism. The general equilibrium dashboard methodology/OECD indicators and key international instruments (ILO Solutions for Climate Action, Decent Work Measurement Framework and Canadian Labour Congress (CLC) Just Transition reveal decent work deficits in fundamental rights, employment creation, social protection and social dialogue. The study recommends gendered integrated rural labour market pathways that address greening uncertainties and promote decent work.

Keywords: Climate Change, Decent Work, Gender, General Equilibrium Dashboard Model, Green Jobs, International Standards, Labour Market, Resource Economics Rural

PAPER

1. Introduction

The primary source of income for most people in the world is returns to their labour, thus creating jobs and decent wages is essential to reductions in poverty and hunger (Norton, 2009). Important progress has been made in reducing the share of extreme working poor (those falling below US$1.90-a-day threshold, 2011 PPP) in total employment over recent decades, particularly under the Millennium Development Goals (MDGs) from 33.2 per cent to 20.0 per cent, globally, over the period from 2000 to 2015. Despite continued improvements in reducing the shares of working poverty, efforts to reduce the absolute numbers of working poor at both thresholds have stalled. In 2015, an estimated 327 million employed people were living in extreme poverty at 967 million on moderate and near poverty. The absolute number has been falling by an annual average of 4.9% (extreme poor) and whereas it increased by 0.7% (moderately and near poor) over the period 2000 to 2015. Climate change will lead to structural changes resulting from adaptation and mitigation directly, and also in the process of change from old to new jobs (Olsen, 2009). Rurality, the traditional focus of food production enters the sustainable development policy debate in three policy contexts: firstly, the international farm crisis or its global environmental and trade repercussions, secondly, domestic policies attempting to redefine rurality beyond the confines of traditional agriculture policy and third and finally, policies for sustaining rural livelihoods that focus on promoting the viability of rural communities' infrastructure, education, health, social services and intergovernmental coordination (Wimberly, 1993). Green growth is one sector that is gaining support as a way to pursue economic growth and development, while preventing environmental degradation, biodiversity loss and unsustainable natural resource use (OECD, 2010).

The concept of green jobs has evolved overtime and now recognises social equity as a key element. Bowen (2012) defines green jobs as occupations and skills with an identifiable environmental focus, but most focus is on employment in industries (or specific projects) the products of which are deemed to be of environmental benefit. Work in agricultural, manufacturing, research and development (R&D), administrative and service activities that contribute substantially to preserving and restoring environmental quality are green jobs (UNEP, 2011). Furthermore, jobs are green when they help reduce negative environmental impact ultimately leading to environmentally, economically and social sustainable enterprises and economies (ILO, 2013). More precisely, green jobs are decent jobs that reduce consumption of energy and raw materials, limit greenhouse gas emissions, minimise waste and pollution and protect and restore ecosystems (ILO, 2013). The decent work dimension of jobs in the environmental sector may be measured according to relevant indicators for instance, The Decent Work Indicators framework adopted at the International Conference of

Labour Statisticians (ICLS) in December 2008. It covers ten substantive elements[2] corresponding to the four strategic pillars of the Decent Work Agenda (DWA): full and productive employment, fundamental rights at work, social protection and the promotion of social dialogue.

Rural workers in developing countries may be engaged in paid and/or unpaid forms of work, and their survival strategies often involve engaging in different forms of work to cope with the seasonal nature and different opportunities available as work for pay or profit. The heterogeneity of rural labour arrangements may include payment in kind (food or other goods), may involve conditional access to a piece of land, or may depend on other specified relationship between employers and workers that are determined by local customs or institutions. However, not much is known about the transition prospects of rural men and women. Literature evidence points out that the potential adverse impact of green growth policies on labour productivity and the costs of employment tend to be overlooked especially with regards to how labour markets work in different types of economies (Bowen, 2012). According to the ILO (2008) relatively little and superficial attention has been paid to the social dimension of sustainable development, in particular to the implications for employment and for decent work.

Activities in rural and informal sectors including agriculture, fisheries, forestry, tourism and artisanal mining are considered as environmental if environmentally sustainable technologies and practices are used (ICLS, 2008). However, labour market changes effected to jobs as the economy is oriented toward greater sustainability should also be assessed and measured for their decency. Firstly, what additional jobs are created, which employment is substituted, which jobs are eliminated without direct replacement and how are workers transformed and redefined as day-to-day skill sets, work methods and profiles are greened? Secondly, how are different gender groups in rural areas affected in particular women, who constitute a greater proportion of rural workers? Gender inequality in rural employment often exhibit different patterns according to social, cultural, religious and economic factors (FAO/ILO, 2010)[3]. Third and finally, is the transition process 'Just' in fulfilling the foundations of a greener and socially just economy considering issues of participation, job creation and maintenance, greening in training, education and skills, trade union rights and social protection.

Using climate change and green growth transition evidence this paper traces developments in key rural sectors including: agriculture, forestry, fisheries, tourism and artisanal mining to determine the relationship between rural labour markets and pathways to promote green growth, functionality and the implications for decent work. The rest of this paper is structured as follows: the next section presents the methodology followed by climate change impacts on key rural sectors. The pathways for green growth and transition evidence are presented next while the last section recommends key measures developed to deal with those impacts and how this will be further linked to local and international standards.

2. Methodology

Several methodological approaches are used; firstly, secondary data is used to understand the perceived effects of climate change on economic activity and employment in general secondly, using the general equilibrium dashboard methodology and the OECD's industry methodology; greening challenges in rural labour markets are outlined. Third and finally, ILO Solutions for Climate Change Action, Decent Work Measurement Framework and the Canadian Labour Congress (CLC) Just Transition methodologies are employed to argue the case for driving solutions for climate change and decent work. General equilibrium dashboard is a state in which all green jobs meet all criteria [organisational level: sector, product/service, production method, green awareness, position in the value chain and job level: occupational profile, required skills and abilities, job decency and green workload]. OECD's environmental industry definition and criteria, divides the environmental industry into 3 groups: pollution management [environmental equipment], green technology and product management group [technologies and processes for clean and efficient use of resources] and resource management group [businesses in the field of energy conservation, management and recycling]. The ILO solutions for climate action pathway guiding the development of this study posits that increased understanding of the climate change impacts on labour markets, lead to coherent climate change and decent work strategic and best practices for shared knowledge observing tripartisan and social dialogue for effective climate transition.

[2] The ten areas are: Employment opportunities (EMPL), adequate earnings and productive work (EARN), decent working time (TIME), Combining work, family and personal life (COMB), Work that should be abolished (ABOL), Stability and Security of Work (STAB), Equal opportunity and treatment in employment (EQUA), Safe Work Environment (SAFE), Social Security (SECU), social dialogue, workers and employers representation (DIAL), economic and social context for decent work (CONT). This framework has evolved since then and now includes one more area on the economic and social context (ILO, 2014).

[3] Some of them such as- the burden of unpaid work at home, lack of education and bargaining power, and limited access to assets- clearly constitute significant economic disadvantages for women compared to men, women tend to be risk averse than men when engaging in rural employment and women's heavy burden of unpaid work is one of the most important factors constraining their access to unpaid work in rural settings and gender patterns of rural employment change over time and differ across countries in response to new trends, shocks and opportunities but some deep set gender inequalities remain. Changes in international trade, migration, financial crises and diversification of the rural economy are a few of the many phenomena that play an important role in changing men and women's rural employment opportunities and roles.

3. Climate change and sectoral labour market challenges

Climate change affects work in key sectors found in rural areas including agriculture, fisheries, forestry, tourism and artisanal mining. Direct and indirect impacts effect demand in the way work is done. The ability of rural workers to cope is a key emerging transition issue which requires immediate attention in the green transition discourse, policy and practice. As shall be shown in the next sections, gender influences different rural groupings transitioning prospects and possibilities.

3.1 Gender, climate change and labour market challenges

The green economy can be an opportunity for women to make strides towards gender equality in the workplace through better paid, non-traditional jobs. A combination of innovative strategies is needed so that women as well as men can benefit from the green economy (Stevens, 2009). This involves a paradigm shift to link the environmental and social consciousness of women with the range of jobs, including manual labour and technical positions, expected to be generated from the shift to a green economy[4].

Globally, women are more likely to be affected by environmental degradation and climate change (ILO, 2012). In the developing world, climate change can intensify the pre-existing inequalities between men and women (Chagutah, 2010; Madzvamuse, 2010). Women predominate among the poorest and are disproportionately concentrated in agriculture and tourism, sectors which depend on natural resources and are often characterised by poor pay and other decent work challenges (ILO, 2012). The consequences are growing risks to rural livelihoods, declining productivity, poverty and insecurity, conflict over access to resources and rural-urban migration; factors which have underlying socio-economic risk factors leading to the vulnerability of women (see Table 1).

Table 1: Climate change, gender and vulnerability in rural labour markets

Climate impact	Underlying socio-economic risk factors	Vulnerability of women
Crop failure	A greater proportion of rural women are small holder farmers (for instance, 70% in Zimbabwe)	Strain on food provision Increased workload
Shortage of safe, clean drinking water	Gendered division of household labour	Additional time required to travel greater distances to collect water from alternative sources, which may not be clean/safe Exposed to violence/sexual abuse when travelling to and from water sources
Disease	Gender division of reproductive labour/ care given Cultural restraints on mobility	Additional time required to care for young, sick and elderly Women of all ages lack health care access
Migration	Males may contribute little to household income (e.g. remittances) Women who become de facto household heads may face difficulties in retaining control over land and other productive assets due to unequal property and land rights	Increased domestic/agricultural load Decreased coping capacity and insecurity of tenure
Disaster	Women and children often lack skills, knowledge and resources	Women and children are likely to die than men during disaster events
Displacement	Particular problems in temporary housing/relocation sites	Women and girls face higher rates of sexual abuse and violence
Resource Scarcity	70% of the world's poor are women Women have lower levels of educational attainment Women are over represented in the informal sector Women earn lower wages and have limited access to markets	Limited time and resources to invest in more resilient land and shelter Limited resources to invest in alternative livelihoods

Source: Chagutah (2010)

From a global perspective, primary sectors, including agriculture and forestry, are expected to be major beneficiaries of the transition to a low carbon economy. However, women comprise less than 20% of the global formal workforce in primary sectors and around 2% in developed countries (Stevens, 2009). The estimated share of female employees'/women in green jobs in relation to all employees in farming/fisheries/forestry is 20%, while 8% are in natural resources (including mining and quarrying). Women in green jobs are concentrated in administrative services at 68% (see Table 2).

[4] Ibid.

Table 2: Women in green job sectors

Sector	Components	Estimated share of female employees (2009)
Primary	Farming/fisheries/forestry	20%
	Natural Resource	8%
Secondary	Manufacturing	24%
	Construction	9%
Tertiary	Engineering Services	12%
	Financial and Business Services	15%
	Eco-tourism	20%
	Eco-tourism	20%

3.2 Agriculture, climate change and labour market challenges

Climate change has materialised as the leading global environmental concern of which agriculture is one of the zones most critically distressed by climate alteration (Joshia and Chartuverdi, 2013). As global temperature rises and climate conditions become more erratic posing threat to vegetation, biodiversity, biological progression they have enduring effect on food security as well as human health[6]. Doubling of the atmospheric carbon dioxide concentration will lead to only a small decrease in global crop production but developing countries are likely to bear the brunt of the problem and similarities of the effect of adaptive measures by farmers imply that these will do little to reduce the disparity between developed and developing countries[7].

A robust model of yield response to climate change for several African crops illustrates that by mid-century, the mean estimates of aggregate production changes in Sub Saharan Africa under the preferred model specification are -22%, -17%, -17%, -18% and -8% for maize, sorghum, millet, groundnut and cassava respectively (Rosenzweig and Parry, 1994). In all cases except cassava, there is a 95% probability that damages exceed 7% and a 5% probability that they exceed 27%[8]. Moreover, countries with highest average yields have the largest projected yield losses, suggesting that well-fertilized modern seed varieties are susceptible to heat related losses.

Some of the most important impacts of global climate change will be felt among the populations, predominantly in developing countries referred to as 'subsistence' or 'smallholder' (Morton, 2007). Their vulnerability to climate change comes from being predominantly located in the tropics and from various socioeconomic, demographic and policy trends limiting their capacity to adapt to climate change[9]. Morton (2007) suggests small farm sizes, low technology, low capitalisation and diverse nonclimatic stressors as increasing vulnerability but resilience factors- family labour, existing patterns of diversification away from agriculture and possession of a store of indigenous knowledge should not be underestimated[10].

Thompson and Cohen (2012) add that many of the poorest and most vulnerable people are women living in rural areas in developing countries who are wholly depended on subsistence agriculture to feed their families. Rural women, female smallholders in particular, may be disadvantaged in terms of access to key productive assets for farming and services such as land, water, rural infrastructure, technology and information, credit and extension services (World Bank, FAO and IFAD, 2008, Brody et al. 2008). These women therefore tend to have limited adaptive capacities, and are highly dependent on climate sensitive resources such as local water and food supplies (IPCC, 2007). Climate change is expected to exacerbate these gender inequalities with women being disproportionately affected by depletion of natural resources and reduced agriculture productivity (Parikh and Denton, 2002).

One effect of climate change relevant to rural employment is related to the risk of declining farm yields of which the gender-differentiated impact will depend on multiple factors, including which crops women produce, as well as their ability to adapt and respond (Cabrera de González et al., 2009). Three critical impacts on women are firstly; female farmers' ability to develop effective coping strategies might be limited compared to male farmers because of their more restricted access to productive resources

[5] Statistics provided in this table are based on ILO estimates 2007 (SustainLabour, 2009) and as such are consistent with the ICLS definition of decent jobs adopted in this paper.
[6] Ibid.
[7] Ibid.
[8] Ibid.
[9] Ibid.
[10] Ibid.

such as technology, knowledge and inputs. Secondly, climate change might worsen the conditions of the wage agricultural labourers, if in response to it; large producers expand informal employment and increase the use of pesticides. Third and finally, climate change might also increase women's unpaid workload, further reducing their opportunities for paid employment, in areas affected by desertification where time required for water collection might increase.

In general, both mitigation and adaptation policies are likely to have gender differentiated effects on employment that need to be better understood, i.e. environmental labelling, if discouraging the purchase of fruits and vegetables from developing countries, may have negative employment effects on female-intensive non-traditional export industries[11]. Climate policies can contribute to rising demand for educated and qualified workers through promoting environmentally sound technologies. However, because of women's lower levels of education in many countries, women are less likely to benefit from such demand unless the relevant training is made available to them[12].

3.2 Forestry, climate change and labour market challenges

In general, women are the primary users of environmental resources for subsistence and income generating products, yet in many cases have no say in how the resources are accessed, controlled or shared (Makonese and Tsanga, 2008). Forests can play an important role in complementing agricultural production to address ambitious global goals and reducing hunger and achieving food security and improved nutrition (Vira et al., 2015). Additionally, forests and trees can be managed to produce better and more nutritionally-balanced diets, offer greater control over food inputs and deliver ecosystem services for crop production[13]. Some 410 million indigenous people and communities depend on forests for their livelihood (ILO, 2012). Globally, 70% of forest products are sourced from 7% of the world forest, of which the latter are predominantly planted or have a planted component (Dale et al. 2009). Additionally, climate change can affect forests by altering the frequency, intensity, duration and timing of fire, drought, and introduced species, insect and pathogen outbreaks, and hurricanes.

Deforestation and land uses including degradation from mining, oil and gas concessions are reported to account 11% of annual global greenhouse gas emissions (Stevens et al., 2014). Legal protection for woodlot communities is therefore not just a land or resource rights problem, but also a climate change problem (Muza, 2016). In the context of high level of forest dependence, challenges of State and NGO-led re-greening practices are inadequate involvement of communities, poorly defined rehabilitation objectives, lack of management plans, unclear responsibilities and benefit sharing arrangements and poor structural activities (Lemenih and Kassa, 2014).

Lessons include a more active role for non-state actors in greening initiatives, more attention to market signals, devolution of management responsibility and clear definition of responsibilities, benefit-sharing arrangements, and better tenure security. It seems that market signals have led to the destruction of rainforests which have been supplanted in places like the Amazon in Brazil by cattle farming and crop production. It seems that government protection and support by civil society (researchers, NGOs) is needed to ensure sustainable forest management.

3.3 Fisheries, climate change and labour market challenges

Fisheries and aquaculture are important sources for food and livelihoods for people along the world's seashores and waterways (Smith et al., 2010), and influence the livelihoods of one billion people. Almost 45 million people worldwide are directly engaged, full time or part time, in the fishery primary sector and an additional estimated 135 million people employed in the secondary sector, including post-harvest activities (Mathiesen, 2012). Information provided to FAO from 86 countries indicates that, in 2008, 5.4 million women worked as fishers and fish farmers in the primary sector and represented 12 percent of the total[14]. In two major producing countries, China and India, women represented 21 percent and 24 percent, respectively, of all fishers and fish farmers[15]. Women make up at least 50 percent of the workforce in inland fisheries, while as much as 60 percent of seafood is marketed by women in Asia and West Africa[16]. Moreover, although comprehensive data are not available on a sex-disaggregated basis, case studies suggest that women may comprise up to 30 percent of all those employed in fisheries, including primary and secondary activities[17]. Aquaculture has been the fastest growing food production sector for the past 4 years, and supplies more than half of the world's food fish (UNEP, 2012). Excluding aquatic plants, aquaculture production reached 52.5 million tonnes representing a value of US 98.5 million in 2008[18]. It has been estimated that 52 million are employed in marine small-holder capture fisheries (and another 56 million in small-scale inland fisheries). Many involved in these sectors are recognizing that it is vital to look beyond the simplified picture of men as fishers and women as

[11] Ibid.
[12] Ibid.
[13] Ibid.
[14] Ibid.
[15] Ibid.
[16] Ibid.
[17] Ibid.
[18] Ibid.

processors and to examine the more complex picture of multifaceted relationships between men and women as boat owners, processors, sellers, family members, community members and co-workers (Mathiesen, 2012). Gender issues in the fisheries and aquaculture sector have seldom been examined, and the important role women that play has often been overlooked and, thus, not taken into account in decision-making processes and outcomes, thereby hindering development for instance:[19]

1. Men and women engage in distinct and often complementary activities that are strongly influenced by the social, cultural and economic contexts in which they live.
2. Male–female relations in the fisheries sector vary greatly and are based on economic status, power relations and access to resources.
3. In most regions, women have rarely participated in commercial offshore and long-distance capture fishing. Ocean-going boats for offshore deep-sea fishing have male crews – not only because of the vigorous work involved, but also because of women's domestic responsibilities and/or social norms.
4. More commonly, in coastal artisanal fishing communities, women manage the smaller boats and canoes that go out fishing. Women are also involved in gathering shells, sea cucumbers and aquatic plants in the intertidal zone. They also contribute as entrepreneurs and provide labour before, during and after the catch in both artisanal and commercial fisheries. In addition, they are often responsible for skilled and time-consuming onshore tasks, such as net making and mending, processing and marketing catches, and providing auxiliary services to the boats.

Climate change will affect fisheries availability, stability, access and utilization (Labour S., 2013). Availability will be impacted as aquatic foods will vary through changes in habitats, stocks and species distribution. Stability of supply will be impacted by changes in seasonality, increased variance in ecosystem productivity and increased supply variability and risks. Access to aquatic foods will be affected by changes in livelihoods and catching or farming opportunities and utilization of aquatic products will also be impacted and, for example, some societies and communities will need to adjust to species not traditionally consumed. Aquatic foods have high nutritional quality contributing 20% or more of average per capita animal protein intake for many poorer countries. Climate change will affect food quality as food resources come under greater pressure and the availability and access to fish supplies will become an increasingly critical development issue. Climate change is a compounding threat to the sustainability of capture fisheries and aquaculture development (Cochrane et al., 2012), see also Table 3.

Table 3: Climate change effect on fisheries livelihoods and labour market challenges

Climate change effect	Livelihoods/Labour Market Issues
Less predictable rain/dry seasons-decreased ability to plan livelihoods activities-e.g. farming and fishing seasons	Increasing vulnerability of riparian and floodplain households and communities Livelihood strategies will have to be modified, for example, with changes in fishers migration patterns due to changes in the timing of fishing
More droughts or floods- damage to productive assets (fish ponds, weirs, rice fields etc and homes)	Increasing vulnerability of riparian and floodplain households and communities
Changing levels of precipitation where rainfall decreases reduced opportunities for farming, fishing and aquaculture as part of rural livelihoods systems	Reduced diversity of rural livelihoods, greater risks in agriculture greater reliance on non-farm income. There are particular gender dimensions, including competition for resource access, risk from extreme events and occupational change in areas such as markets, distribution and processing, in which women currently play a significant role Displacement of populations into coastal areas leading to influx of new fishers
Water stress and competition of water resources	Affect aquaculture operations and inland fisheries production, and are likely to increase conflicts among water-dependent activities
Extreme events	Impact on infrastructure, ranging from landing and farming sites to post harvest facilities and transport routes. They will also affect settlements, with communities living in low-lying areas at particular risk
Changes in distribution species	Composition and habitats will require changes in fishing practices and aquaculture operations, as well as in the location of landing, farming and processing facilities

Source: Chagutah (2010)

3.4. Tourism, climate change and labour market challenges

Travel and tourism's impact on the economic and social impact of a country can be enormous: opening it up for business, trade and capital investment, creating jobs and entrepreneurialism for the workforce and protecting heritage and cultural values (Mowforth and Munt, 2015). Travel and tourism generated

[19] Ibid.

US$7.6 trillion (10% of global GDP) and 277 million jobs (1 in 11 jobs) for the global economy in 2014[20].

Tourism is a climate-dependent industry and so many destinations owe their popularity to their pleasant climates during traditional holiday seasons (Amelung et al., 2007). The Tourism Climatic Index (TCI) reveals that the locations of climatically ideal tourism conditions are likely to shift poleward under projected climate change[21]. Tourism is currently considered among the economic sectors least prepared for the risks and opportunities posed by climate change and is only now developing the capacity to advance knowledge necessary to inform business, communities and government about the issues and potential ways forward (Scott, 2011). At a global scale, climate change will ultimately lead to welfare loss, unevenly spread across regions (Bigano, 2004). Tourism is increasing contribution to climate change, especially through the use of air travel (Becken, 2007).

According to the UNWTO, women make up the majority of the tourism workforce, but they tend to be in the lowest paid, sometimes even un-paid, and lowest status jobs. Strong associations persist in the popular imagination between tourism and prostitution (Ferguson, 2009). Indeed for many, this is the extent of gender issues in tourism[22]. Certainly, the sexual exploitation of women and children is a serious issue that needs to be addressed and the emerging phenomenon of sex tourism in developing countries has been extensively researched by feminists (Pettman, 1997; Jeffreys, 1999). Sexual exploitation of children in tourism occurs in multiple tourism destinations and even in places which do not have any real tourism infrastructure (ECPAT, 2008)[23]. Many African countries have encouraged tourism to attract foreign investment and to fund infrastructure development[24]. While this, coupled with a renewed focus on Africa from tourist-sending countries has sparked tourism growth on the African continent, this growth has predictably, been accompanied by an increase in child sex tourism (CST). Victims of CST are often caught in poverty, from minority groups, dependent on seasonal economies, working children, children living on the street and children abused or neglected in the home and AIDS orphans.

Scholars within tourism studies have long argued that tourism is a highly gendered industry (Kinniard et al.,1994; Kinniard and Hall, 1994). Research has identified a clear segmentation of men's and women's work in tourism. The majority of women's work is concentrated in seasonal, part time, low paid activities such as retail, hospitality and cleaning (Sinclair 1997; Chant 1977). Global gender inequalities are embedded within the promotion and marketing as tourism destinations (Ferguson, 2009). There are 2 distinct ways in which gendered assumptions operate in tourism development policy; implicitly (gender blind) and gender aware[25]. Gender blind involve how macro-level tourism development policy relies on gender inequalities embedded in processes of restructuring of the global economy. Gender aware aspects of tourism development policy; focus on policies which openly seek to affect change in gender equality or promoting women's empowerment.

3.5. Artisanal mining, climate change and labour market challenges

Mining is an important economic activity in many developed and developing countries. The formal mining sector employs more than 3.7 million workers. In addition, more than 20 million people work in artisanal and small-scale mining (ASM) (Hentschel, 2002). In 2010, 1.5 million people were employed in the mining sector in developed nations, and 2.2 million in developing/emerging nations (Hruschka and Echavarria, 2011). The number of people working in mining jobs dropped significantly during the 2008 recession, although many of these jobs have since returned[26]. In addition, artisanal and small-scale mining employs an estimated 25 million people worldwide, and indirectly supports more than 150 million people[27]. Mining takes place in more than 100 countries, with more than 50 regarded by the World Bank as "mining countries" because of the importance of mining to their exports, domestic markets, or to employment.

A changing climate presents physical risks to mining and metals operations because these industries are often located in challenging geographies, relying on fixed assets with long lifetimes, involve global supply chains, manage climate-sensitive water and energy resources, and balance the interests of various stakeholders (International Council on Mining and Metals, 2013). A key transition issue is around the opportunity to turn the industry into an agent of change and solution providers, rather than a generator of unsustainable lock-ins and a resisting force (Mont Masson-Clair, 2015). While the impact of climate change on large scale and small scale mining may vary in terms of scale, the impact on workers is more or less the same. Natural disasters pose immediate health and safety risks, while warmer temperatures may attract worker recruitment, retention, safety and productivity by increasing risks of accidents, creating or exacerbating food and water shortages and causing greater prevalence of disease (Table 4).

Table 4: Climate change effect in mining labour markets

Climate change effect	Labour Market Issues
Rising temperatures flooding, natural disasters, and drought	Increases the risk of heart-related illnesses and inhibit decision-making increasing the likelihood of injuries, accidents, and fatalities and decreasing productivity.
	Underground cooling systems may be inadequate to handle changes in temperatures and availability of water and energy
	Increase the incidence, prevalence and geographic reach of tropical diseases such as malaria, yellow fever, cholera and schistosomiasis with consequences for workforce health Flooding and rising temperature will increase the spread of tropical diseases that affect community health
	Undermine food security and rising temperatures will exacerbate water shortages, undermining worker health and productivity
	Increased requests for financial and employee support, in response to natural disasters in host communities
	Damage to livelihoods and poverty will elevate the need for basic services and restoration of economic activity. If these are also home communities for employee and contractor workforces, such incidences will directly affect worker health attendance and productivity
	Increased requests for financial and employee support, in response to natural disasters in host communities
	Drought, extreme weather, and flooding may decrease food security, worsen poverty, induce mitigation, contribute to civil unrest and increase conflict over resources
	Community water infrastructure and watershed restoration projects may be required to mitigate reputational risks and to meet needs of all users
	Force migration of coastal peoples, whose movement to new areas may exacerbate social problems and conflicts in host communities

Source: Adapted from International Council on Mining and Metals, 2013

Due to the illegality of their operations, artisanal miners cannot access official markets and depend on intermediary traders[28]. Their minerals are also deemed unattractive by fair trade organizations due to their environmentally degrading activities. They face the constant risk of being arrested too. In essence, artisanal miners face many risks and challenges only to make less money than the people they sell their minerals to. Not only are they at the risk of rock-falls, shaft collapses, water-borne diseases, animal attacks and injury, they also fall victim to turf wars and harassment from peers. They work on low-value ore-bodies while using labour intensive equipment and inefficient processing techniques which result in very low recoveries. They lack adequate geological knowledge of the ore-bodies and do not possess adequate mining skills. They have very little knowledge of the economic principles that govern the extraction industry and as a result their operations are run on a 'Gambler Mentality'.

The vulnerability of artisanal miners and women in particular is high during droughts or economic crises (Muza, 2009). In Zimbabwe for instance, women, who constitute 30% of artisanal miners also face some gender-specific challenges[29]. They are harassed by male counterparts including gold dealers in the sector. Although all artisanal miners suffer police arrests, the women's situation is worse in that because of the family care roles they play, they are sometimes forced to negotiate for 'lighter' charges outside the law. This is perpetuated by structural inequalities and stereotypes that discriminate against women, especially the misconception that the mining sector is a preserve of men. This is so despite the fact that women are disproportionately overwhelmed by negative impacts of mining, such as loss of agricultural land, unequal employment opportunities, increased incidences of Sexual Transmitted Infections (STIs), teenage pregnancies, access to clean and safe water and climate change which has affected subsistence farming, ultimately removing the guarantee of putting food on the table.

4. Pathways for green transitioning in key rural sectors: the case of Zimbabwe

Zimbabwe is severely vulnerable to climate change and its vulnerability is set to increase between 2010 and 2030 (DARA; Climate Vulnerability Monitor, 2012). It is ranked 156th on the Human Development Index (UNDP; Human Development Index, 2014). Zimbabwe's CO2 emissions are 0.7 tonnes per capita, while the global average is 4.9 tonnes per capita (World Bank; World Development Indicators: Energy dependency, efficiency and carbon dioxide emissions, 2010). There are consequences of not changing the current policies for industries with a greater environmental impact. Green growth pathways in Zimbabwe have largely focused on climate adaptation and mitigation strategies in ecotourism, reforestation, land and water management, organic agriculture, the development of clean sources of energy, recycling of green waste, green mining and green growth fisheries and aquaculture.

29 http://www.zela.org/index.php/latest-news/46-engendering-policy-in-the-artisanal-and-small-scale-mining-sector-in-zimbabwe#_ftn2.

4.1 Organic agriculture

Organic Agriculture (OA) initiatives in Zimbabwe are mainly developed by farming communities similar to those in Kenya and South Africa (Parrott and Elzakker, 2003). While increased uptake of OA on food supply and food security depend on geographical and socio-economic conditions and on the scale considered (Halberg et al. 2006), ethical concerns are significant drivers of integrated crop protection (IP) and organic farming (OA). However, animal manure shortage, slow organic matter decomposition and high labour requirements constrain OA (Svotwa et al. 2009). Evidence from the Organic Conservation Agriculture (OCA) project shows a high proportion of women (65.5%) engaged in the OCA project, despite not having used affirmative processes to increase participation which points to a number of factors, including the organic appeal to women producers (combined OA with TK); a higher proportion of women in the communal areas due to work opportunities for the men-folk; and or the majority of men in the household are watching to see if OA offers opportunities before fully engaged (McAllster, 2012). Of the engaged OCA farmers, 66% of the household are male headed households, 44% are female headed with a small number of child headed households. One of the most successful associations is led by a woman. In most cases, the females heading households are either widowed or divorced. However, the highest percentage of women actively participating in OA are within traditional family structures, with their lack of control over resources, asset and income being a key limiting factor, and posing a challenge for them expanding their enterprises.

Through a Global Environment Facility's biodiversity thematic area[30] implemented in two phases from 2006 and 2011, 400 members from Makoni Organic Farmers Association (MOFA) have received organic farming skills training in the application of crop rotation, livestock and green manure, composting, mulches and cover crops. The project links farmers efforts to upstream policy measures such as the national waste strategy and biodiversity strategies, the forestry based and wildlife land reform policies, as well as the environment and natural resources strategic plan for the period 2011 – 2015[31]. The 450 member project won coveted Equator Prize 2014. Research on unlocking the organic potential of Zimbabwe suggests key recommendations addressing some decent work indicators including firstly, a national agricultural policy which provides for organic farming, organic farming training, budgetary support and loan facilities. Secondly, an educational policy that provides for curricula on organic farming education at all levels. Thirdly, national organic promotion, processing and marketing policies linked to international (IFOAM), regional (CAADP), sub-regional (RISDP), and national (ZOPPA, SAZ); Fourthly, affordable registration costs and efficient processes and fifth and finally quality relationships between key stakeholder groups that include policy makers, policy implementers, research institutions, private sector as buyers, technology suppliers and NGOs.

4.2 Recycling of agriculture waste, land and water management and clean energy sources

Provision of clean energy sources, recycling of agricultural waste, land and water management are other pathways for greening the Zimbabwean economy. Reduction of green house gas (GHG) emissions emerges as a key mitigation factor in rural economies. Livestock generate GHG mainly in the form of methane emissions arising from digestion processes and nitrous oxide emissions arising from excretions. The cultivation of crops contributes to the concentration of greenhouse gases mainly by requiring the use of fertiliser as well as emitting nitrous oxide from crop residues reintroduced into the ground. Mining pollutes water and land and also contribute to GHG emissions. Forestry emissions are driven by deforestation for agriculture land and forest degradation due to fuel wood consumption as well as formal and informal logging. Tourism increases contribution to climate change, especially through the use of air travel (Becken, 2007). The global air travel tax emerged as a realistic compromise between restricting travel and achieving emissions reduction.

A new recycling company Clean and Green Zimbabwe was launched with a vision to maximize on recyclable recoveries. The company has directly created more than 70 jobs dire directly and indirectly unemployed youth are earning an income by selling their waste to the organisation. The company has so far collected 350 tonnes of waste[32]. The country's waste management strategies employ the traditional closed system which focuses only on the collection, transportation and disposal of waste. The system is failing to cope with the large amounts of waste being generated and noted that there was need to employ a more sustainable approach anchored on the reduction and recycle principles. Another arganisation, Environment Africa (EA) is pushing the concept of waste separation at source, use of colour-coded bins and liners for waste separation and ultimately recycling. Waste is segregated according to type and recyclability from the waste stream at point of generation or source. Recyclable wastes include paper, glass, plastic, polystyrene, cans or tins and biodegradable waste[33]. Enterprising young minds from Sakubva a high density suburb in Zimbabwe's Mutare city came together to venture into an indigenous waste management company called Mutare Plastic Recycling Centre. It is the first of

[30] Supported by the Global Environment Facility's Small Grants Programme (GEFSGP) of UNDP, the farmers are leading the way in environmental conservation and sustainable use of resources for livelihood improvement and poverty reduction.

its kind in the city. The youths are not yet able to add value to the recycled plastic, so they sell it mainly as pellets or raw plastic to companies mostly in Harare, where it is used to make irrigation pipes, plastic bags, lunch boxes and other plastic products[34].

In rural areas of Zimbabwe, 80-90% of people are heavily dependent on wood fuel, light their homes with kerosene, and carry out essential food processing tasks, such as milling grain, using diesel-powered systems. Total electricity generation in 2009 stood at 7,900 GWh, of which 53.3%, or 4,303 GWh, was produced from renewable sources. Electricity consumption per capita in 2009 stood at 1,022 kWh (REEEP, 2012)[35]. Zimbabwe could move forward to a renewable revolution and create job opportunities by improving access to financing new renewable energy technologies and realizing Zimbabwe's capacity to create job opportunities in renewable energy sector (IRENA, 2014). According to IRENA, in 2014 an estimated 7.7 million people worked directly or indirectly in the sector, with an additional 1.5 million in large-scale hydropower. Solar PV is the largest employer, with 2.5 million jobs. Zimbabwe has abundant sunshine throughout the year and has a high potential in Solar PV[36].

4. 3 Eco-tourism

In 2014, travel and tourism's direct contribution to employment was 181.000 jobs while total contribution to employment was 426 200 (Mowforth and Munt, 2015). With decreasing rainfall and rising temperatures, significant declines in biodiversity are expected to occur in most parts of the country especially the western regions where most of the estates are located. Ecotourism is defined as 'responsible travel to natural resources areas that conserves the environment and sustains the well-being of local people' (Stevens, 2009). The ecotourism green pathway in Zimbabwe stresses community participation in decision-making processes in relation to eco-touristic ventures and subsequent benefits derived from such ventures flowing back to local communities (Muzvidziwa, 2013). Eco-tourism places emphasis on conservation through utilisation, instead of emphasising preservation only. It helps conservation of natural environment and enhances the socio-economic lives of the local community. It is a strategy with potential to mostly benefit locally disadvantaged and marginalised communities living near or around tourist areas. Primary school curriculum and traditional conservation methods strengthen ecotourism (Marunda and Chaneta, 2014). Good governance, positive international relations and policies remain major factors in determining the overall viability and sustainability of the ecotourism sector, hence facilitating sustainable development (Chiutsi, 2011).

In order to promote gender equality, support opportunities for women and end violence against women, it is important to empower women as a first step[37]. Women are involved in eco-tourism through the preservation of forests, rivers and lakes and also participate in responsible nature industries. Amagugu International Heritage Centre in Bulawayo whose motto is 'where culture and nature meet' promotes women enterprises including crafts making and participatory cultural activities[38]. The tourism industry can contribute to this effort by creating opportunities for women and spread awareness of gender issues. Having economic opportunities and education is one of the most important ways for women to empower themselves to seek a better quality of life for themselves, their families and their communities[39].

4.4 Reforestation.

In Zimbabwe, women need environmental resources and in particular forest produce like fruits, roots, leaves and insects for food and medicine, firewood for heating and lighting, grass for thatching their huts and many other uses (Makonese and Tsanga, 2008). Protecting and re-establishing forests for their economic and ecosystem services including carbon stocks is a key green pathway. 66% of Zimbabwe's land area is under various forest types compared with 27% which is under cultivation. Exotic plantations occupy about 156 000 ha of land of which over 90% is in the Eastern Districts. The heaviest concentrations of forests occur in the gazetted state of forest areas, national parks areas, the eastern highlands and large scale commercial farms. On the other hand, the woody vegetation cover in most communal areas is low and variable with heavily populated districts such as Mutasa and Chivi having only 26% and 30% covered respectively. Though woodlots establishment is gaining momentum as a key rural sector providing employment to rural men and women (Muza, 2016), key decent work indicators would need to be recognised, especially improving security of tenure for women.

4.5 Green Mining

Up to 2 million people are affected by artisanal mining in Zimbabwe. These people are mostly involved in the extraction of gold, diamonds, tantalite and chrome. 500 000 people are directly involved in artisanal mining with over 150 000 of them being children and women. The World Economic Forum ranked

Zimbabwe 88 out of 135 countries in its Gender Gap Index 2011, a position relatively consistent with its gender blind policies in key economic sectors like mining[40]. The misconception that the mining sector is a preserve of men has further undermined policy responsiveness to gender-specific challenges faced by women in mining who now constitute 30% of artisanal miners in Zimbabwe[41].

Green mining activities involve, shutting down illegal and unregulated mines, choosing environmentally friendly general mining processes, implementing recently discovered green mining technologies, cleaning up the sites of shut-down mines, re-evaluating cut-off grades and research and development of green mining technology[42]. Two major methods of implementing green mining reform are governmental regulation and innovative technologies[43]. Poor governance practices in the mining sector precipitated hazardous mining practices with severe ecological damages and human rights violations on communities living in mining areas. In Manicaland Province for example, alluvial diamond and gold mining activities in Chimanimani, Marange and Penhalonga has exposed communities to environmental degradation, water pollution, forced dislocations and loss of livelihoods (CRD Report, 2014). Attempts by communities living in mining areas to fight for their rights to a secured environment has been met with brutality by mining companies leading to loss of life in some instances[44].

Apart from direct labour market impacts related to mining activities in general, landmines also threaten rural livelihoods, Zimbabwe has one of the densest minefields in the world, with about 5 500 landmines per kilometre, according to the Halo Trust, which did the Mukumbura demining project.[45] Since independence, in 1980, more than 1 500 people and 120 000 livestock have been killed in landmine accidents[46]. In Gonarezhou National Park, a 53 kilometre stretch of landmine field, 300 people have lost their lives in that area alone since 1980. More than 400 cattle and over 500 wild animals have also been killed by mines[47]. Previous attempts to formalise artisanal small-scale mining ignored the concrete needs of women and thus did not effectively improve the status of women[48]. This gender blindness persists in the prevailing illegality policy which perpetuates structural inequalities, worsening the women's situation as they are forced upon arrest to negotiate for 'lighter' charges outside the law to cater for the family care roles they play[49].

4.5 Green growth fisheries and aquaculture

Conventional fisheries and aquaculture production methods exploit renewable natural resources with a substantial potential for environmental degradation if the industries production practices are not sustainable a feature that are uncommon (Pualy et al. 2003). The industries are important users of energy with significant carbon footprint (Acshe, 2011). As far back as possible Tyedmers et al., (2005) estimate that the world's fishing fleets are using 1.2% of the global oil consumption, primarily as fuel, and by a rough estimate this number will increase to 2% if aquaculture is included. Green growth initiatives in the fisheries and aquaculture sector include harvesting, growing and trading with efficient and sustainable use of natural resources, ensuring that economic benefits from fisheries and aquaculture are equitably distributed and socially beneficial and reducing the carbon footprint of the fishery and aquaculture sectors (including production, processing and trade) and pursuing opportunities to use coastal and marine ecosystems as carbon shocks (UNEP, 2012). Aquaculture Zimbabwe is partnering with established fish farmers, donor agencies, international agencies and government departments to help subsistence farmers in Zimbabwe to diversify crop and livestock production with climate sensitive methods and using locally available inputs and feeds. Women are the majority of subsistence farmers in Zimbabwe; hence the initiative is expected to benefit more women.

5. General equilibrium dashboard model with OECD indicators and the case for just transition and decent work

While green growth involves economic, environmental and social contributions, the current focus of green pathways (discussed in section 4) is economic and environmental efficiency at the expense of social contributions in particular, the decent work agenda. As shall be illustrated in this section, there are key transition uncertainties and decent work deficits. The 11 general equilibrium dashboard transition indicators scored against the green pathways transition evidence (illustrated in section 4) show that labour markets are very certain (VC) about the green pathway sectors, products/services, production methods, green awareness and land and water management issues. However, rural labour

markets are also very uncertain (VU) about the green pathways position in the value chain, occupational profiles, required skills and abilities and job decency. Labour markets are also certain (C) about the development of clean sources of energy, pollution management group, resource management group and green technology and management group pathways (See Table 6).

Table 6: General Equilibrium Dashboard Transition Gaps

VC=Very Certain C=Certain U=Uncertain VU=Very Uncertain

Evidence from Table 6 supports that green activities have significant job creation potential (OECD, 2011) and can be the new engine of growth (UNEP, 2011). However, there is much that still needs to be understood and investments in research and development will inform key stakeholders on how to transition smoothly. There is still reasonable uncertainty that all jobs generated will be decent and will eliminate persistent poverty. Current knowledge and practices are developed in the context of labour requirements for production and not from the perspective of working conditions and decent work for instance, employment opportunities expected in agriculture, fisheries, forestry, artisanal mining and tourism are clearly outlined. Missing from the green pathways are decent work indicators for instance how the work will lead to adequate earnings and productive work, decent work time, combining work and family life, work that should be abolished, stability and security of work, equal opportunity and treatment in employment, safe work environment, social security, safe work environment, social security, social dialogue, workers and employment representation, economic and social context of decent.

While human resource procedures in the formal sector seeking gender equity clearly articulate most decent work indicators in employment search, recruitment, training, equitable pay and getting organised, activities in resource based sectors remain informal and are currently not integrated in rural policies for the creation of green jobs. Yet conventional rural sector practices exhibit decent work deficits for instance, family labour mentioned as a resilience factor to the extent that it involves child labour is not consistent with the values of decent work. New skills required in renewable energy, conservation and other climate-sensitive tasks may require long hours of training for women away from their families and might also require them to pay. In mining for instance, green technology and equipment require technical know-how which most informal miners especially women currently do not possess. Lack of rules and laws to protect workers in informal employment exposes them to decent work deficits including loss of property and jobs during crisis contexts (Muza, 2009) and also in the process of change from old to new jobs.

Green policies also based on such conventional rural sector practices miss out key elements of decent work and in such instances 'potential is overestimated and environmental policies may have much less attractive labour market consequences' (Morris et al., 2009). In this case, 'job creation has

[50] Refers to the nature or purpose of the job, irrespective of the sector it is performed in. Almost any occupation can be considered green as long as it contributes to reducing harmful impacts of human activity on the environment either directly/indirectly. As a result, occupations ranging from managers, workers to labourers can all at some point be considered as being green.

[51] Certain jobs require worker to possess certain specialized green skills and abilities. Determining whether a job can be considered as being green can in some cases be done based on the necessary skills and competencies required to perform it.

[52] The UNEP and ILO have both stressed the fact that green jobs which offer adequate wages, safe working conditions, job security, reasonable career prospects and workers (UNEP 2006, p.4). The Apollo Alliance has also taken up this dimension in its definition of green job stating that 'if a job improves the environment; but doesn't provide a family-supporting wage or a career ladder to move low-income workers into high-skilled occupations, it is not a green collar job'. Job decency is therefore a key dimension of green jobs.

53 Some workers may do some of their work in green areas and some of their work in traditional areas (Connection Research, 2009.p. 17). In this case, it is important to adequately measure the part of the workload that is officially dedicated to green tasks in order t determine if the job can be considered as green.

no merit as a basis for judging decency' (Hughes, 2011) and policies to promote green jobs maybe 'terribly counterproductive' (Alvarez et al., 2010). Again, it is highly questionable whether a government campaign to spur 'green jobs' would have net economic benefits (Michael & Murps, 2009). In this case, 'green jobs do not automatically constitute decent work, as many are "dirty, dangerous and difficult for instance, employment in industries such as recycling, waste management and biomass energy tend to be precarious and low-paid' (ILO, 2012).

6. Towards a gendered integrated pathway for decent work

The gendered integrated pathway for decent work is based on four pillars of fundamental rights, employment creation, social protection and social dialogue, also acknowledging gender equity in the sense that women constitute the majority of the rural labour force and also have high environmental awareness and are important partners in green transitioning. Equitable access to more and better opportunities in rural areas enable rural women to become effective actors and engines of growth; as well as to produce or acquire the food, water, fuel and social services their families need (Cabrera de González et al., 2009). This pathway follows appropriate labour standards that promote both men and women's interests and operationalises the decent work indicators and the general equilibrium dashboard concerns, gaps and opportunities. It recommends targeted policies that improve the livelihoods of rural women in resource-based economies.

6.1 Green jobs and fundamental rights

As illustrated in the preceding discussion, rural workers in informal labour markets work under difficult and unpredictable conditions and more often, their rights are violated. Because, they are not recognised formal workers and are often not protected by law, the integrated pathway recognises fundamental rights at work including the right to green jobs collective bargaining, eradication of forced or compulsory labour and abolishing of child labour. Existing rural groupings including commodity associations, village groups, farmer field schools or other can be used as vehicles for local organisation to enhance collective bargaining. Different rural groupings from agriculture, fisheries, forestry, tourism and artisanal mining will advocate for green jobs issues through District Councillors or Ward Committees who will then lobby governments and employees for decent work in informal labour markets. The decent work and Just Transition maps can feed into the natural resources strategic plans.

6.2 Green jobs and employment creation.

Employment creation under an gendered integrated pathway addresses key four emerging issues regarding jobs created, jobs substituted, jobs eliminated without direct replacement and worker transformation and redefinition. In all scenarios, worker skills will be revised; though some will be made redundant others will be acquired. However, decent work will only be realised if investments in accompanying green technologies are time and labour saving and thus create more time for women to participate in other productive work and also have quality family life. Gender-sensitive financial programmes and packages that empower women to develop and nurture complementary green spaces relevant for sustainable and productive green employment are introduced.

6.3 Green jobs and social protection

Transitioning to the green economy means new ways of doing work as well as new environments for doing work. To feed to the gendered integrated pathway, green jobs promoted in the rural informal sector are safe and provide security, observe healthy and safety regulations, provide sufficient income for a person to live and the work is dignified and offer prospects for personal development. It is linked to some form of social security that provides protection if the worker is unable to work. Because rural sectors are resource-based and sensitive to climate change, the green pathways adopted to create green jobs promote safe working conditions for women and their children. Green playing spaces may be provided for young children to enable women to carry out their work productively. The work spaces for women could be developed to provide shelter and cover against harsh climate conditions. Health and safety regulation trainings and information can be provided on the job or during other community meetings. Green profitable value chains for women and the requirements for success in such endeavours can be recommended for women in informal markets so that women can earn more and also provide the scope for their personal development.

6.4 Social dialogue

The gendered integrated pathway recognises social dialogue for green transitioning as critical in formalising informal workers concerns and feed into the country's green discourse, policy and practice. Informal workers in resource based rural activities have direct experience working in rural economies. Consultation of rural informal workers and encouraging them to express their concerns contributes to decent work at all levels. Particularly for women, who are the majority and have direct experience in environmental practice. Their views are important in policy formulation.

Environmental advocacy through the relevant ministerial portfolios for instance the Ministry of Labour and Social Welfare, the Employees Council, the Workers Union the green transition needs of informal workers can be presented for motion. Environmental advocacy through the private sector ensures that new technologies introduced are in line with local needs and expectations and also address gender issues. Environmental Advocacy through international governmental organisations also ensures that funding and humanitarian assistance is channelled for actual community needs and gaps.

Improved rural social dialogue (involving employers, workers and government representatives) that involves greening experts and gender advocates support a more balanced policy and research agenda. Additionally, other approaches to understanding the greening transition gaps that take into account decent work and gender equality issues may be considered. Perhaps a complementary monitoring framework (for example, to complement the decent work indicator framework) may be proposed to meet the gendered integrated pathway for decent work in rural areas concerning green jobs and fundamental rights, employment creation, social protection and social dialogue.

Decent work indicators for agriculture and rural areas: conceptual issues, data collection challenges and possible areas for improvement

C. Oya | SOAS – University of London | London | United Kingdom

DOI: 10.1481/icasVII.2016.a05b

ABSTRACT

This paper aims to achieve three main objectives. First, to assess the relevance of concepts and indicators of Decent Work (DW) for rural areas and employment in agriculture, especially in low-income countries, where coverage, data availability and reliability are particularly problematic. Second, to examine some of the main reasons for the lack of data on DW for rural areas and agriculture, particularly with reference to problems with data collection, such as: the scarcity of employment-focused surveys; sampling challenges that lead to some categories of the working poor to be missed out or under-represented; questionnaire design issues; challenges in survey implementation from selection to training to supervision of interviewers. Third, the paper proposes a selection of more relevant indicators as well as some ways to improve data collection and their quality to better capture the realities of DW, especially in low-income countries (LICs). In this regard the paper presents options for the integration of DW indicators in existing national agricultural surveys, noting the main practical challenges and possible solutions.

PAPER

1. Introduction

This background paper aims to achieve three main objectives. First, to assess the relevance of concepts and indicators of Decent Work (DW) for rural areas and employment in agriculture, especially in low-income countries, where coverage, data availability and reliability are particularly problematic. Second, to examine some of the main reasons for the lack of data on DW for rural areas and agriculture, in terms of problems with data collection, particularly: the scarcity of employment-focused surveys; sampling challenges that lead to some categories of the working poor to be missed out or under-represented; questionnaire design issues; challenges in survey implementation from selection to training to supervision of interviewers. Third, the paper will attempt to propose a selection of more relevant indicators as well as some ways to improve data collection and their quality to better capture the realities of DW, especially in low-income countries (LICs).

The first Section of the paper focuses on three problems and tensions in the implementation of a DW agenda in developing countries and especially in the measurement challenges this agenda raises. By looking at the available lists of Decent Work Indicators (DWIs), their conceptual origins, their availability from existing data repositories, ideas about alternative indices, debates about their applicability to different contexts, and a critical appraisal of the quality of what is available, this section highlights three basic problems with DW concepts and indicators:

1. Context specificity is important for relevance of concepts and indicators. A long and rigid list of DWIs may reflect aims for universalism and the imperative of international comparability. However, while all dimensions DW are desirable, not all indicators are relevant and applicable to all contexts, so there is an external validity problem if an extensive list of DWI is used. As a result, there is a danger of focusing on too many indicators/dimensions many of which suffer from very poor coverage in terms of countries, i.e. some countries with only a very limited set of available data for some very broad background indicators for economic opportunities (employment rates, for instance).
2. Many of the available indicators in several low-income countries, especially in Africa, are basic employment indicators that serve as 'background information' (how many people are active, or employed in rural areas, or the employment rate) but do not provide any indication of 'quality' and key indicators of quality (returns to labour, frequency of employment i.e. underemployment rates, non-wage conditions, etc.) are often missed from agriculture/rural datasets. Especially in agriculture a proper measurement of overall working conditions (including quality job aspects) is crucial. In this sector, the employed population tends to have specific employment conditions which tend to be structurally different from other economic sectors. Standards DWIs might therefore result inadequate to measure job quality in agriculture.
3. Generally the quality of available labour statistics for rural areas in developing countries, especially

in low-income countries (LICs) in Africa, is very poor and may contain biases that would require some rethinking of survey design issues as explored in more detail in Section 2 of this paper.

The scarcity and low quality of labour statistics for agriculture and rural areas stem from two main factors:

(a) Scarcity of employment-focused surveys, since labour force surveys (LFS) are not sufficiently frequent or not focused on rural areas, and most household budget surveys (HBS) cover too many topics, contain extensive and time-consuming modules on consumption, and are focused on welfare indicators (education, health, consumption) rather than on employment and earnings;

(b) Inadequate survey design to capture the realities of rural employment, especially in LICs, including sampling and non-sampling problems.

Section 2 of this paper discusses some of these problems, especially issues of survey design. It also proposes a number of possible areas for improvement, in relation to the most suitable DWI as well as to survey design options. The main alternatives would require:

1. Some more selectivity in DW indicators, i.e. trying to focus on a smaller but more relevant set of indicators, including some that are not currently being collected (for example, detailed data on returns to labour, whether self- or wage-employment, as well as more precise measures of underemployment and occupation multiplicity/multiple job-holding).

2. Better survey designs for greater rural employment focus, including longer modules on DW indicators, alternative sampling methods, better design of questionnaires and questions, and far more training and supervision of interviewers and data collectors.

The paper will particularly focus on the types of countries that are more affected by the scarcity and inadequacy of rural labour statistics, namely low-income countries, especially in Africa. There will be therefore more use of examples from Sub-Saharan Africa, in order to better inform pilot exercises in Burkina Faso and Togo, coordinated by FAO in collaboration with the ILO.

2. From concepts to indicators: the meaning and measurement of DW in rural areas

This section offers an overview of some conceptual issues, how the concept of 'DW' has been built and the dimensions attached to it, as well as some tensions between its holistic character and its applicability in a wide range of contexts and situations. It will be argued that its applicability is variable across contexts and that many dimensions of DW indicators may not be fully relevant or feasible in LIC contexts, where agriculture represents the main source of livelihood (as own-account or wage work) and most people reside in rural areas. This section will particularly focus on dimensions of quantity (measures of employment and underemployment for different types of employment) and quality (especially on returns to labour and non-wage benefits).

Based on work previously done at FAO (ESS)-ILO, and on knowledge of existing databases (ILOStat as an international repository of various national sources, and FAO-RIGA databases, which are based on LSMS[1] datasets) a broad assessment of data availability will be provided and some priorities suggested. This section is organised around a number of themes and main arguments, some related to conceptual questions and some more strictly linked to data issues, as summarized below:

a. In the absence of a simple and universal definition of DW, the choice has been to conceive multiple dimensions, but without a clear sense of what is most important or relevant for different contexts. Some of the dimensions and DWI, while desirable in themselves, are only applicable to particular labour markets and country contexts. As a concept, DW, should work in different contexts, but a rigid set of dimensions may not make the concept internally and externally valid.

b. The evidence base is weak, especially because of problems of data availability and coverage, especially for LICs. The majority of indicators available are basic labour market indicators, or what can be considered 'background' employment information, i.e. the DW pillars of 'socio-economic context' and 'employment opportunities'.

c. The second concern with regards to data problems is that what is available is not always reliable because some of the most conventional indicators may suffer from biases. It is the case of the distinction between 'self-employment' and 'wage employment' and the quality of data on returns to labour.

d. Conceptually and statistically, an important challenge is the fact that occupation multiplicity (when a person combines two or more jobs) and underemployment are pervasive realities in many LICs and especially in rural areas, but they are not sufficiently captured by official statistics, because of reliance on problematic notions of 'main occupation' and the way 'employment status' is conceptualized and measured. An implication is that statistics of employment status are often problematic, as a result of the above, and rural wage employment is frequently underestimated and limited to a particular set of wage

[1] Living Standards Measurement Surveys.

jobs (typically more formal and stable).

The concepts and definitions of DW have gone through a lengthy period of development and operationalisation. The ILO has developed a set of guidelines and a working definition that has been evolving in the last 10 years. DW has been broadly defined by the ILO as being productive work for women and men in conditions of freedom, equity, security and human dignity. The definition rests on basically four pillars, namely employment creation and enterprise development (Pillar I); social protection (Pillar II); standards and rights at work (Pillar III); and governance and social dialogue (Pillar IV). The most challenging task has been to operationalize the concept in all its dimensions through a series of indicators. Only in 2012 a manual[2] for concepts and definitions was published (and further developed in ILO 2013a), although many years before a substantial literature on 'DW' and its measurement had been generated (note, in particular, the special issue of the International Labour Review in 2003). This reflects the difficulties in achieving a universally applicable set of concepts as well as in finding a sufficiently robust set of indicators. In this respect, according to Sehnbruch et al. (2015), the concept of DW has been less successful than the UNDP-linked concept of human development for various reasons. First, it is not sufficiently embedded in a long and well established theoretical tradition that has had great impact on development thinking (i.e. Sen's capability approach). Second, complex and sophisticated dashboard indicators such as those proposed for DW are harder to communicate and diffuse than methodologically simple and easy to understand indices, such as the UNDP HDI, despite its unavoidable reductionism. Third, these authors also rightly suggest that the 'empirical operationalization of the DW approach is probably its biggest sticking point' and reflects the challenge of finding consensus about a simple synthetic indicator because of the tripartite nature of the main promoting organization, the ILO[3]. Furthermore, these challenges compound the already perceived neglect of employment issues in the international development agenda (besides an ex-post inclusion of 'DW' under MDG1b), while the new proposals for Sustainable Development Goals do not advance a significant improvement in the visibility of the DW agenda[4].

2.1 Too many indicators and dimensions? The applicability of the DW concept to rural employment in LICs

The process of conceptualization and measurement development around DW has led to the proliferation of indicators, which try to encompass its various dimensions. The current list of DW indicators includes 4 pillars and 11 dimensions. Each dimension contains a number of indicators, some about basic background information on employment (like employment rates) and some more specifically focused on questions of employment 'quality'. The list is long, with 60 indicators (see ILO 2012 and 2013a for a full explanation of these dimensions and each indicator). The dimension on 'economic and social context', including 12 indicators, provides very general background statistics, such as inflation rate, labour share of GDP or GDP per capita or some education variables. The dimension on 'employment opportunities' includes 11 indicators, most of which are general background employment indicators (such as active population, labour force participation, employment rate, unemployment rate and so on). The other dimensions (adequate earnings, working time, work to abolish, stability/security, etc.) are more focused, contain a smaller number of indicators and are more relevant to issues of employment 'quality' so, in a sense, many of the indicators in these dimensions should be critical for a good measure of DW deficit[5]. These are in fact the kinds of indicators that are often quoted in relation to DW deficit in OECD countries.

In sum, this long list includes all indicators that would be desirable for a full picture of DW situation, including general and specific aspects of employment as well as quantity and quality indicators. The problem is that some indicators, despite universal commitments to DW, may not be relevant across widely different labour market contexts, where employment realities reflect varying levels of economic development, productive structures, social structures and institutional development. For example, the unemployment rate is an important indicator of labour market performance, but it loses meaning and significance in poor countries where most people cannot afford to be unemployed due to the absence of any social protection system[6].It is therefore not surprising that most LICs and indeed many countries in SSA register relatively low unemployment rates in their single digits, especially in rural areas (Baah-Boateng 2013).

[2] Decent Work Indicators; Concepts and definitions. Available at http://www.ilo.org/wcmsp5/groups/public/---dgreports/---integration/documents/publication/wcms_229374.pdf.

[3] Although the ILO is the driving institution and the hub for the development and implementation of the DW agenda, this has also been appropriated by the UN system more broadly as reflected in the commitment of the 2005 World Summit of the United Nations General Assembly later reaffirmed in July 2006 at the high-level segment of the substantive session of the United Nations Economic and Social Council (ECOSOC).

[4] DW is diluted in its joint inclusion with sustained economic growth in just one of the 17 Goals. See Goal 8 https://sustainabledevelopment.un.org/sdgsproposal . It is also true that the multiplication of goals and instruments make most goals less visible than in the original MDG agenda, so 'DW' is not the only victim of this proliferation of goals.

[5] The notion of 'deficit' attached to DW can be inferred from the indicators given their wide range. So, for example situations with higher incidence of child labour, more under-employment, or more excessive working hours, higher proportion of low earnings, higher proportion of working poor, less union density, more occupational hazards, higher gender wage gaps or higher rate of precarious employment could all be interpreted as contributing to DW 'deficits'.

[6] Unemployment rates are typically low in very poor LICs and especially in rural areas compared to urban areas, despite the obvious fact that rural working conditions are generally less decent than urban ones.

Attempts to construct rankings on the basis of even smaller sets of indicators are fraught with problems precisely because of the different relevance of these indicators to different contexts. For example, the special issue of the International Labour Review 142(2) in 2003 included a number of articles proposing DW indices, based on selected indicators, which could help classify countries according to DW deficit. One of these attempts, by Bescond et al. (2003), selected 7 indicators and devised a method to rank countries with the use of the trimmed mean of available indicators (meaning that the two extreme values are dropped). Different country indices would therefore be based on different sets of indicators. While the overall ranking made some sense since richer countries scored better than poorer developing countries, there were anomalies such as a relatively high ranking for Tanzania compared to countries like Mauritius and Spain. The main reason for this anomaly was precisely the low unemployment rates in Tanzania and low female-male labour participation rate gaps, which reflect the fact that most people, including women, simply cannot afford to be unemployed or inactive. It is however hardly plausible that the DW situation in Tanzania is better than in Spain and Portugal. In a nutshell, if understanding DW deficit in Denmark requires 40 or 50 indicators because of the nature of labour markets and social and employment structures there, this does not mean that the same indicators should be applied to Burundi for the sake of international comparability. Insufficient coverage and too many missing values already make international comparability very difficult[7].

These examples and a close inspection of the applicability of several DW indicators to situations of informal, irregular employment and absence of social protection systems, underscores the importance of context specificity to analyse labour market performance and the problems with approaches that seek universal concepts and indicators and give primacy to international comparability. Many of these dimensions and indicators may be desirable in themselves but not applicable to some contexts. Some may be non-negotiable as is the case of the core labour standards, namely (a) no child labour, (b) no forced labour, (c) freedom of association and right to collective bargaining, and (d) no discrimination (across various dimensions). A DW agenda cannot ignore these even in poor countries, as it is a rights-based framework and, despite operational difficulties to enforce some of these rights, the effort to measure them cannot be avoided. The question is what other indicators are most suitable and relevant, knowing what is available, what data are collected with more reliability and what relevant indicators are missing in order to build a more realistic and effective DW agenda for rural areas in LICs.

2.2 What is available and from what sources?

A simple inspection of the available data in specialized international repositories like ILOSTAT-KILM shows that many of the available indicators in most low-income countries, especially in Africa, are basic employment indicators that serve as 'background information' (how many people are active, or employed in rural areas, or the employment rate) but do not provide any indication of 'quality', as key indicators of quality (returns to labour, employment below a desired capacity i.e. underemployment rates, non-wage conditions, etc.) are often missing from national agriculture/rural datasets.

A recent exercise conducted by staff at the FAO-ESS department tried to assess the coverage of 26 selected basic DWIs worldwide[8]. The assessment of available DWIs was based on the collection and classification of indicators according to data sources (ILO-STAT, World Development Indicators and World Trade Organization Statistics), availability/coverage, and disaggregation of data. Approximately 66 percent of the total DWIs for rural areas fall under Pillar 1 (employment creation), i.e. basic background information on employment for indicators such as employment ratios, total employment, unemployment rates, or labour force participation rate. Although important for the first pillar of DWI, these indicators only provide a very superficial picture of the DW deficit in a country and say little about the quality of actually existing employment.

In the main international repository for labour statistics (ILOSTAT and KILM), the coverage of the indicator for employment status, which is essential to distinguish between self-employed and wage-employed, is limited, particularly at a disaggregated level (rural vs urban). For example, for all African countries, most of which are low-income, employment status data are available for 73 percent of countries at aggregate level but only for 24 percent for rural areas (Table 1). For another sample of 7 non-African LICs, 4 out of 7 have aggregate statistics for employment status but only one of these 4 countries has disaggregated data for rural areas. In addition, some countries have disaggregated rural/urban information for wage employed people, but coverage is limited because the surveys these are based on are youth-focused only[9].

Recently, the ILO has been committed to collecting youth DW related statistics through dedicated LFSs, namely school-to-work transition surveys (SWTSs)[10]. Such surveys, administered in more than 25 countries (both developing and in transition), were designed on the basis of the ILO statistical framework. The ILO project towards the collection of youth statistical indicators represents a first

[7] The MDG agenda included the target 1b 'Achieve full and productive employment and decent work for all, including women and young people' but this in practice did not translate into a single indicator of DW with comparable data for all countries.

[8] An internal working paper with this material will be published soon. I had access to early drafts.

[9] These were school-to-work surveys, and thus they had a very specific purpose when they were conceived.

[10] http://www.ilo.org/employment/areas/WCMS_234860/lang--en/index.htm.

attempt to expand labour market information for the world of youth, including information on rural characteristics of the labour market. Indicators collected through these surveys are in general well-suited to inform about urban labour market difficulties faced by youth in the transition from school to work. Nevertheless, labour market indicators for rural areas may require context-specific information whose reliability might be undermined if collection is done through a standardized labour module, as generally designed for urban areas.

Table 1: Employment status –availability by number of countries (Africa)

Availability	**(number of countries)**	**%**
For rural	43	73%
Overall aggregate	14	24%
Total	59	100%

Source: Own elaboration from ILOSTAT data

Most of the indicators pertaining to the four pillars of DWIs that are not of a 'background kind' or related to the notion of 'employment opportunities' are missing for rural areas and agriculture[11]. Arguably a basic indicator of DW is the level and trends in agricultural wages, an area where major DW deficits are found. A recent check in ILOSTAT database showed that only 7 out of 59 African countries, and only one out of 7 non-African LICs, have data for agricultural wages. Disaggregated wage data for rural/urban strata are even scarcer, which shows the extent to which a key measure of DW is missing from available official datasets. Although this indicator is not directly included in the list of priority DWI prepared by the FAO-ESS paper, it should be considered of high priority. This is because the working poor in many LICs may be more dependent on casual wages in agriculture so information about their levels and trends is critical for any assessment of DW deficits in rural areas (Oya and Pontara 2015). Likewise, information on the incidence of migrant and seasonal/casual employment is virtually non-existent in Africa and most LICs in international data repositories (WB, ILO, FAO) but in some cases could be potentially calculated from HBS and LFS when available and if employment modules include questions on time-use. The shortage of statistical information for basic DWIs in agriculture/rural contexts is therefore alarming. Knowing the degree of underemployment is also probably a priority in contexts where full-time permanent employment is the exception and irregular employment the norm. However, a simple inspection of available statistics in ILOSTAT-KILM shows that in SSA there are only 6 countries with some data, only at aggregate level. And even for these countries the reliability is dubious since most have very low levels of recorded underemployment, i.e. below 10 percent of recorded employment, which is not particular plausible (e.g. less than 4 percent in Zimbabwe in 2004). Again, this indicator can be estimated for some countries where HBS and LFS produce time-related data, but it cannot be assumed to be available whenever a HBS or LFS is accessible.

Most of the data available are derived from Population Censuses, which are low frequency (typically every 10 years), Labour Force Surveys (LFS), which are relatively scarce especially in LICs, and, in the absence of these sources, what can be calculated from Household Budget Surveys (HBS) that collect some basic information on employment. One problem with LFS and HBS, as noted in the FAO-ESS paper, is that 'while LFSs cover a wide array of DW related issues, they may exclude the agricultural sector… [HBS] usually fail to provide detailed statistics on all the pillars of the DW Agenda' (p. 19). Also, only a fraction of countries are covered and sometimes with low frequency, so data may be easily out-of-date.

In sum, a major challenge is the scarcity of 'rural employment'-focused surveys in most low-income countries and generally in many developing countries. This is partly because of scarcity of LFSs, because agricultural surveys are essentially focused on production and land statistics, and because other national household surveys are focused on consumption and social welfare indicators (LSMS-type surveys, household budget surveys – HBS -, Demographic and Health Surveys – DHS – to name the best known). This means that (rural) employment issues have been basically falling between the cracks and explains the large number of missing values in international data repositories for employment statistics. The other major challenge is that not all the indicators available are sufficiently relevant/applicable to LIC contexts whereas key DWI seem missing, as will be argued in the next section.

2.3 Are the available rural employment data sufficiently reliable and relevant?

Generally the quality of available labour statistics for rural areas in developing countries, especially in low-income countries (LICs) in Africa, is very poor and may contain biases that would require some rethinking of survey design issues, as explored in more detail below[12].

[11] Detailed information on the pillars and different dimensions of the DW measurement framework can be found in the ILO manual (2013a) - Available at: http://www.ilo.org/wcmsp5/groups/public/---dgreports/---stat/documents/publication/wcms_223121.pdf.

[12] See Jerven (2013), who also provides compelling evidence of the unreliability of basic macroeconomic indicators

There are also issues with relevance. The discussion of multiplicity of DWI in the previous section argued that some of the key indicators of the labour market are not particularly appropriate or useful to understand labour market performance especially in rural settings of poor countries. The World Bank seems to agree with this argument: 'the typical indicators of labour force participation (for example, the employment-to-population ratio, the unemployment rate, main occupation and sector of activity) derived from the standard questions about the "main activity" are generally inappropriate to capture employment patterns such as these which tend to be significantly more complex' (emphasis mine)[13]. Thus it is not surprising that unemployment rates vary enormously across developing countries, even within Africa (particularly comparing Southern African countries with the rest of SSA), thereby reflecting problems of applicability and data collection[14].

There are other indicators like employment status, which establish rigid categories, which may work in contexts where a single well-defined (and regular) activity per individual dominates, as in developed countries, but are less reliable to describe the complexity of rural employment, where there is typically occupation multiplicity, seasonality, irregular employment and generally substantial heterogeneity of rural livelihoods. This has been captured by an abundant literature on the 'rural non-farm economy' (RNFE) (Reardon 1997; Davis et al. 2010), but diversity and multiplicity of roles also happens within agricultural activities. In this sense, as will be argued in more detail in section 2.3.3, and especially but not only in SSA, an activity that is often badly captured is rural wage employment, especially agricultural wage employment.

Part of the problem with relevance and reliability lies in the applicability and operationalization of the most basic definitions. By 'employment', or what the World Bank has recently called 'jobs' (World Bank 2012), statisticians and data users usually mean 'work performed for pay or profit', which can be remunerated in a variety of ways, in cash or in kind[15]. Some analysts call this a 'market oriented' job, because there is some market transaction involved, but the participants in the transaction can be of many different types and contracts may vary widely (Belchamber and Schetagne 2013)[16]. To be sure, there are many types of work that are not explicitly remunerated in any way, but the boundaries between existing categories of 'work' are sometimes blurred, especially in the rural areas of poor countries. What the ILO now calls 'unpaid trainee work' (Belchamber and Schetagne 2013),16 for instance unpaid apprenticeships, are in fact very precarious, and common, forms of employment in the so-called 'informal sector' (more below), since the skills and knowledge acquired by a trainee could be classified as a 'wage'. Moreover, an activity that generates goods that may have a market value but that are consumed within the household can also be considered and is indeed normally considered 'employment', as in the case of what is called 'subsistence agriculture'. Nonetheless, in reality most rural people, even the poorest, have some engagement with markets (output and factor markets) so it is really hard to find purely 'subsistence' households.

Definitions of categories for employment status are also harder to operationalise in poorer countries, particularly for 'wage employment' and unpaid 'contributing' family workers. The notion of 'wage employment', and more generally the 'wage contract', may seem obvious in most countries in the world, and defined by ILO statistical conventions where an employee-employer relationship is assumed, but is actually hard to properly operationalize in rural areas of developing countries, especially in poor countries, characterized by widespread poverty, casual work and occupation multiplicity (section 2.3.3). There may for example be disguised domestic workers also classified as 'unpaid family workers, if there is no explicit cash remuneration and there is some family tie with the worker. There may also be many young people who 'help' in the household farm but also engage in multitude of other casual remunerated activities but are classified as 'unpaid family workers, a category that absorbs a very large proportion of the reported employed population in most LICs.

The key prefix 'rural' attached to employment is not without its challenges either, particularly when comparing countries at very different levels of development and with very different labour structures. Many studies on rural employment in low-income countries tend to take the 'rural' for granted. Researchers sometimes forget that the boundary between the rural and urban differs widely particularly when demographic criteria are used. For example, the cut-off point ranges from 200 inhabitants in Denmark to 50,000 in Japan, and two neighbouring African countries like Senegal and Guinea use very different cut-off point to define urbanity (10,000 and 1,500 respectively) (Dirven et al. 2011). Moreover, in the real world of households and individuals, often characterized by substantial intra-annual and intra-household mobility the rural-urban boundaries may be even more blurred (Breman 1996). Lerche (2010)

in Africa, like GDP, often used in econometric analysis, and documents the major challenges faced by national statistical agencies to produce enough and good-quality data on various aspects of development.

[13] See website at http://go.worldbank.org/KAI66PHUY0.

[14] See Luebker (2008b), for an illustration of this point in the case of Zimbabwe. He shows that, in Harare, almost one half of those considered employed by ILO definition thought of themselves as unemployed. See also Baah-Boateng (2013).

[15] The 19th ILS conference defined work as 'any activity performed by persons of any sex and age to produce goods or to provide services for use by others or for own use'. http://ilo.org/wcmsp5/groups/public/---dgreports/---stat/documents/normativeinstrument/wcms_230304.pdf.

[16] See also ILO (2013b) at http://www.ilo.org/wcmsp5/groups/public/---dgreports/---stat/documents/event/wcms_175150.pdf.

and many authors writing on labour in India focus on the increasing fluidity of employment patterns straddling the urban-rural divide. In China this is a particularly important issue, as the rural-urban interconnections are as important to understand household and individual patterns as what happens within defined 'rural' areas (Zhang 2015). While multiple occupations can be found in 'rural' areas, typically 'rural' occupations like agricultural wage employment may also attract urban-based workers, for example in Latin America, as shown by Ortiz (2015) in relation to both coffee and citrus harvesters who live in town and cities not too distant from the farms. And there are plenty of other examples. The point is that it may be increasingly difficult to define employment and DW in terms of their 'rurality' and this may lead to a greater focus on sector- or activity specific employment indicators beyond the rural-urban divide. The next four sub-sections extend this discussion to four central questions:

a. Centrality of seasonality and irregular rural employment in LICs.

b. Whether notions of 'formal' and 'informal' would help us capture DW deficit in rural areas of LICs.

c. Neglect and statistical invisibility of rural wage employment, especially in African countries.

d. Challenges in capturing the employment features and DW deficit of small-scale producers.

2.3.1 The irregularity of rural employment

A key challenge in the application of DW concepts and indicators is the fact that most employment in rural areas tends to be irregular, or does not conform to the patterns typically associated with 'permanent' or 'regular' employment (the latter, for example, is the preferred term in the Indian context for workers with permanent contracts who work full-time)[17].

Employment status categories (e.g., paid employee, own-account worker, employer, unpaid family worker, and so on) derive from the 'labour force approach', which is usually linked to notions of wage employment that are primarily relevant for developed countries and designed to contribute to national account statistics and unemployment figures (Standing 2006; Breman and van der Linden 2014). Breman and van der Linden (2014) link this approach to the notion of 'Standard Employment Relationship', i.e. regular salaried employment subject to regulations and a variety of forms of protection. At least, this is the way many national statistical agencies, the interviewers they hire and many respondents tend to interpret the concept. The concept needs to be carefully operationalized with a broad enough definition and the consideration of a variety of scenarios. Section 3.2 on questionnaire design explores this.

When the norm is irregular, seasonal and casual employment, i.e. a vast majority of rural people do not depend on one full-time activity with high frequency (duration in terms of months of work and frequency as hours per week), their livelihoods in reality hinge on two basic aspects of work:

a. The effective number of 'days' (8-hour equivalent days) they manage to work in any given calendar year with explicit or implicit remuneration (i.e. both returns to self-employment and to wage employment in cash or in kind, including self-consumption).

b. The explicit or implicit returns to those activities (per day of work).

Therefore, in these contexts, the big issue is time-related underemployment, which is perhaps one of the most relevant and useful DWI for rural areas in LICs. One of the main reasons for underemployment (as one key element of labour underutilization[18]) is seasonality of agricultural activities, which tend to dominate many rural settings despite the increasing rise of non-farm rural incomes (Davis et al. 2010 and 2014). In contexts of low-technology, low-productivity agriculture, most agricultural activities are highly seasonal, at times erratic, because of their reliance on vagaries of weather, and uncertain in terms of returns, due to high risks of crop failure or low productivity. In the case of semi-arid areas in Africa, the agricultural season may not last more than 4-5 months, from the time of land preparation to the harvest, with slack periods in between. Apart from the uncertainty of natural environments, farming is characterized by the fact that production time exceeds labour time to respect the natural rhythm of plants and animals, so employment in farming is quite different from employment in factories or in other non-primary activities, (Mann and Dickinson 1978; Bernstein 2010). These contexts thus generate obstacles for the development of capitalist agriculture and more permanent agricultural activities, and are exacerbated by the dependence on rainfed farming systems and limited availability of irrigation in most LIC contexts. As a result, rural people either remain idle without engaging in gainful economic activities or try to complement what they do with other non-farm activities. As an abundant literature has shown, the latter is the norm rather than the exception (Davis et al. 2010 and 2014; Reardon 1997). In fact, it may be the case that an individual is 'irregularly' employed in two or three different activities, but the sum of days of work accumulated in the different activities over a given year equates to almost

[17] Winters et al. (2008) prefer to use the term 'permanent' or FYFT (full-year full-time) to distinguish from other forms of employment that may be 'full-year' but are only part-time or full-time but only for a period of time in a year (such as a season). Both terms 'regular' and 'permanent' are often used interchangeably.

[18] The other elements are unemployment and 'potential labour force', as defined by the 19th ILS resolution. See footnote above. http://ilo.org/wcmsp5/groups/public/---dgreports/---stat/documents/normativeinstrument/wcms_230304.pdf.

a 'regular' or full-time status. In such contexts employment statistics derived from questions with short reference periods, such as the conventional 7-days, may lead to biases depending on whether the survey took place at the peak of the agricultural season or during the slack period. Therefore, a 12-month reference period is more suitable to capture the true extent of underemployment. This is why it is important to collect detailed information on effective time in work, so that distinctions can be made between different degrees of 'irregularity' and underemployment.

Pervasive underemployment and irregular jobs can happen amidst instances of 'overemployment' especially in the form of 'excessive working hours', another important DWI. Since most employment in rural areas of developing countries is not protected by labour legislation on maximum number of hours, the duration of a 'day of work' can vary widely from one job to another from one period of the year to another. This situation is particularly important at times of peak labour demand for agricultural activities, such as weeding or harvesting. Given the importance of harvesting on time, or sowing shortly after the rains, as in much of rain-fed semi-arid areas, farmers are forced to use their family and hired labour intensively, implying more than 10 hours of work per person in any given day. This can also entail the use of child labour, whether during school holidays or not. A lot of casual wage jobs in agriculture are defined in terms of tasks even when the mode of payment is daily. So, a worker will be asked to perform a task and, depending on his/her productivity. This task could take half-day or even require extra time the following day. At the same time, there are also people who work excessive hours because during certain periods of time they have to work in multiple jobs and extend the day of work to very long working hours. Thus, someone may start very early and work in the farm until midday, then go to work in the market and perhaps add another casual job later in the evening. This can be particularly burdensome for women when they combine productive and domestic/reproductive activities at times when productive activities are very demanding. In sum, a scenario of underemployment coupled with excessive hours of work (overemployment) is possible:

a. A worker may be effectively 'active' working in agricultural tasks (as self-employed or wage employed or both) for a fraction of the year, say 120 days, which would mean 'under-employed' in that activity.

b. However, the hours worked in some of these 120 days may be 10 or 12 or more, in which case there is over-employment or 'excessive hours of work'. The question is whether 'over-time' (rather than over-employment) is compensated or not and whether the worker would prefer to work fewer hours, which might mean less income if payment is task-based or piece-rate. All this is obviously hard to ascertain in situations where the labour relation is inherently 'informal', i.e. no contract, no hours stipulated, just tasks to be completed.

In sum, for the purposes of relevant and realistic DWI in relation to employment regularity, data on the number of effective days of work per year, for all recorded occupations would be needed in contexts where 'regular' employment is the exception. Moreover, estimates of instances of 'excessive hours' of work, which may happen in particular periods, are also important for a more encompassing consideration of DW in relation to time-use.

2.3.2 Definitions: do "formality" and "informality" help?

The irregularity of employment, multiplicity of jobs, variable hours and remuneration would suggest that this is a context of widespread 'informality'. Indeed, most of the employment in rural areas of LICs is 'informal' according to the usual definitions of informality, whether 'legalistic', scale- or productivity-based. The problem is that the dichotomy formal-informal means different things to different people and is defined and operationalized in multiple ways (Maloney and Arias 2007 – in Perry et al., chapter 1; Maloney 2004), and may create problems of applicability to diverse contexts as it happens with some DWI. Sometimes, the nature of the labour contract is emphasized, whether workers have formal contracts, receive benefits or pay taxes, for example. Other times, 'informality' is equated with the type of employer and especially its scale of operations, so a 'shortcut' is devised whereby enterprises are considered 'informal' if employing less than 10 workers and thus these workers may be classified as 'informal' by virtue of the scale of their employers rather than the nature of their labour relation. This can create biases insofar as there is a possibility of small-scale operators (especially in services) that may formally employ people and be 'formal' in the legal sense.

The ILOSTAT-KLM statistical repository only includes 18 countries in SSA with some data, often dated, on the proportion of informal employment in non-agricultural employment at aggregate level and in some cases coverage is limited to urban areas or to the capital city. This type of information is almost impossible to find in these compiled databases for rural areas and agriculture. The ILO technical notes point out that 'information for the indicator is often based on national definitions and users are advised to review definitions carefully when attempting to assess country comparisons', so there does not seem to be one universal definition in use. There are multiple layers in the definition and therefore multiple choices for national agencies to opt for one or a different combination of elements. The ILO combines categories of employment status with the 'legalistic' definition of their labour relations, and the type of employer ('productivity' definition), but has moved towards the 'legalistic' definition, focused on the nature of labour relations and contracts, to accommodate situations in which the employment relation is 'informal' even if it happens within 'formal' units[19]. This combination of layers of formality creates multiple situations of 'informality' as illustrated by Maloney and Arias (2007). In some cases a combination that is adapted to a country context may result in a definition that is more operational but that excludes some groups. For example, in India informal work/employment (clearly distinguished from 'informal economy' and the 'informal sector') is defined as: 'Unorganized workers consist of those working in the unorganized sector or households, excluding regular workers with social security benefits provided by the employers, and the workers in the formal sector without any employment and social security benefits provided by the employers' (NCEUS 2009: 3). The inclusion of formal sector workers who do not enjoy the benefits of formality is important. The 'unorganised' sector is defined in relation to ownership (individuals and households) and scale (less than 10 workers), including 'all agricultural activities undertaken on agricultural holdings', quite a common option in most developing countries, where 'informality' is restricted to the nature of the employer and its scale.

Although knowing the extent to which an employment relation is 'informal' or takes place in an 'informal' setting may be useful, the applicability of the different definitions creates its own problems. In fact, the rigid guidelines applied make the concept of 'formal' largely irrelevant to the agricultural sector in LICs, especially when casual wage work and what is called 'subsistence agriculture' (more precisely 'own-use production work') dominate. However, this does not mean that there may not be employment that conforms to some of the definitions of 'formality', i.e. large-scale plantations where some workers may be deducted taxes on their pay, who have written contracts, albeit temporary, and where some statutory benefits (sick leave, annual leave, etc.) are available (Wendimu and Gibbon 2014, for an application in an Ethiopian context).

Given the challenges discussed above, leading authors like Breman (2006) and Wuyts (2011) have questioned the usefulness of the 'formal'-'informal' distinction and especially its inconsistent operationalization across contexts. They argue that what matters is knowing the dimensions and conditions that characterize a given employment and report them separately for different topics. Trying to establish an indicator of 'informality' is akin to the production of a composite DW index from the various dimensions it is supposed to encompass. As argued by Breman (2006) among others, what really matters is the nature of the employment relation or the form of work rather than the scale or productivity of the employer/producer irregular employment, no written contract, no benefits or rights, lack of formal registration, etc.).

For small-scale producers, the issue becomes even more irrelevant and complicated since they would not qualify as 'formal' either in relation to the nature and scale of the production unit (the small-scale own-account farm, for example) or to the nature of their employment (nor formally protected or registered, irregular, with uncertain remuneration, etc.). Moreover, rigid classifications may obscure a continuum of degrees of 'informality' among small-scale producers, from those with less market involvement (as sellers and buyers) to those who are primarily market-oriented producers[20]. As Wuyts (2011) argues, the trouble is also that the application of rigid notions of 'informality' (i.e. that the self-employed are 'informal' by definition and that some 'informal' activities are therefore correspondent to self-employment) may lead to biases in the representation of employment status, inflating self-employment and underestimating wage employment (see more below in 2.3.3).

In light of these challenges and tensions, it may be advisable not to apply rigid formal-informal distinctions in the context of rural employment in developing countries, but rather focus on key central dimensions of DW and measure them properly without recourse to broad categorizations and dubious composite indices. Therefore, indicators of time-related underemployment, security, protection, registration, taxation and benefits, may be better to analyse separately and comparatively instead of being pooled and diluted in an aggregate index/classification of more inconsistent applicability, particularly when there are distinct categories of work (small producers, more or less market-oriented, casual wage workers, seasonal workers, etc.). What is at stake is their applicability to rural/agriculture contexts and not whether they can be combined in any meaningful 'reduced' composite index.

2.3.3 Rural/agricultural wage employment: biases and challenges[21]

According to the 2013 World Bank World Development Report on 'Jobs' (World Bank 2012, 6): 'a job does not always come with a wage'. In fact, Figure 1 in that report suggests that, on aggregate, employment is usually dominated by non-wage employment (a combination of own-account farming and non-agricultural self-employment). In most SSA countries and in many LICs the category of 'wage employees' category usually represents between 2 and 10 percent of the total employed population,

[19] See, for instance, definitions for informal employment by the ILO, at http://www.ilo.org/wcmsp5/groups/public/---dgreports/---stat/documents/normativeinstrument/wcms_087622.pdf and http://ilo.org/public/english/bureau/stat/download/papers/def.pdf and http://ilo.org/wcmsp5/groups/public/---dgreports/---stat/documents/meetingdocument/wcms_223918.pdf.

[20] Moreover, in some cases and increasingly so small-scale producers may operate within cooperatives or producer organisations, also with varying degrees of integration, and therefore part of a different employment category beyond their degree of 'informality'.

[21] The arguments and evidence in this section draw from Oya (2013) and Oya and Pontara (2015), which include more details.

the vast majority being classified as either self-employed or unpaid family workers, but there are some exceptions like the richest African countries as well as those located in Southern Africa (Oya 2010, Table 2). Beyond Southern African and African Small Island States the official statistical picture consistently shows very low incidence of wage employment in aggregate terms and especially in rural areas. For example, in the 2004-05 LFS in Ethiopia, a country with a large population, only 2.3 percent of rural people employed were paid employees by private companies, NGOs or individuals (including 0.5 percent of domestic workers). Anyone with some fieldwork experience in rural Ethiopia would question these figures, as wage jobs are very common and people working for wages far from a small minority. As will be argued below, the problem lies in the conventions of 'main occupation' and the way large-scale surveys are conducted.

There are important differences between regions and countries. The incidence of agricultural wage employment, in rural Africa is less than 3 percent in aggregate, compared with 22 percent of men and 11.4 percent of women in South Asia, and 21 percent and 2.3 percent respectively in Latin America (World Bank 2007). In addition, non-agricultural rural wage employment applies to only 9 percent of men and 3 percent of women in most African countries, whereas it represents a much higher proportion South Asia, Middle East and North Africa (MENA), East Asia and Latin America (World Bank 2007, 205 Table 9.2). Despite these figures, the Bank acknowledges that 'Making the rural labour market a more effective pathway out of poverty is…a major challenge that remains poorly understood and sorely neglected in policy making'.

Based on the RIGA databases and selected countries, a study by Davis et al. (2010), reporting income sources, confirms these contrasts by region and gives evidence of some large and possibly inconsistent discrepancies in findings between African countries[22]. In Latin American countries, rural labour market participation rates (based on questions of having worked as wage workers, not about the 'main activity') are quite high, while the three African countries considered present a very inconsistent picture in Africa: 55 percent of rural people having worked for agricultural wages in Malawi, compared to 3.7 percent in Ghana and 3.8 percent in Nigeria.

This neglect or apparent invisibility of rural wage workers is a serious challenge if we are interested in DW in rural areas. Indeed, research shows that most often the poorest rural people tend to depend more on casual wage employment (Sender 2003; NCEUS 2007; FAO-IUF 2005; Kevane 1994). A particularly problematic omission is paid domestic work, as opposed to domestic work tout court. In most countries there are either no statistics at all on this category or the values are almost insignificant as shown in the example above in Ethiopia. For example, in Zimbabwe and Botswana, 'wage employment in private households' (i.e. domestic workers) is quite a significant employment category in official statistics, at almost 5 percent of total employment in both countries (Luebker, 2008a: 32, and Central Statistical Office [Botswana], 2008: 20). In contrast, in other countries this category of workers seems invisible from official statistics. It is plausible that even in rural areas of poor countries thousands of domestic workers are employed in the houses of people employed by 'formal' enterprises and certainly in those of civil servants. It is precisely in these kinds of jobs where the potential DW deficit is greatest (see Cramer et al. 2008, for evidence from Mozambique). Hence the biggest priority should be to capture the true significance of this kind of employment in rural areas of LICs in order not to underestimate the extent of DW deficit in a country. The reasons for these low recorded levels of rural wage employment may be variegated, as different hypotheses have been considered by the literature, namely:

a. high land/labour ratios and low population densities coupled with low productivity, which reduce the incentive to hire labour and also constrain wage labour supply (Berry 1993, Barrett et al. 2005, Mellor 2014)[23].

b. Small-scale producers' resistance to become proletarianized and their protracted attachment to their land and own-account farming[24]. While there is some contested evidence on this occurrence, total avoidance of market compulsion to work for wages is unlikely (Bernstein 2010)[25].

c. This thesis is complemented with the idea that most labour hiring in African contexts takes the form of reciprocal labour exchange in the form of collective workgroups[26].

d. The hypothesis of 'resistance' would be consistent with some evidence that households participate in agricultural wage employment because of liquidity constraints, so they may pull out and focus on

[22] The RIGA (Rural Income Generating Activities) programme and database (http://www.fao.org/economic/riga/riga-database/en/) is an attempt to extract more detailed labour statistics and specifically wage employment data from existing national household surveys (LSMS-HBS). Davis et al. (2010) and Winters et al. (2008) report the key findings.

[23] See Oya (2013, 254 and Table 2) for a critique of this hypothesis.

24 See Hyden (2006, 138-160) on the idea of 'uncaptured peasantry'. For criticisms of this position see Kitching (1989), Sender and Smith (1990), and Mueller (2015).

[25] See also Zhang (2015) on China.

[26] See Whitehead (2006) and Swindell (1985, chapter 5) for an analysis of the nature, decline and persistence of cooperative/reciprocal labour exchange and the extent to which collective workgroup may conceal disguised forms of wage labour, when reciprocity is not demonstrated and some individuals tend to benefit much more than others.

their own farm activities when improved access to social protection and/or finance reduces the need to rely on casual wage employment, such as ganyu in Malawi (Bryceson 2006)[27].

Among these hypotheses, one of the most convincing is that many low-income African countries still have underdeveloped capitalist sectors and have the lowest incomes per capita in the world. Historical evidence suggests that convincingly that as income per capita increases, the proportion of reported self-employment is substantially reduced (Gindling and Newhouse 2012).

However, none of these hypotheses questions the quality of data. So, a plausible alternative hypothesis is that some of this evidence essentially derives from the fact that data collection systems are inadequate and have failed to capture the significance and nature of rural wage employment, at least on the basis of more conventional questions (Oya 2013, Mwamadzingo 2003, 31; White et al. 2006; Cramer et al. 2008; Zhang 2015). This has partly to do with definition issues and their operationalization, as discussed in section 2.3 and 2.3.1 above. The reason this hypothesis is suggested is two-fold. First, the problems of reliability of rural labour market and agricultural statistics more generally have been shown through basic consistency checks, comparisons and some survey experiments (Carletto et al. 2015; Jerven and Johnston 2015; Sender 2003). Second, abundant micro-level labour surveys show a very different picture.

Various studies published in Oya and Pontara (2015) illustrate this point. For example, Mueller (2015), writing on Tanzania, finds in the West Usambaras Mountains, that around 60 percent of rural households had at least one member engaged in wage employment, in contrast with an official figure of 11 percent from national Integrated Labour Force Surveys (ILFS) in 2000/01. Around 22 percent of rural adults work for wages during the reference period of his study, compared to the 3.3 percent of waged or salaried workers in the economically active population based on the same ILFS. Although Mueller's and the ILFS methods are different and questions are not the same, the discrepancies suggest that we miss an important part of the picture of the rural labour market precisely because of how questions are formulated. Other studies (Petit and Rizzo 2015) also document the pervasive practice of agricultural wage labour, especially among the poorest households, in countries like Ethiopia and Rwanda where official estimates of the incidence of wage employment in rural areas do not exceed 10 percent[28]. Other contributions on South Africa and Lesotho also point to the extent to which self-employment is overstated and how migrant labour is insufficiently captured (Pons-Vignon 2015; Johnston 2015). But these problems are not limited to LICS in Africa. Even in countries where labour statistics are relatively good, such as India, biases and underreporting occur, as Jha (2015) argues especially in relation to seasonal migrant labourers. In China the problems are even more serious. As indicated by Zhang (2015), one major challenge there is that 'hired agricultural workers' do not exist as an official statistical category. The use of costs of hired labour inputs is also fraught with problems (Zhang 2015), including the conflation of very diverse forms of wage employment. Rizzo et al. (2015), writing on Tanzania, argue that the limited evidence on informal employment, especially for non-agricultural activities, is largely due to many forms of wage employment being mistakenly reported as self-employment. The importance and dynamism of rural and agricultural labour markets may however be partly captured by analysing specific questions sometimes contained in nationally representative surveys, like LSMS. A recent study (Dillon and Barrett 2014) , based on data from LSMS and ISA surveys led by the WB, looks more specifically and in detail at questions about hiring (employing) labour for agricultural activities. When these questions are asked (rather than 'your main occupation in the last 7 days'), a picture of important and dynamic agricultural labour markets emerges. According to this study, the incidence of labour hiring (in terms of farmers employing hired labour) ranged from 30 percent in Ethiopia to almost 50 percent in Niger, for a sample of 5 countries and various agricultural operations. This shows that LSMS-type surveys can potentially be used to extract this kind of information as long as employment modules contain the relevant questions.

To account for the discrepancies between official statistics and micro-level survey evidence as well as with qualitative research, methodological problems in data collection must be debated. This will be done in more detail in the discussion of survey design (Section 3). In previous research (Oya 2013), I have suggested four reasons why rural wage employment data are unreliable and scarce in most of Africa and many other non-African LICs:

a. Lack of labour force surveys (LFS) focusing on the rural sector and small-scale enterprises;

b. Growing marginalization and simplification of questions on labour and employment in nationally-representative household surveys (HBS), which are unsurprisingly biased towards the collection of consumption data for poverty indicators;

[27] However, this may apply in relation to the worst forms of casual wage employment in agriculture, which may be seen as 'last resort' but (a) not all forms of rural and agricultural wage employment are of this kind and (b) the likelihood that access to finance and assets might improve for the vast majority of small-scale producers in poor countries is very low because governments and NGOs have limited resources to substantially expand the outreach of these kinds of interventions. There is also evidence that cash transfers programmes in Malawi relax the labour constraint faced by poorer farming households and even allows them to hire ganyu for their own farms. See http://www.fao.org/economic/ptop/programmes/malawi/en/.

[28] See also Erlebach (2006) a rare in-depth study of rural wage employment in Rwanda, which confirms the huge importance of wage jobs for the poorest rural people.

c. Inadequacy of some statistical conventions, definitions and survey practices, some already explored in previous sections of this paper;

e. Issues about the definition and boundaries of the 'household'.

Section 3 will discuss the last three points. On the first point, the relative scarcity of LFS in Africa and LICs can be inspected by looking at existing survey inventories at the ILO and the World Bank[29], especially in comparison with Latin America and Asia (Mwamadzingo 2003). Generally, since the 'poverty reduction agenda' started dominating the international aid agenda HBS of the Living Standards Measurement Surveys (LSMS) type have overtaken traditional labour force surveys as sources of basic labour data in terms of frequency (Rizzo et al. 2015; Johnston 2015). The paucity of rural wage employment data in these countries has a knock-on effect on published research, which depends heavily on the use of international repositories and data from national household surveys, so that results in scarcity of published research too. In contrast, research on small-scale farming is abundant and, yet, data are not sufficiently rich so as to capture DW dimensions to be applied to these quantitatively important but highly diverse group.

2.3.4 Accounting for decent work among small-scale producers

This section focuses on some of main methodological and conceptual challenges in the definition of 'smallholders' and in the operationalisation of DWI in the situations of self-employment in agriculture.

In many parts of SSA and many LICs, most rural dwellers have some access to land, so they are liable to be recorded as agricultural producers, given their attachment to such land. This, however, does not mean that they depend primarily on their land-based activities as much of the RNFE literature has shown. The issue is that, as a group/category, is excessively heterogeneous, even if it concentrates a significant proportion of the 'rural poor' according to much of the literature. If a survey collects enough background information about farm households or small-scale farmers at least a continuum of cases can be devised along the set of the categories below:

a. Small (agricultural) producers who consistently employ labour and for whom the only relevant questionnaire is the module on 'agricultural production' (and sales), including information on the labour they hire, possibly obtaining relevant information for DWI. Although it is not ideal to obtain DW data from employers (in this case small-scale producers), this route may be better than failing to sample the casual workers employed by them. Relevant DWI that could be collected from this category are agricultural wages, incidence of labour market participation in poorly paid casual agricultural jobs, and non-wage aspects of the employment relation.

b. Small (agricultural) producers who employ labour but also frequently or significantly work for others (in farm and non-farm sectors), in which case it is equally important to collect detailed information about agricultural production and wage employment. Information on wages, non-wage conditions (benefits) and time-related under-employment can be collected from this category.

c. Small (agricultural) producers who may not or only sporadically employ labour and mainly rely on family labour and who do not work outside their farm, in which case detailed information about their agricultural production' work done on the farm and agricultural sales is necessary. Here the focus of DWI data collection can be on the irregularity and levels of earnings (farm income), time-related underemployment, child labour and excessive hours during peak periods.

d. Small (agricultural) producers or landless workers who essentially depend on their wages (agricultural and non-agricultural) and for whom the key modules would be one on wage jobs. The focus of data collection would be on the quality of jobs accessed as well as on time-related underemployment.

Small-scale producers will be normally situated along the continuum of those categories. Note that the same 'profiles' may also be engaged in own-activities in non-agricultural sectors, for which a questionnaire ought to include a specific module too. This heuristic classification serves to illustrate the fact that 'small-scale producers' as a single category may be too ambiguous and broad. To tackle this issue there are three main conceptual and methodological challenges that need to be addressed in order to better capture DW among small-scale producers:

1. Defining the 'smallholder' as an agricultural producer, in terms of scale, use of labour and other attributes.

2. Distinguishing 'smallholders' from other groups of people in the 'rural sector', especially from wage workers.

3. Distinguishing different classes of smallholders.

[29] http://www.ilo.org/global/statistics-and-databases/lang--en/index.htm http://go.worldbank.org/JF4LVHJBS0.

2.3.4.1 Defining a 'smallholder' or self-employed small-scale producer

As with other labour categories, the definition of small-scale producer may not be as straightforward as that of simply 'own-account worker' in the agricultural sector. A key issue is what is meant by 'small', as references to farm size only may result in some inconsistencies and bias.

Dixon et al. (2004), in an FAO book/report (Smallholders, globalization and policy analysis), note that 'the definition of smallholders differs between countries and between agro-ecological zones. In favourable areas with high population densities, they often cultivate less than one ha of land, whereas they may cultivate 10 ha or more in semi-arid areas, or manage 10 head of livestock. Often, no sharp distinction between smallholders and other larger farms is necessary.' The quote reflects the confusion around the meaning of 'smallholder'. The Ethical Trading Initiative (ETI) Smallholder Guidelines (2005) explicitly state that 'the definition of smallholder differs significantly according to crop, and to the social, cultural, economic and political context' (p. 13). As an alternative to definitions based on farm size the ETI opts for a definition that encompasses a number of well-established criteria whereby 'smallholder farmers' or small-scale producers:

a. produce relatively small volumes of output on relatively small plots of land;

b. may produce an export commodity as a main livelihood activity or as part of a portfolio of livelihood activities;

c. are generally less well-resourced than 'commercial-scale' farmers;

d. are usually considered as part of the 'informal economy' (not be registered, excluded from aspects of labour legislation, limited records);

e. may be men or women;

f. may depend on family labour, but may hire significant numbers of workers;

g. are often vulnerable in supply chains.

These multiple criteria refer to production scale, market orientation, relative resource endowment, levels of 'informality' and labour use. These are common to many other definitions and often implicitly assumed more than explicitly stated. In relation to 'scale' a challenge is whether farm size should be preferable to farm capitalisation or business scale (e.g. annual turnover). This is particularly important in the light of bad measurement of land size in contexts of scarce resources for data collection (Carletto et al. 2015; Hannertz and Losch 2006). Moreover a particular farm size means different things depending on the crop, the technology and the production system. For example, in Ethiopia, compare a 2ha technologically sophisticated flower farm that may require US$ 1 million of start-up investment with a cereal (teff) farm of equal size that can be started with a few hundred dollars to start up or even less. In large agricultural producing countries in Latin America, such as Argentina, the definitions are on a completely different scale. An institutional report in 2007 (Scheinkerman et al. 2007) defined 'small producers' in terms of labour use and some farm size ceilings, usually set at 500ha (!). As Berdegué and Fuentealba (2011) note in relation to Latin American smallholders, 'the "2 hectare" definition is a measure of our ignorance and not of our understanding of smallholder farming, nor of what is needed for well-designed strategies and policies'. However it is widely used in the literature (cf. Wiggins et al., 2010; Hazell et al., 2010; IFAD, 2010). Many surveys tend to concentrate on (badly) measuring land, when they could more systematically collect up-to-date data on investment and capitalization. Furthermore, given the fact that in many contexts (such as India) land can be used under multiple tenancy systems it makes sense to talk about 'cultivated land' rather than owned land.

The definition of 'small-scale' producers/farmers also hinges on data collected on labour use. Bernstein (2010) suggests that typically small-scale producers are defined as those whose farm size is determined by the availability of family labour and often conflated with the idea of 'subsistence production'. Thus in its 'pure' form, a small farmer would only use family labour on a relatively small farm, size-wise, and without selling labour in the labour market, i.e. without being a wage worker as well. The Fairtrade Labelling Organisation (FLO) also defines a smallholder as a producer who is dependent on family, as opposed to non-family, labour. However, it is well known that small-scale agricultural production heavily depends on casual wage labour inputs, and the exclusion of this category therefore introduces another serious bias in the definition (Cramer et al. 2014).

As with other labour categories, context matters also for the operationalization of definitions of small-scale farmers. The key lesson from this discussion is that surveys may start with a broad 'international' definition based on a combination of criteria (relative production scale and labour use patterns), but then will have to adapt such definitions to each context in terms of: country, crop and technology. In other words, universal criteria such as 'less than 2 hectares' or 'only using family labour' should be avoided. Surveys ought to collect more and better information on business scale (production scale, investment) and on the use of labour (whether family or hired, permanent, seasonal or casual), i.e. directly by asking small-scale producers.

2.3.4.2 Distinguishing smallholder farmers from other people in the 'rural sector'

The problems in defining 'small farmers' have an impact on the distinction between 'small farmers' and 'wage workers' in rural areas. This distinction may be problematic in rural contexts of LICs, characterized by occupation multiplicity, insofar as many smallholders could also be considered 'wage workers'. In many parts of SSA, South Asia and elsewhere, large segments of the 'smallholder population' straddle occupations between different forms of wage labour and their own-account farming, in addition to petty non-farm business. They frequently combine the 'places' of capital and labour, which makes their treatment in analytical and statistical terms rather complicated (Bernstein 2010). Whether they are more reliant on their own account farming or on wage employment is an empirical question that many household surveys fail to adequately ask and probe, resulting in biased representations of what people do in rural areas and underestimates of the incidence of rural wage labour as argued in section 2.3.3.

A couple of practical examples may help illustrate these ambiguities, which require careful survey design:

Box 1. Employment status: ambiguities and diversity. Case 1

Case 1. Border between Senegal and Mauritania, semi-arid context

Mr Diop has a 1ha farm along the bank of the Senegal river in Senegal. He combines the cultivation of a small plot of irrigated rice for commercial purposes and millet and vegetables for own family consumption and some for the market. He and members of his family travel across the border to find employment in a horticultural plantation named GDM, which employs hundreds of casual labourers on a daily basis especially during harvesting times. Diop and his family use the money obtained with their seasonal work to buy fertilizers, complement the purchase of food (some of which is cheap imported rice) and to pay for irrigation costs. Mr Diop has been a member of the state-promoted rural cooperative for the past 20 years and is now member of a small GIE (*Group d'Interet Economique*), set up by a number of wealthier farmers of the area to attract NGO funding and credit. They use the GIE also to lobby the government for more support in irrigation facilities and more remunerative marketing arrangements. None of the Diops is member of a trade union on the Mauritanian side to look after their interests as employees of GDM.

NOTE: DIOP & FAMILY COULD BE EASILY CLASSIFIED AS SMALLHOLDER RICE FARMERS, SINCE THEIR LOBBYING INTERESTS AND FARM CASH INCOME DERIVE FROM RICE FARMING AT A SMALL SCALE, BUT THEY ARE ALSO WAGE WORKERS INSOFAR AS THEIR EMPLOYMENT IN A NEIGHBOURING PLANTATION ACROSS THE BORDER IS CRUCIAL FOR THEIR LIVELIHOODS AND THE SURVIVAL OF THEIR SMALL FARM. **A CATEGORY SMALLHOLDER/MIGRANT WORKER WOULD BE RELEVANT TO THIS CASE.**

Box 2. Employment status: ambiguities and diversity. Case 2

Case 2. Tobacco outgrower farmer in Manica, Mozambique

Mr Bolacha is a small outgrower tobacco farmer in the province of Manica, central Mozambique. Bolacha is a Mozambican citizen and return migrant from Zimbabwe after the events of the fast track land reform in 2000. He managed to get some land in his family village and used his contacts with tobacco farming companies to obtain an outgrowing contract with one of them, farming 1.5 ha of tobacco, in addition to 1.5 ha of maize and vegetables. He also owns three cows. Mr Bolacha has invested much of his savings from years of work as farm labourer in Zimbabwe in his own-account farming. He employs family labour in his tobacco and food crop fields although his son has recently migrated to neighbouring provincial capital Chimoio to work in private transport as a driver.

Bolacha depends enormously on the support of his tobacco buyer, in terms of credit, technical assistance and access to fertiliser. He has also joined an association of tobacco outgrowers to lobby for better contractual conditions.

Bolacha employs one permanent worker as his family labour is not sufficient, especially for highly time demanding operations in tobacco cultivation and basic processing. At the time of harvesting he also routinely employs 5-10 casual daily workers from his village and surroundings.

NOTE: **THIS CASE WOULD BE CLOSER TO A SMALLHOLDER-EMPLOYER** WITH TYPICAL COMMERCIAL FARMER INTERESTS AND LOBBYING NEEDS VIS-À-VIS CORPORATE AGRIBUSINESS/BUYERS. HIS PAST AS A FARM LABOURER COMPLICATES HIS SELF-REPRESENTATION AS HE SEES HIMSELF AS A 'SIMPLE HARD WORKER' AND NOT AS AN EMPLOYER.

These two illustrations shows the potential for bias if the two cases are simply classified as 'small farmers' with implications for a proper understanding of DW deficit in each of these cases. Therefore, when collecting information on people who may be generally classified as 'small farmers.', it is important to work with context-specific categories that contemplate the possibility of non-overlapping definitions and which would allow a more precise distinction, for example between 'small-scale agricultural own account workers' and 'people who mostly depend on casual agricultural wage incomes for their own and their families survival'. Both may have land and farm but are not affected by the same DW deficit issues.

2.3.4.3. Distinguishing among different 'classes' of small-scale producers and generating DW deficit estimates for small producers

Assuming that a distinction between categories can be established, the next challenge is to account for heterogeneity within these categories. In the case of small farmers who mostly depend on their own-account farming to live, how do we account for wide differences in assets, vulnerability, farm practices and labour relations among them? How do we account for the differences between a 'small farmer' who barely produces surplus for the market from one who is strongly commercially oriented and largely depends on markets for his/her survival with much higher returns to his/her labour and capital? The constraints they face may be different and their aspirations and priorities may also differ.

Much of the agrarian political economy literature works with such distinctions. For example, in the literature on India it is common to see a distinction between: poor (marginal) smallholders, middle farmers and richer farmers (NCEUS 2007). These distinctions may be articulated in terms of relative DW deficits. For a self-employed farmer, the key issues in terms of the quality of this employment would be:

1. Time used in the activity (given a level of farm income, less time is better than more time, and particularly avoidance of excessive hours during the peak season).

2. Returns to labour time, in terms of net returns to the farm business but including the returns to the household labour employed (Samphantharak and Townsend 2012), which requires imputing monetary values to hard-to-estimate agricultural production (Carletto et al. 2015).

3. Volatility of farm income, determined by the volatility of production, especially in contexts of rainfed agriculture, and the volatility of farm prices in the contexts of liberalization. Uncertainty and vulnerability are indeed issues that affect the DW status of small producers.

4. Assets consumed/used, new assets acquired (investment) and an estimate of returns to capital, by considering the opportunity cost of assets used (especially land) – (Carletto et al. 2015).

5. Access to producer organizations or forms of associational power that may help them manage risk and vulnerability.

6. OSH (occupational safety and health) hazards, including possible pesticide poisoning or attacks from wild animals, and availability/access to mechanisms to prevent such hazards.

7. Access to social protection mechanisms, which can enhance income security and reduce need for last-resort low-paid activities (usually characterised by high DW deficit).

Collecting accurate information on the 7 above aspects, especially on the first and the second, will provide the basis for a realistic account of DW status among small-scale producers and will allow for identification of classes of small farmers that are more severely affected by DW deficit. The challenge will be to define, if necessary, any benchmarks whereby a DW 'deficit' is established. This is unlikely to work ex-ante unless a measure of minimum returns, related to ongoing minimum wages, average agricultural wages or to the national poverty line can be accepted as suitable benchmarks to assess returns to small-scale farming. For both under-employment and excessive working hours, weekly or monthly benchmarks could be also applied if time-use is accurately measured. Whether producers access cooperatives or other forms of collective representation may be used as benchmark, but such indicator would not tell us the extent to which individual producers do benefit from or are active in these organizations. Finally, far more difficult is to find benchmarks for aspects 3 and 4. However, a maximum level of farm income volatility (as coefficient of variation), informed by knowledge of national realities, could be devised, particularly through simple questions on maximum and minimum farm incomes over different periods; also, the acquisition or not of new assets could be used as benchmark for DW deficit in relation to assets, or any evidence of asset depletion (sales, loss) as a qualitative measure. This would be however harder to operationalise. An option may also be to find a benchmark for business incomes and asset use in other sectors/areas and assess the relative distance between these and the results for agricultural producers, as a proxy for DW deficit.

Meanwhile, data for OSH are likely to be hard to find in available surveys and the range of hazards may be large, which can complicate the choice of key risks for measurement purposes, especially when hazards vary a lot from one agro-ecological context to another. Access to basic social protection measures may be relevant in some cases and not in others, but it is not advisable to miss out such possibility, since it does have an impact on DW standards.

To be sure, obtaining accurate information on the above indicators/issues is a major challenge in LICs, given the measurement problems with basic agricultural data and incomes in smallholder population settings (Carletto et al. 2015), which will be briefly discussed in the section on questionnaire design.

2.4. Towards a more relevant and operational set of DWIs in low-income countries

Based on the detailed considerations on various aspects of the relevance and reliability of DWIs in rural areas, and considering some of the specific challenges in dealing with irregular employment, 'informality', capturing wage employment and devising specific DWI for small-scale producers, this section briefly selects a set of indicators that may be more relevant to the rural contexts of LICs and contain a more consistent mix of key aspects of DW in these contexts. Considering what was said in section 2.1 on the excessively long list of dimensions and indicators, a more limited and necessarily more selective set would make operationalization easier and would also allow for a concentration of efforts and resources in improving the reliability of the data for these indicators and adding new dimensions that have not been properly accounted for. The table below shows a selection from the list of 'main' and 'additional' DWIs as devised by the ILO (2012). This is followed by a shortlist of additional indicators that do not feature in the main ILO list but are related to some of the 'main' ILO DWIs. The additional indicators would be helpful in terms of complementing and improving the evidence collected for the main DWI. They are designed to capture the particular vulnerability of certain groups of workers whose employment experience is characterised by irregularity and by the need to straddle multiple casual activities in order to survive. The incidence of employment remunerated in kind is also an indicator of precariousness and casualization. Finally, and given problems with capturing child labour a particular indicator can be added to capture child labour that is performed for pay and someone else, which is important

Table 2: DW Indicators: priority selection from available lists

Indicator from DWI list (and ILO link)	Sources	Comments and possible adjustments
Children not in school (%) – CONT1	Census, UNESCO, DHS	Key issue will be to use consistent sources since there can be discrepancies between official data and DHS-type data
Employment by status(%) – EMPL8	Census, LFS, HBS	Problematic if 'main occupation' and 7-day question apply
Labour underutilization or Time-related underemployment (%) – TIME4	LFS, HBS	It should not be limited to hours within last 7 days but extended to 12 months reference period – Ideally surveys should capture total number of days of work per year effectively done
Working poor – EARN1	HBS	Relies on good estimates of poverty lines and needs to be disaggregated by employment status
Low pay rate (below 2/3 of median) – EARN2	LFS, HBS?	Requires detailed wage data across different activities and including casual workers and especially in agriculture where the worst paid jobs tend to concentrate
Average real wages (especially in agriculture) or an 'agriculture wage index' –adaptation of EARN4 and EARN6	LFS, HBS?	Special focus on agriculture and wages paid to casual workers – since these are the most likely to be over-represented among the working poor and the poorest of the poor
Excessive hours (in relation to week) –TIME1	LFS, HBS	Not easy to operationalize when there is no minimum for rural / agricultural employment but important especially for peak agricultural labour periods when working days can be very long (10-14 hours)
Child labour (with disaggregation) – ABOL1	LFS	It may be hard to apply in situations of 'disguised child labour'
Forced labour – ABOL4	LFS	Hard to operationalize and requiring various probing questions in a questionnaire
Precarious employment rate –STAB1	LFS, HBS	Criteria for 'precarious' need to be discussed by context
Casual workers in agriculture / rural (% total employment) – as part of STAB1	LFS, HBS	Needs a suitable concept of 'casual' – less than 6 months and less than 20 hours per week?
Occupational segregation by sex – EQUA1	LFS, HBS	Question is benchmark especially in contexts where activities are highly gendered
Occupational injury frequency rate, fatal and non-fatal – combination of SAFE1, SAFE2 and SAFE3	LFS	Hard to find consistent and complete data across rural sectors
Labour inspectors per 10,000 employed persons – SAFE4	LFS	Possibly available at aggregate level but less so for agriculture / rural areas
Trade union density rate – DIAL1	LFS	Not likely to differentiate between LICs as all characterized by very low densities

Table 3: DW Indicators: new additional indicators for consideration

Additional indicators	Sources (potentially)	Comments and possible adjustments
Number of days per year effectively worked	LFS, HBS and micro-surveys	The main challenge is to obtain an accurate indicator when several casual activities predominate – the use of an employment matrix can help
Longest period of time without any remunerated work	LFS, HBS and micro-surveys	This complements the previous indicator and helps identify groups of workers particularly vulnerable to periods of lack of work
Occupation multiplicity (total number of reported economic activities)	LFS, HBS and micro-survey	As above – the use of an employment matrix can help address this need
Paid child labour (excluding unpaid contributing family labour)	LFS, HBS and micro-surveys	This requires a distinction between child labour performed as 'contributing family workers' and child labour for someone else, sometimes involving direct payment
Percentage of wage workers paid in kind (including small-scale producers)	LFS, HBS and micro-surveys	This can be an additional percentage indicator to complement previous indicators on precarious employment and casual work and particularly important in rural areas of LICs
Occupational safety and health – specific agriculture specific indicators	LFS, HBS, Agricultural surveys, and micro-surveys	This is part of the core DW agenda but can be adapted to realities of agricultural contexts and be applied also to own-account producers and contributing family workers. Examples are: 1. Incidence of hazards per worker such as snake bites, infections, and so on in any given year 2. Use of pesticides and other hazardous material/equipment (per worker per year)
Farm income volatility	HBS, Agricultural surveys	Considering the challenges in obtaining reliable indicators of returns to labour in own-account farming, data on volatility may be especially important, since the variation in remuneration via farm incomes is a major driver of poverty and seasonal shocks. This indicator can be constructed through questions on highest and lowest farm incomes in a given year and comparing three years, if a measure of continuous farm income over 12 months is hard to obtain
Association/producer organisation density rate	HBS, Agricultural surveys and micro-surveys	While trade union density can only apply to wage employees, a measure of collective bargaining and associational power may also be relevant for self-employed producers, particularly small-scale farmers. The indicator can be similar to the trade union density but referred to producer organisations (instead of trade unions) and small-scale farmers (instead of wage workers)

and perhaps a form of child labour even more alarming than child labour within a family operation (farm, non-farm business).

The key DWIs listed above can potentially assist in establishing a framework that is particularly relevant for rural areas and LICs in particular. DW deficits in these realms are critical and can provide a consistent picture of labour market performance and the realities of employment in poorer countries. They are also particularly important for agriculture and also apply to small producer.

3. Survey design challenges and options

The previous section has provided an extensive discussion of key conceptual and methodological challenges in the applicability of a DW statistical agenda for rural employment especially in LICs and in SSA. One of the key arguments advanced in that section is that methods and the way data are collected matter a lot for the achievement of this difficult aim. There is an increasing awareness that collecting household and individual-level information on employment, production, and incomes is marred by difficulties and practical challenges, and results in the misapplication of international conventions. In short, survey design matters for all kinds of data. And it matters particularly for key data on agricultural production, poverty and indeed labour, particularly, but not only, in LICs.

The World Bank and its Surveys and Methods team have engaged in recent years in an ambitious programme of data quality experiments. Some have been conducted to assess issues of survey design and effects on employment data[30]. For example experiments were conducted in Tanzania which 'assess the effect of different ways of collecting labour statistics. It uses two different modules, a long module and a short module, and administers each to either the person him/herself or to someone else in the household answering on their behalf (a proxy respondent). Both proxy respondents and self-reporting respondents are sampled randomly from the roster of household members[31].

The central concern of all data collection activities should be exposing the 'truth' and the avoidance of any systematic biases. In reality, it is impossible to make socio-economic observations that are entirely free of biases – the real world is not a laboratory. That said, it is important to attempt to prevent the worst forms of bias, and particularly systematic biases. There are different types of biases that can lead to measurement error in labour surveys: cultural and wealth differences between respondent and interviewer leading to under-reporting or exaggeration of activities; application of inadequate categories/conventions on key concepts/ indicators; language issues, especially when translation is needed and key terms have not been properly translated; expectations of benefits and incentives on the part of the respondent, leading to responses driven by how the respondent thinks answers could increase benefits.

Some of the points made in this section and the recommendations provided are based on extensive experience in conducting rural labour surveys and in the associated literature of micro-level case studies that have developed and implemented similar methods (see Oya 2013, Oya and Pontara 2015, and various references therein). By and large, many of these case studies make use of mixed methods in micro-level surveys, and place emphasis on capturing occupation multiplicity and the specificities of each type of labour relation in each context[32]. Research methods in these studies are in some ways innovative, especially in their attempt to better capture nuances and concealed aspects of labour relations, labour market participation and workers' mobility. A careful integration of quantitative surveys and in-depth qualitative research focused on longitudinal aspects of employment histories, is a demanding but rewarding approach. In addition, qualitative research can contribute to better survey design by ascertaining key terminologies and concepts, and give insights into the perceptions and aspirations of different categories of rural people. Common to this research is some differences in the design of the questionnaires, the sampling decisions to capture the 'hidden populations', the selection and the training of interviewers, as compared to large-scale nationally representative surveys. The point here is that national surveys could indeed learn from the micro-survey experience and scaled lessons up, even if perhaps not all innovations are equally feasible in the context of a large-scale nationally representative household survey.

The challenge of integrating such innovations into established frameworks for national household surveys cannot be underestimated. There is of course a need for embedding the improvements in the collection of rural labour data into the national statistics strategies of developing countries. Sometimes compromises may be necessary as it is impossible to have the 'ideal' questionnaire or survey design. There is currently an ongoing process of revisions in data collection systems. Many African countries are revising their GDPs, for example (Jerven et al 2015), and generally both aid agencies and governments in most developing regions are working to tackle some of the challenges discussed in this paper (see, for example, AFRISTAT and Paris21 Secretariat 2008 and http://www.copenhagenconsensus.com; Glassman and Sandefur 2014 and their work at the CGD). The main argument is the need to make sure that some of the efforts at improving the measurement and statistical capacities especially of LICs are sustainable over the long run through their institutionalization in data collection systems and protocols. In that regard, the recommendations in this paper and the tools to be subsequently piloted at country level should provide a basis to inform and influence national strategies for data collection. It is foreseen that for that to happen, countries should allocate sufficient funding for the collection of the relevant data, as well as to strengthen their NSO capacity for collection and tabulation/ analysis. Unfortunately much of the data collected is never really tabulated and analysed, especially at more disaggregated levels.

While there are far too many survey quality issues that could be discussed, this section will focus on the most salient aspects that may affect the quality of DWI in rural areas of LICs.

3.1. Sampling issues

There are various sampling issues and decisions that are central to any survey design. First is the sample size and whether the data are planned to be statistically representative of a population. For statistically representative data a key question is the level at which inference is to be made (national, provincial, district) and the degree of heterogeneity of the target population. In cases where the whole rural population is the target then heterogeneity is likely to be a challenge and detailed information is needed for adequate stratification (by administrative area, agro-ecological zone, density, gender, age, production scale, socio-economic status, etc.). Thus, required sample size may be large if substantial heterogeneity is anticipated. Second, when the goal is not broad national-level statistical inference but capturing a particular issue (wage variation and determinants in agricultural employment) or a particular population (child labour, seasonal migrant labour), sample design must take into account the challenges of finding relevant respondents (especially for 'hidden populations') in the absence of adequate sample frames. Related to this is whether sampling is based on a residence-based

[30] See http://go.worldbank.org/KAI66PHUY0.
[31] Look for SHWALITA (Survey of Household Welfare and Labour in Tanzania) http://edi-global.com/publications/.
[32] See also collection of papers in forthcoming Oya and Pontara (2015).

framework or on a job-based one. In contexts where significant numbers of workers (especially in agriculture, harvesting) are resident in urban areas and work seasonally in agriculture, a job-based framework may be more suitable, or simply a framework where seasonal migrant labour is captured regardless of the 'permanent' residence of respondents (see also discussion of household roster below).

National household surveys aim to obtain statistically representative data for the overall population. While this aim is justifiable the conventional methods used to attain sometimes come at the expense of little or biased coverage of some particular groups, which can be considered in sampling terms as 'hidden populations'. Seasonal migrants, children at work, people subject to human trafficking, people not residing in 'normal' residential units or not being part of official household lists at village level. There are many cases and all relevant for an accurate picture of rural DW deficits. This underscores the need to rethink sampling methods to make sure hidden populations are included even in nationally representative samples.

In this regard, seasonality is a related aspect that has implications for sampling. In section 2.3.1 the paper has discussed the centrality of 'irregular' employment in LIC contexts and how some activities are concentrated in particular periods compared to other activities. This means that the time of the survey matters and that sampling may have to be adapted to make sure all relevant activities are captured. Although this is possible through 'good recall'[33], the reality is that misreporting of details of activities may be due to interviews taking place when the activity is not ongoing. In contexts of multiple occupations the time of the survey may thus lead to under-reporting of some activities, especially if they are of a casual nature. There are also implications for some of the 'hard-to-reach' populations who may only be available at a particular place during a particular period of time. Therefore, in contexts where migrant labour (for agricultural and non-agricultural employment) needs to be captured, survey designers will need to identify the periods when this 'population' can be found for interview purposes. Missing the right period may mean missing these specific groups altogether. The main mechanisms to circumvent these challenges are twofold. First, survey designers may decide to organize data collection in different rounds within a given year (as it is done for HBS) once seasonal patterns have been identified. Second, questionnaires can be designed to provide full information on all activities for a 12-month reference period, making sure interviewers are well trained to probe answers and make sure there is not any activity that goes unreported.

Another issue is sample size. Most national household surveys have a large enough sample size for statistical representitivity at fairly aggregate levels (national, rural/urban, provincial/regional). However, this works in contexts where there is sufficient population homogeneity within these aggregate strata. If multiple distinct groups who are not randomly distributed exist in a given context, then the risk of missing them out or under-sampling is great. For example, agricultural wage workers and migrant labourers may be concentrated in particular pockets of dynamic export agriculture (Ejido in Spain, Sao Francisco Valley in Northeast Brazil, flower producing areas in Ethiopia, etc.). In addition, the different categories of small-scale producers may also be more concentrated in some places and harder to find in others without any random pattern. Information about more conventional groupings by gender or age-groups is also necessary to make sure stratified random sampling works well. These situations require not only a larger sample size but also 'pre-survey scoping research' to attempt to identify whether there may important 'hidden groups' in a given national context, and where these 'hidden groups' concentrate or in what kind of residential units they tend to live to adapt sampling methods to capture these groups while keeping the core probability sampling techniques. What do we mean by 'pre-survey scoping research'?

Essentially the combination of carefully designed qualitative scoping research to reveal some of the patterns mentioned above, in addition to consultation with experts with extensive fieldwork experience in the rural areas of a given country.

In addition to the scoping research implemented to improve the sampling process, when data collection starts, there are also other options for serious consideration:

1. Conducting a fresh full census to construct an up-to-date sample frame, including residential units that may house temporary migrants or people without fixed residence, as well as areas where child labour and forced labour are known to be present.

2. Including additional stratification in the sampling stages to be able to capture some of the hard-to-reach groups.

Cramer et al. (2014) elaborate on the first point. Their argument is that official household surveys in African countries (and one could argue also in other developing countries) such as Ethiopia and Uganda are based on samples drawn from lists of rural households provided by village-level authorities[34]. The problem is that sometimes these lists are politically manipulated, i.e. often used as the basis for the distribution of scarce resources such as food aid, or subsidized agricultural inputs and credit., which may lead to potential biases in

[33] Good recall refers to the capacity of respondents to remember activities in which they have engaged in the reference period. For example remembering all activities for a 12 month-period would be very good recall compared to just remembering activities in the past 7 or 30 days.

[34] See also a related example on 'hidden' migrant populations in peri-urban areas of Vietnam (Pincus and Sender 2008).

reporting if authorities have an interest in excluding particular groups[35]. Fieldwork experience also suggests that, apart from potential systematic exclusion of some marginalized groups, many of these lists are far from up-to-date and may exclude newly arrived individuals or households[36].The alternative adopted by the FTEPR research (Fair Trade Employment and Poverty Reduction project www.ftepr.org), documented by Cramer et al. (2014), and which can be proposed in the FAO pilot surveys, is to create a sample frame on the basis of a new and complete census of all types of housing structures discovered in the research sub-sites that have been previously selected for the survey. The definition of the 'Residential Unit' is broad enough to minimize biases towards more 'established' households, hence worded as any structure in which at least one person was sleeping. This would mean that a very basic structure, even without a roof, where squatters sleep (likely to be temporary migrants), could be considered for the sampling frame. A challenge would be whether this method can be 'mainstreamed' in national surveys, since these follow long-established sampling frameworks, household-based lists (rather than simply residential units) and use the same methods over long periods of time to ensure comparability over time. In principle, the advantages of the proposed innovations probably outweigh the possible logistical constraints but one cannot underestimate the potential resistance to such changes. However, one possibility, assuming that there is a sufficiently recent population census, would be to combine existing official sampling frames, especially if countries have renewed and updated the local registers, with ad-hoc additional lists prepared by fieldworkers for potential respondents who are temporarily in the area (e.g. migrant workers, people without fixed residence etc.) but fail to be included in official registers. Such combination of sources would not be too onerous and would substantially improve the coverage.

The above innovation is at the heart of debates about operationalizing the concept of the 'household'. Trying to work with a universal concept of the 'household', which is central to most surveys, is in fact a major challenge, but frequently ignored by survey designers and data users. There is increasingly substantial research, including survey experiments, which highlight some of the challenges and biases derived from the uses and misuses of the concept of 'household' (O'Laughlin 1995; Randall and Coast 2015). In the next section on questionnaire design, we elaborate further on this, looking in particular at the questionnaire requirements for an adequate identification of household rosters for the purposes of measuring DWI.

However, as advanced above, rigid definitions of the household may lead to exclusion of key groups. Carr-Hill (2014) notes how population censuses and household surveys routinely 'omit by design' or under-report mobile 'footloose' populations, particularly nomadic or pastoralist populations, internally displaced people who may have lost their homes, and institutional populations (such as but not only care homes, factory barracks, hospitals, the military, refugee camps, etc.). In practice, he argues, surveys also tend to miss out fragile, disjointed or multiple occupancy households, people living in slums, and areas that pose some security risks. To this it could be added that in situations where child trafficking, forced labour and child labour happen, conventional surveys are unlikely to capture them because they get misreported as de facto 'contributing family workers' at their employers' households[37].

With regards to 'fragile, disjointed or multiple occupancy households' and similar cases, Randall and Coast (2015) discuss evidence from Tanzania and Burkina Faso, where 'households' may be of different types and organised in different ways, defying the application of rigid household definitions, and requiring new typologies, like the one they propose of 'open' and 'closed' households. Accounting for pastoralist groups is quite difficult because of their mobility but also because of the social organisation and the different prevailing notions of 'household'. For example, official surveys tend to split-up Masai 'open' households ignoring their preference to consider themselves to be one economic unit of production and consumption. Part of the problem is also survey logistics and the difficulty of dealing with loosely extended households. When these nuances are not captured at the design stage, the implication is that (often poorly trained) interviewers are left to decide who to include and why in a given household roster, reflecting the power of interviewers in translating these complex concepts into something meaningful in both small- and large-N surveys (Randall et al. 2013).

Taking into account the challenges with rigid definitions of the household and the fact that a lot of the DWI apply to the level of the individual, an important sampling issue is whether the key unit of observation is the household or the individual. In reality this dichotomy is problematic since both are interrelated. However, for practical purposes and given that labour indicators normally refer to the individual, the anchor unit of observation should be the individual as long as an appropriate system to define the household roster is adopted (see section 3.2.1). This is important especially when own-account activities involve the pooling of family labour, especially in farming and the analysis of the activity could be done at 'household level'. However, in practice it is possible to collect household-level evidence (including on the 'farm enterprise') even when the anchor unit of observation is the individual who acts as 'principal respondent' and from whom a household is empirically defined. Then individual- and household-level information can be linked through identifying codes. What matters is that enumerators are well trained to know when they need to ask at the level of individual and when at household level.

In sum, although it is a challenge to question well-established and deep-rooted conventional sampling methods, the issues discussed in this section are serious and should provide the basis for some re-thinking,

[35] See, for instance, related ethnographic work in Ethiopia by Bishop and Hilhorst, (2010) cited in Cramer et al. (2014).

[36] See examples in Cramer e t al. (2014).

[37] See, for example, Anyidoho, N. and P. Ainsworth (2009) on West Africa.

and notably to consider:

a. Measures to capture 'hidden' or 'hard to reach' populations (like the ones mentioned here, such as avoiding official lists or including different types of residential units).

b. The operationalization of a more flexible definition of 'households', to accommodate a variety of circumstances that may be important in any particular national and local context.

c. The focus on individuals as anchor units of observation for DWIs, while context-relevant and empirically observed household units are also addressed in the data collection process, resulting in three types of data: individual, household (including a 'family activity') and job/activity. What matters is that the three levels are consistently linked and no relevant information is missed out.

3.2. Questionnaire design

This section focuses on key aspects of questionnaire design that can have an impact on the quality of data for DWI. The discussion is also based on available survey experiments (especially at the World Bank), relevant literature on survey methodology and especially the author's own survey experience. The focus is on two key issues: the household roster, or who is included in the list of household members and the information collected therein; employment modules and labour data issues. A key message is that the consideration of alternative definitions (household roster), the re-organization of employment modules to avoid typical biases, and the precision and context specificity in questions and wording are key to obtain higher quality data.

3.2.1. The household roster

Who is included or not in a household roster matters a lot for indicators of well-being, which are frequently collected at household level but then normalized per individual, consumption and income being leading examples.

Recent survey experiments with alternative definitions of the household and different ways of preparing a household roster show a significant impact on survey outcomes. According to Beaman and Dillon (2012) slight changes in definitions of the 'household' lead to significant variations in both household size and household composition, with important implications for the measurement of basic outcome variables, such as per capita consumption expenditure, asset statistics and per adult equivalent agricultural output measures, which may affect any analysis of DW deficits. The conundrum is that, on the one hand, a consistent and easy to interpret household definition is required for time and population comparisons, but, on the other hand, over time and for a given population, 'the definition must also identify the correct economic or decision making unit, which may in fact differ according to the research question'.

Leone et al. (2010) and Randall and Coast (2014: 6), reporting on various case studies, show that 'children move between households on a weekly or longer-term basis' rendering multiple households 'open'. Therefore, the decision of where to include a child is not straightforward if the criterion is one of residence and/or consumption. Akresh and Edmonds (2010), in another experiment, show that that households are extremely fluid, and characterized by substantial mobility of some of their individuals with 10 percent of individuals spending some time away over a three year period, averaging 16 of the 36 months away. This phenomenon is not randomly distributed across household members but affects specific categories such as the youth, hence leading to potential bias and miscounting if rigid definitions of residential status are applied. Avoiding this kind of bias would require consideration of different and less stringent residential criteria or using alternative criteria such as 'economic linkages' regardless of residence patterns as suggested in the paragraph below.

In light of the rigidity and potential bias of standard 'residential' definitions of the household (such as being resident for over 6 months in past 12 months), Cramer et al. (2014) and the FTEPR research (FTEPR 2014) opted for an 'economic' definition of the household roster to avoid the bias of missing out key individuals who may be important to understand the wellbeing of the household. The concept of a list of 'economically linked' individuals offers additional and extremely useful information on labour market participation and the other characteristics of individuals usually considered 'absent' (according to strict residential definitions) and therefore irrelevant to an analysis of the welfare of rural populations[38].

The implication of this discussion is that a more detailed and thorough measurement of household composition in multi-purpose household surveys is essential to avoid systematic biases in the estimation of key outcome variables. In addition, some changes in definitions could be contemplated, such as the option of using 'economic linkages' between members and not simple residential rules. The main possible drawback

[38] The four following categories of linked individuals could be thus identified and surveyed (directly or through proxy respondent): (1) those who live permanently with the principal respondent and who share income and expenditure; (2) those who, even if not sharing residential accommodation on a regular basis, make significant economic contributions (in cash or in kind) to the expenses of the household/respondent; (3) those who, even if not sharing residential accommodation, regularly depend on economic contributions in cash or in kind from the respondent or others in the RU; (4) those who, even if not resident at all in the same place as the respondent, either can be relied upon by the respondent, or receive contributions from the respondent.

is related to training. Applying an economic definition of the household is less straightforward and therefore more training time-consuming than a conventional residential definition. Sometimes the criteria for 'economic linkage' may be ambiguous and sometimes may result in unmanageable household rosters. These problems, however, can be tackled through careful selection, training and supervision.

3.2.2. Employment modules

An important question for good quality DWIs is measurement error. Some indicators are particularly vulnerable to this kind of non-sampling error. There are different areas in which quality particularly matters for DWI:

1. Identification of economic activities in which an individual has been engaged in the past 12 months, and the key characteristics of each of these activities.

2. Collection of sufficient information on each of these activities, with priority given to the ones that contribute most to the livelihood of individual/households.

3. Avoiding large measurement errors in time-related questions as well as in questions on returns to labour (whether self-employment or wage employment).

4. Capturing child labour and forced labour in contexts where respondents may want to conceal such practices.

3.2.2.1. Accounting for occupation multiplicity and accuracy in the definition of occupations/activities

This is by far one of the key challenges and one of the reasons why some key indicators of the labour market (employment rate, employment status, sector of employment etc.) are particularly sensitive to what questions are asked and how. LFS and some HICES and MICS include questions on 'secondary' job holding, but virtually all headline statistics refer to the 'main' job. While it is best practice, even by ILO standards, to use an activity list to determine whether somebody was employed and the nature of each job, this is not systematically applied or analysed (Oya 2010).

The usual reliance on the tricky notion of the 'main job-holding', designed to give a single classification for every individual surveyed, is problematic even if the goal is an aggregate picture for international comparability. Unfortunately, in contexts of occupation multiplicity, irregularity and strong seasonality, the interpretations and use of the concept of 'main activity' are influenced by the biases of both respondents and interviewers. Moreover, conventional reference periods are problematic[39]. Many countries still rely on standard questions with a seven-day reference period (designed to generate internationally comparable statistics) which, in contexts of strong seasonality, irregularity of activities and occupation multiplicity, can lead to significant statistical biases and thus turn to be meaningless for international comparisons. The use of relatively short timeframes tends to compound the biases introduced by the reliance on notions of 'main activity' when this is defined in terms of time. As practiced in India, a combination of different reference periods (12 months, 30 days and 7 days) applied to same or different questions may help reduce this bias.

Properly identifying and capturing different kinds of activities is also challenging. This is because certain types of activities, and indeed many wage jobs that are particularly relevant for the most deprived rural people – characterized by severely exploitative conditions, even forms of bondage – are highly stigmatized and can, for that reason, easily be under-reported and overlooked. Mueller (2015) provides examples of the most widely terms used for casual wage work (kibarua) in Tanzania, an activity that can be often under-reported or unreported altogether. Oya (2015) also finds particular activities like charcoal making and trading in rural Mauritania of going under-reported because of official bans on them, thereby leading to biases if not enough probing is done, since this is one of the most important sources of accumulation and survival for many rural people in remote areas of the country[40]. , as shown in his comparison between official statistics and micro-survey data. Oya (2013), Chand and Srivastava (2014).

An adequate identification of all the economic activities of individuals and households also requires appropriate wording. Much is lost in bad translation as suggested in section 2.3.3. For example, key terms like 'salary' or 'wage', 'gainful activity' or 'remunerated activity' may be linked by design and practice to limited sets of activities and jobs because of what respondents (and interviewers) usually understand by those terms (Rizzo et al. 2015). Oya (2015) on Senegal, and Rizzo et al. (2015) provide concrete examples of instances in which a poor translation or a misinterpretation of key terms leads to measurement error and bias[41]. The issue is not only adequate use of local terms and preparing suitable

[39] There are differences across surveys in this respect though.

[40] See also Oya (2013) and Chand and Srivastava (2014) for other examples of 'stigmatized' activities that result in under-reporting of female employment.

[41] Rizzo et al. (2014) provide detailed examples of the problems of questionnaire design and specifically how questions on employment are 'lost in translation' in the context of Tanzania, leading to a biased characterization of employment patterns for informal labour, and to wage employment being classified as self-employment. Oya (2015) documents a variety of terms normally used in rural vernacular Wolof in Senegal for concrete occupations in the broad spectrum of casual wage work. By contrast, inadequate translations because of bad guidelines to interviewers result in these specific relevant terms not being used to capture wage jobs and therefore missing them altogether.

glossaries for enumerators, but also the importance of systematic and careful probing, which in some surveys is often overlooked because of time constraints and wrong incentive systems.

Adequate wording and probing of course require conceptual clarity, as survey designers need to clearly train interviewers about what each key concept means. Although this may seem obvious, fieldwork experience is often compounded by a biased conceptualization of key terms. For instance, this is the case with the distinction between wage employment and self-employment, with the result that a particular occupation (e.g. street vendor) is automatically related to a given status (e.g. self-employment) without the required probing (Oya 2015). Huang (2013, 349), in the context of China, argues that Chinese statistics reduce wage workers to '[a] high-status category of regular "employees-workers" that excludes the great majority of the labouring people of present-day China'. Wuyts (2011), Rizzo et al. (2015) and Breman (2006) provide other similar examples concerning large segments of 'informal workers' The solution is a theoretically and empirically grounded definition that avoids strict boundaries: thus 'wage employment' refers to any form of work for another person or entity in exchange of any kind of compensation whether in kind (including land, for example) or in cash. If the 'employer' provides all or the bulk of the means of production (i.e., land, working capital, equipment, seeds, and so on) the labour relation is characterized by a wage-contract even if in a disguised form, e.g., as labour tenancy or sharecropping (see Banaji 2010).

Probing is also critical to capture a range of forms of child labour, forced labour and to understand the gendered nature of labour markets and various forms of occupational segregation. Since these are sensitive issues, the wording in standard questionnaires may not be the most suitable, hence interviewers must respond by adapting the wording or finding ways of circumventing the sensitivity about these topics by using the most appropriate and least 'threatening' terms as well as maintaining a fluid conversation during the interview, which may put at ease the respondent.

What matters is to get a full picture of the employment situation of an individual in these heterogeneous and fluid contexts is the accurate enumeration of the complete set of economic activities in which individuals engage over an extended period of time (e.g., 12 months) and the relative importance of each of them for their subsistence. The RNFE literature not only systematically documents the importance of occupation multiplicity and livelihood diversification, but also the contingency of the dominance of one particular activity or another. In China, most rural people are engaged in more than one activity—farming and off-farm employment but, as Huang maintains (2013, 359) their final classification hinges on what activity they are engaged for more than 6 months a year. In many African countries, characterized by relative land abundance and proliferation of small-scale producers (whether viable or not) the idea of 'main occupation' may be particularly misleading, resulting in either respondents or enumerators emphasizing own-account farming (because it reflects property attachment as well as a more 'regular' activity regardless of its returns) at the expense of other more irregular but perhaps more remunerative activities.

The alternative to the use of 'main activity' is clear: a full enumeration of all relevant economic activities in the past 12 months, whether in the form of self-employment or wage employment or other employment status categories. In practice, this information can be collected through a carefully designed and context-specific (in order to capture key local activities and key local terms) 'employment matrix' (example in Appendix A1). The list can be designed based on prior research in the country and a context-specific knowledge of the most important types of employment in rural areas. This matrix does not only include a checklist of all context-relevant activities in which the individual has participated, but can also include information on duration and frequency of each activity, their seasonal pattern, the location and whether they performed the activity accompanied by a child or not. The latter can be an important question for DW evidence. Even if it does not entail child labour (it could be a woman carrying a baby on her back while working) it shows the burden of a combination of productive and reproductive tasks on women and can feed into evidence on occupational gender segregation.

3.2.2.2. Tailoring questionnaires to specific types of employment

Once we are confident all activities and their duration and frequency have been identified, we need accurate information on each of these activities, especially the most important ones in terms of returns (remuneration), security (duration and frequency), and other conditions related to the quality of employment, whether in terms of health & safety, collective bargaining, gender (or other type of) discrimination, or additional non-wage benefits. The challenge is that each activity has its own specificities so questions should be tailored to each type. Therefore, rather than using a single set of standard questions for each of these activities, separate modules can be prepared to collect relevant information in each case. As the GIRM-WB (2007) report shows, specifically designed modules work well for own-account farming, wage employment in agriculture, own-account non-agricultural business, wage-employment in non-agricultural activities, and questions specific to contributing family workers. Therefore, a combination of the sector of activity and employment status can be used to devise specific questionnaire modules to collect detailed information on each of the key activities listed. Within each sub-module there may be reporting of more than one instance, e.g. two or three jobs as casual wage worker in agriculture, or two different non-agricultural businesses. Depending on the number of questions included, this can be operationalized by adding different rows per question (one row corresponding to one job) or by applying the same sub-module separately for each job (this may be too cumbersome in cases where the number of activities and jobs reported is very large).

Each type of activity entails its own challenges. Own-account farming and generally household business require accurate data on aspects such as: production, sales, input costs, use of hired and household labour, assets, land measurement, credit, associations, etc. The problems in accurately measuring each of these items are dependent on the type of crop or type of business, so context specificity does matter. Carletto et al. (2015) and Samphantharak and Townsend (2012) present detailed accounts of the main challenges some of which will be explored in more detail in the section below.

Wage employment requires accurate data on different aspects: the nature/type of employer (scale, 'formality' or not; relations, etc.), types of contractual arrangements, whether only labour is provided (and not tools or land), payment methods, levels of remuneration, frequency, non-wage benefits, issues of harassment and conflict, trade unions, etc.

Likewise, questionnaires should contain specific questions that may help shed some light on DW deficit for small-scale producers, following the examples and recommendations made in section 2.3.4. In particular good estimates of returns to labour, farm income trends and volatility, and of underemployment as well as overemployment will be very useful for a pictire of DW for this group. In addition, other measures of quality of employment, related to hardship and risks associated with small-scale farming, as well as indications of associational power can provide additional elements for a more complete picture of DW among small-scale producers.

These are just illustrations of the sorts of issues that the survey design must tackle in order to prepare sufficiently detailed employment modules that will be necessary if DWI are to be improved.

3.2.2.3. Minimizing errors in estimates of returns to labour – understanding remuneration systems

The accuracy of some of the data needs mentioned in the previous section is crucial. In particular, and for contexts of rural areas in LICs, the accuracy of measures of underemployment and overemployment can be addressed with carefully designed employment matrices (Appendix A1). In addition, good quality data on returns to labour should be ensured in any system for DW measurement in agriculture and rural areas. However, the reality is that this kind of information is often missing or fraught with measurement errors. Generally there is a major evidence gap on labour returns, especially for rural wage employment. Sender (2003, 414) notes in particular that:

'[In] most developing economies no efforts at all are made to collect time-series data on the wages of those employed in small-scale farm and non-farm rural enterprises, especially on the wages of those who are irregularly, seasonally, or casually employed.'

Collection of reliable information on wages is particularly challenging in rural areas of LICs, especially in agriculture because payment systems vary and are sometimes complex (Hatlebakk 2004; Rogaly 2005). For example, in agriculture, payments can often be in the form of either a daily wage (following local 'norms'), a piece-rate wage (e.g. monetary rate per kg of output harvested) or, more typically, a task-based wage (clearing x area of land; sowing x number of rows, or pruning x number of trees). To complicate matters, in some workplaces workers may receive a daily wage but they must complete a task so the payment becomes de facto task-based. As argued by Cramer et al. (2008) 'the literature on piece-rate systems and farm wage differentials attempts to explain marked differences between how workers are paid, even when they are doing similar things and in comparable locations'.

Other authors have documented substantial variation, and particular forms of labour market segmentation that are related to complex labour relations (Bardhan and Rudra 1986; Rogaly 2005; Ortiz 2015; Cramer et al. 2008). There may be great variation even within the same local context, depending on crop, type of employer, type of sector, season, and market conditions. This underscores the need for detailed modules with sufficient number of relevant questions. It is therefore quite possible that a full questionnaire page must be devoted to capture the nuances of these payments and make sure that all relevant data is collected in order for data users to estimate comparable and reliable daily wages. For example, if a casual worker is employed by the task, detailed information about the task is needed, especially with regards to the time to complete it. Sometimes casual workers are paid daily but they need to complete a task. In case this is not completed, they may need to continue the day after, in which case the payment is not daily but task-based (see FTEPR 2014; Wendimu and Gibbon 2015). Another complication that requires attention is the use of –in-kind payments and methods to impute value to the goods offered in exchange for labour. The quality of these estimates is crucial for any DWIs related to earnings.

The challenges in capturing earnings are not limited to those working for wages. Indeed, a measure of earnings/ returns to labour for the self-employed, especially small-scale producers, may even be more difficult. In fact, recent literature suggests that for small-farming activities the quality of the data collected in large-scale surveys leaves much to desire. For example, net farm income for smallholder farmers is hard to measure for different reasons. The fluctuations in farm revenues, the deliberate misreporting of production, consumption and sales, recall problems in relation to precise quantities of consumption items or to labour time use, the complicated valuation of opportunity costs (own or family labour or equipment depreciation), and many other problems mean that questionnaire design, training of interviewers and their supervision are crucial for good quality data. Samphantharak and Townsend (2012), based on a survey experiment in Thailand, emphasize the importance of four important challenges for household enterprises (including farming):

a. Distinguishing and measuring accrued vs cash incomes and between purchased and used inputs.

b. Measuring the implicit compensation of household labour, which can be done with different alternatives of shadow wages depending on whether the household workers also participate in the labour market or not.

c. Paying attention to gifts and transfers, including labour exchange, which should also be valued

d. Dealing with valuation and depreciation of assets.

With regards to the last point, the collection of relevant information on assets, both productive assets (such as irrigation equipment, motorbike, tractors, etc.) and consumer durables is certainly an important task, whether to estimate long-term returns to household enterprises or to adequately characterize the socio-economic status of respondents, whether self-employed or wage employed. Assets and durables are generally easier to observe and verify (thus less potential for measurement error) than current consumption And, as they provide a measure of long-term wealth, such information may be used to complement data on earnings, which tend to fluctuate every year due to the nature of the activities involved (Howe et al. 2012). Both smallholder farmers and rural wage workers may be substantially differentiated in terms of available assets and this can be a reflection of having been exposed to more DW in the medium-long term.

More specifically in relation to own-account farming, Carletto et al. (2015), writing on SSA, confirm that the evidence base about farm size, productivity, and contribution of agriculture to welfare is very poor. The problems are, however, not uniformly distributed across types of farmers and crops (hence the importance of identifying these categories ex-ante as suggested in section 2.3.4.3). Carletto et al. (2015) document a number of specific problems:

a. Accounting for inter-cropping, which substantially affects measures of returns to farming. Depending on the pervasiveness of the practice and the level of production in question, it is advisable to consider all crops mixed in an inter-cropping arrangements. There may be recall problems for some harder-to-measure agricultural products, thus making inter-cropping estimates somewhat unreliable. The priority is to capture orders of magnitude first to then choose the crops that are more important for the team.

b. Land measurement and problems with recall and administrative data. The alternative of GPS-based measurement is increasingly applied and is not without its problems but clearly reduces potential measurement error on a very important indicator. It is recommended that, to the extent possible, enumerators probe respondents' reporting of land area by randomly choosing plots and measure them with GPS devices.

c. The production of some crops is harder to measure than others: generally root crops and 'fast crops' (onions and vegetables), which may be harvested continuously are far more negatively affected by recall bias than other annual crops characterized by one (or perhaps) two key harvest seasons and also often marketed. This would require rethinking questions and measurement methods to capture the volume of harvested output with higher frequency data perhaps. Therefore, questions about production/harvest in cotton will have to somewhat differ from questions about production/harvest of cassava. An option is to obtain rich qualitative information on production and harvesting patterns for these crops. The questionnaire can make a particular distinction between crops that generate cash and crops that are consumed by the household in large proportions. For the latter a shadow market price can be applied to provide a monetary value to the physical production estimates.

d. Regardless of the type of crop, a common problem is the use of non-standard measurement units (banana bunches, heaps of cassava, '50kg sacks, etc.), which translate in inconsistent weights and introduce non-random biases on production estimates, which are crucial to estimate returns to labour in own-account farming. The methodological option is to calculate accurate conversion factors to specific non-standard units encountered in the survey and using CAPI to facilitate this process and input context-specific conversion factors.

e. Imputing monetary value to self-consumption when relevant price data are not available. This would require more adequate information on relevant (local) prices for agricultural products consumed within the household, taking into account the importance of seasonality in these prices.

The discussion in this section suggests that the only way to minimize the measurement errors identified in the literature on economic activities / employment is to add detailed questionnaire modules and design activity-specific questions to obtain consistent estimates of earnings. Generally, detailed information on farm budgets should be collected separately in order to obtain more accurate measurement of returns to labour in family activities, entailing a detailed farm budget module with the net data then being compared to the less detailed agricultural revenue information collected through an employment module, for example.

Detailed modules have a substantial (positive) impact on the quality of data. Experimental research on poverty-related questions indeed suggests that 'equivalent as well as same households answer the same questions differently when interviewed with a short questionnaire vs. the longer counterpart', which suggests a potentially serious bias in short questionnaire-surveys for complex issues like poverty and employment (Kilic and Sohnesen 2015). A long questionnaire, in turn, raises issues of sequencing. For this purpose there are a couple of rules of thumb that can help. First, the key questions for the high-priority DWIs, e.g. earnings and underemployment, should not come too late in the questionnaire as respondents may be tired at the end of it and these questions require attention and use of memory. Second, there should be a logical flow between different questionnaire modules. So, the employment matrix should come first for all employment-related (DW) questions, followed by relevant modules for each key type of activity (own account activity, agricultural wage employment, non-agricultural wage employment, etc.). The end of the questionnaire should include questions that are complementary to the main focus (DW – employment) but not essential.

The challenges and recommendations included in this and other sections above suggest that there is an advantage in developing longer employment modules and generally longer questionnaires. There is however a trade-off between lengthening questionnaire and practical, financial and logistical constraints. Long interviews, if conducted in one go, may also affect the quality of the information collected in each case, if respondents and interviewers get tired. However, available evidence from survey experiments suggests that the pros of more detailed and longer questionnaires outweigh the cons, as in the case of poverty indicators (Kilic and Sohnesen 2015).

3.3 Selection and training of interviewers

It is not enough to improve questionnaire design and adopt more flexible sampling approaches. The quality of DW indicators highly depends on careful selection of interviewers, much more intensive training than usual (including conceptual training on key concepts) and close supervision, particularly in pilot and early data collection phases.

For example to be able to capture the nuances of distinctions between self-employment and wage-employment; the particularities of remuneration methods for different occupations; the characteristics of the 'household'; the different types of small producer; the OSH issues; instances of child labour and forced labour; forms of discrimination; to name a few key issues, interviewers would have to be carefully trained to understand these conceptual and methodological differences and work with plenty of concrete examples from the country where the survey will take place. For example, addressing child labour is not straightforward in contexts where the use of child labour is pervasive even if not always resulting in out-of-school children. Enumerators and supervisors may not see this as 'child labour' and will need to be carefully trained so that they can consistently capture it and make sure they use the right terminology (local terms) and deal with existing sensitivities in a suitable way. Preparation of training will therefore require substantial scoping research to understand context specificity and better communicate concepts to interviewers. The conduction of careful scoping research processes may be done before a large-scale survey is conducted and ahead of training and questionnaire design. This is an important investment, the results of which can be carried forward to different rounds of similar surveys. However, it should not be simply seen as a one-off investment, insofar as conditions and context also evolve. If survey rounds follow a 5-year frequency, for example, some updates of the scoping work may be needed although the time taken may be less than during the first core round. Survey designers will assess the main changes in context between surveys and decide on the kind of scoping needed, particularly on the focus of the scoping as there may just be come issues to focus on (migration patterns, new activities emerging and so on). The scoping work required to improve survey design should be institutionalized, i.e. not simply contracted out to external consultants. While the latter could assist in the process, national data collection agencies should have focal points to conduct this scoping research so that practices are not externally driven.

Scoping and deeper training are critical factors contributing to better probing skills. Well-trained interviewers certainly have to probe to make sure they understand in which category the respondent is, or what kind of wage contracts the respondent has been involved in, for example. In some instances there may be 'social desirability bias' among respondents, whereby own-account activities are seen as morally superior or desirable compared to 'working for others', or where certain activities are deemed demeaning and not worth reporting. Therefore the probing will have to be particularly careful to make sure the respondent is not under- or un-reporting wage work activities, or any activities that may be considered illicit in some contexts (e.g. charcoal making, smuggling), various forms of discrimination, and activities that should be abolished under the DW agenda (child labour, forced labour). In order to make sure interviewers do enough and good probing three basic conditions generally apply:

a. Adequate incentive systems, so for example avoiding piece-rate payment (per questionnaire) which may lead to excessive urgency and speed in administration.

b. In-depth training on the key concepts and indicators, turning interviewers in quasi co-researchers, making sure there is substantial 'buy-in' for the survey among them. This means that periodic/ annual training for annual agricultural surveys, for example, should not be simply limited to 1-2 days of work going through the questionnaire but should include some time for basic conceptual discussion around indicators and how probing can be done for the most challenging questions, all this complemented with more days of pilot work.

c. Close and sustained supervision in the field, especially in the early stages, to make sure that any systematic errors are avoided and that different situations are tackled with the help of supervisors.

3.4. Survey implementation

Once design, selection and training are completed a key issue is implementation. Below are a number of key recommendations that may work in most contexts although survey designers will have to understand the context of the survey to address any particular practicalities.

a. **Survey teams**. Normally it is better to work in smaller teams, each guided by an experienced and very well trained supervisor. A smaller team of about four enumerators may be easier to manage especially when internal conflict arises (between enumerators or between supervisor and enumerators) as discipline is critical in situations where fieldwork is physically and mentally demanding. A close supervision is critical, and being able to go through questionnaires and different scenarios in the evenings is also highly advisable, to make sure any corrections can be made on the spot. Another possibility is having smaller teams or even individual enumerators who spend long periods of time in the same village and administer the different questionnaires to be used. This would facilitate the familiarization of the enumerator with the context or could be compatible with the reliance on a locally-resident enumerator with adequate training. The composition of teams is also important. First, a good mix of experienced and less experienced but highly skilled enumerators is advisable. Having only very experienced enumerators may be problematic if new concept or new forms of implementing the survey are important for the study. Enumerators with excellent interpersonal and communication skills and good capacity to understand new concepts brought by training are essential. Particularly with a long and detailed questionnaire it is imperative to find interviewers who can turn the sequence of questions into a conversation, which requires them being engaging. Second, it is preferable to have with direct experience in rural areas of the sampled zones and a high command of the key languages spoken in each area, bearing in mind the possible presence of migrants from other parts of the country. This means that each candidate should be thoroughly tested on the relevant languages before embarking on fieldwork. Overall, however, the main priority is to conduct intensive and in-depth training, followed by sufficient pilot-testing (a few times in two or three different sites for at least one week) and a system of close supervision with regular inputs from main survey designers.

b. **Place of interview**. Places where respondents potentially are not free to talk should be avoided. These include public areas where others can overhear and in particular the workplace where the presence of employers or supervisors or even other workers may intimidate respondents. Generally, all interviews should be conducted in private and without the possibility of external interference. Survey teams should also stick to sampling targets and avoid being driven to particular respondents by 'gatekeepers', such as village chiefs or other local authorities.

c. **Survey technologies**. Survey design also needs to consider the ways in which available technologies can help better implementation, faster data processing and minimisation of interview errors. An increasingly popular option is the use of computer assisted personal interviews (CAPI) instead of conventional questionnaires on paper. The main advantages are: (a) reducing the potential number of data entry mistakes by a set of filters and consistency checks; (b) substantially cutting or even eliminating data processing time, since data are automatically entered into a database as enumerators fill in tablet questionnaires; (c) as data are 'live' and arrive 'just in time' researchers and survey designers can cross-check consistency and run some analysis as survey goes on, without having to wait until the survey has been completed. Appendix A2 considers the main pros and cons of this option.

4. Summary of key recommendations

The discussion in this background paper has tried to (a) assess the relevance of concepts and indicators of Decent Work (DW) for rural areas and employment in agriculture; (b) examine some of the main reasons for the lack of data on DW for rural areas and agriculture, in terms of problems with data collection; and (c) propose a selection of more relevant and suitable indicators as well as some ways to improve data collection.

The main implications of this analysis are:

1. The concept and indicators of DW present problems of applicability and relevance in rural contexts of LICs, especially in SSA. Context specificity is indeed important for the relevance of concepts and indicators. A long and rigid list of DWI may reflect aims for universalism and the imperative of international comparability. Therefore it is proposed that more selectivity is a applied to the choice of DWI, i.e. trying to focus on a smaller but more relevant set of indicators, including some that are not currently being collected (for example, detailed data on returns to labour, whether self- or wage-employment, as well as more precise measures of underemployment and occupation multiplicity/multiple job-holding). Since not all dimensions/indicators may apply equally across countries, it may not be possible to have a single set of DW deficit indicators that is internationally comparable. Section 2.4 provided a list of DWIs that could be the basis for a primary attention if rural and agricultural sectors, particularly in LICs, are the main focus of analysis.

2. Despite advances in the conceptualization of labour categories and conventions, there are tensions and challenges that should be addressed and not ignored. Distinctions between categories of employment status need to be operationalized more carefully, so that the true incidence of self-employment and wage employment is adequately captured through a variety of methods and questions. This is important as there are different options of DWIs to be applied to self-employment vs wage employment situations. Distinctions in terms of levels of 'formality', given variation in definitions and applicability, may obscure more than reveal about DW deficit in rural employment. Thus, dimensions normally associated with 'informality' should be spelt out and reported separately.

3. More precise estimates of the degree of underemployment and 'overemployment' by individual as well as by type of activity (job) are needed for a more accurate picture of time-related DW deficits, which are crucial especially for the working poor who frequently straddle different irregular jobs.

4. Better survey designs for greater rural employment focus, including:

a. Suitable sampling methods to ensure coverage and inclusion of 'hard to reach populations' (seasonal migrants, child labour, forced labour, people in less accessible areas, etc.)

b. Longer and better designed modules on employment questions, e.g. the use of employment matrices, separate sub-modules with specific questions for each type of activity, and careful design of questions on returns to labour, both for self-employment and wage employment

c. Context-specific questions for aspects of DW not related to earnings, thus OSH, access to social protection and gender-related discrimination.

5. Improvements in sampling and questionnaire design will be insufficient if the quality of those who participate in surveys (from designers to supervisors, interviewers and data users) does not improve. There needs to be conceptual clarity and methodological awareness among all these groups. Careful selection and training of interviewers and field teams, as well as appropriate incentive systems are crucial for success in data collection.

Finally, it is clear that most of these recommendations can be applied in the context of independent micro-level surveys that operate with some degree of freedom over design choices. However, an important objective is also to 'mainstream' these methods into existing nationally representative household surveys. In other words, some of the 'solutions' proposed here could be incorporated in the design of such large-scale surveys. My own experience is that this is challenging because (a) of resistance from national statistical agencies to changes (path dependency) (b) because of the fear of losing international comparability, and (c) due to alleged logistical/financial constraints (which affect any survey anyway). This means that, realistically, perhaps not all methodological alternatives proposed in this paper can be embedded in official systems but some can. In that case the question would be to identify the most important alternative options, something that is likely to depend on the national context.

APPENDIX A1. EXAMPLE OF EMPLOYMENT MATRIX

Note to the enumerator: Provide a complete list of all activities engaged in by The Respondent and ask questions for each of these activities
Matrix E1. Describe ALL of the activities / occupations on which you have worked DURING THE PAST 12 MONTHS
[**Note to enumerators:** It is expected that each Respondent will have undertaken SEVERAL activities]

Type of Occupation / Work	**1(a) Number of months**	**1b) Usually, how many days per month?**	**1(c) Usually, how many hours per day?**	**1(d) How long does it/did it usually take for you to travel to your place of work in this occupation?**	**1(e) Did anybody help/work for you in this activity for a payment in cash or in kind Yes No**
1a. Farmer (on your own or on your family farm)				. … .hours __ minutes	1 2
1b. Agricultural labourer (on large farm as permanent or seasonal worker)				. … .hours __ minutes	1 2
1c. Agricultural labourer (on any other type of farm as casual worker)				. … .hours __ minutes	1 2
1d. Fishing (using your own or family equipment)				. … .hours __ minutes	1 2
1e. Fishing (for a wage or part of the catch)				. … .hours __ minutes	1 2
2a. Collecting, begging, recycling, foraging				. … .hours __ minutes	1 2
2b Wood/charcoal/ collector and seller				. … .hours __ minutes	1 2
3a. Sales / wholesale trade / shop-keeper (warehouse)				. … .hours __ minutes	1 2
3b. Sales / retail trade (street vendor)				. … .hours __ minutes	1 2
4a. Transportation (bicycle, motorcycle –boda boda-, fares collector, porter, wheel barrow pusher)				. … .hours __ minutes	1 2
4b. Transportation (lorry driver, bus driver or chauffeur)				. … .hours __ minutes	1 2
5. Construction labourer / brick making / sand collecting/ quarrying/ stone breaking				. … .hours __ minutes	1 2
6. Carpenter/Mason				. … .hours	1 2

				_ _ minutes	
Type of Occupation / Work	**(a) Number of months**	**(b) Usually, how many days per month?**	**(c) Usually, how many hours per day?**	**(d) How long does it/did it usually take for you to travel to your place of work in this occupation?**	**(e) Did anybody help/work for you in this activity for a payment in cash or in kind** Yes No
7. Cleaner (in a company, hotel, etc.)				. ….hours _ _ minutes	1 2
8. Domestic servant (in a private house)				. ….hours _ _ minutes	1 2
9. Restaurant / bar (server) / food stall worker (inc. hotel) / local drinking hall				. ….hours _ _ minutes	1 2
10. Security guard, including vehicle (car, motorcycle etc.) guard				. ….hours _ _ minutes	1 2
11. Factory worker (including processing for tea, coffee, etc.)				. ….hours _ _ minutes	1 2
12a. Professional / technical (teacher, electrician, mechanic, plumber etc.)				. ….hours _ _ minutes	1 2
12b. Managerial / administrative / team supervisor				. ….hours _ _ minutes	1 2
13. Clerical / secretarial				. ….hours _ _ minutes	1 2
14. Food / drink preparation or processing				. ….hours _ _ minutes	1 2
15. Craftsmanship (incl. tailoring, crafting, cobbling, basket production, pottery)				. ….hours _ _ minutes	1 2
16. Personal services (laundry, barbers, photography)				. ….hours _ _ minutes	1 2
17. Other, describe: ………………………………………………………… ………………………………………………………… ……………………………………				. ….hours _ _ minutes	1 2

Matrix E2. Describe the characteristics of the Respondent's employment/work/activity carried out (each column)

Street, fixed location; 7.Street, no fixed location/moving around; 8. Field/bush; 9. Other……… ..

APPENDIX A2. Computer assisted personal interviews (CAPI)

Since the innovation of tablet computing this practice is increasingly becoming the norm in social science research, due to a number of inherent advantages. These include:

a. Cost: Usually, after only a relatively small number of interviews (depending on setup, about 100-200 interviews per tablet computer) the cost of the initial investment will be amortised. The main reason for this is that CAPIs induce significant savings of recurrent costs because of procedures like the printing and shipment of questionnaires, data backup (physical copying), and in particular manual data entry are no longer required. Especially the latter point regularly constitutes a considerable saving of financial and human resources.

b. Availability of data: Electronically generated data is immediately available for data analysis and cross-checks by researchers and survey designers, with no need for separate data entry. Given modern forms of telecommunication, collected data can be analysed both by field officers as well as researchers based in different places, on the same day that it was collected, assuming interviewers and supervisor can access internet.

c. Data consistency and quality: due to the possibility to programme a wide range of internal consistency checks, skip & fill rules, data validation tools, as well as in-built questionnaire navigation and guidance, CAPIs routinely generate data that is much more consistent and of higher quality compared to that collected on paper. Interviewers are prevented from committed to the majority of common mistakes (such as typos, illogical answers, or asking wrong questions), because the electronic questionnaire will highlight/disallow inconsistent answers and generally guide interviews as required in any specific case, i.e. only displaying questions that are applicable to a particular respondent based on previous answers. As a result, the need for data cleaning is greatly reduced (implying another significant cost saving). Moreover, electronic equipment also facilitate the use of media during the conduction of interviews. This is important as a source of key notes to add to questionnaires, for example on measurement units when these are not conventional or consistent, so interviewer can take pictures to illustrate the case.

These advantages make a compelling case for the use of CAPIs, especially in circumstances where questionnaires are highly standardised and repeated in large numbers. Familiarisation with the computer devices aside, arguably there will be a reduced need for interviewer training, because the scope for errors is vastly reduced. Field experience by the FTEPR study also suggests, that conventionally expressed challenges related to rural fieldwork are usually of little concern:

a. Battery life of modern devices is usually sufficient to last for at least 8 hours, i.e. at least one full or two half working days. In most circumstances, external batteries (including car batteries) or generators can be used to charge devices in cases of power outages.

b. Most modern devices are GPS enabled, which create a large potential for further facilitation of the sampling and data collection process. (as discussed above)

c. Rugged cases are available for most devices, making them highly resistant against most adverse situations in the field (including dust, rain, falling, etc.)

d. The often-feared alienating effect of computing devices has not been observed by the FTEPR team, which has used this technology in highly remote areas in Uganda and Ethiopia without respondents reacting negatively to the use of computers instead of paper questionnaires. To the contrary, more often than not, respondents showed an increased curiosity and interest to participate and cooperate.

The main challenge associated with CAPIs are concerned with the time spent on programming and setup, maintaining the devices in the field, as well as the initial cost of investment. To effectively make use of the potential of CAPIs, it is essential that sufficient time and resources are reserved to allow the careful programming (and testing) of the electronic questionnaire. Specific experience is required to successfully develop a functioning electronic questionnaire, including the necessary validation rules, underlying navigation and ski- & fill logic, etc. Depending on the length of the questionnaire, an experienced programmer can be expected to spend between one and three weeks (full-time) to finalise such a tool. Furthermore, as with all technological equipment, maintenance in the field is an important aspect of this approach. For this reason, it is crucial that at least one member of the survey team (usually the field supervisor) is well-versed in the use and maintenance of the devices, in case any error or fault should occur. In addition, the initial cost of investment is of course considerable, especially if survey entails a large number of enumerators. This may be an important consideration, especially if the financial savings derived from no need for data entry and no printing of questionnaires are not substantial as some World Bank specialists have pointed out (Kilic 2012).

Another possible challenge is battery and charging devices in situations where there are frequent and extended power cuts. In such scenarios an alternative plan with paper questionnaires or having a back-up power generator would be advisable to prevent any delays or even interruption of fieldwork due to logistical constraints.

Finally, there will be additional training needs since not all selected enumerators will have expertise in the use of CAPIs for purposes of questionnaire-based interview. However, in our experience, the training involved is relatively straightforward and most enumerators nowadays are used to working with tablets and smartphones.

In sum, the various pros and cons of using CAPIs as part of the survey have to be weighed up against each other. The main recommendation is that, provided that qualified team members can be relied on, the advantages of using electronic questionnaires greatly outnumber the downsides.

Measuring and monitoring decent work in rural areas in support of sustainable development

M. Castillo | ILO | Geneva | Swizterland
D. Levakova | ILO | Geneva | Swizterland
H. Kashef | ILO | Geneva | Swizterland

DOI: 10.1481/icasVII.2016.a05c

ABSTRACT

Making progress towards sustainable development and poverty reduction will require a concerted effort to promote decent work in rural areas, particularly among developing countries. It will require analysis of targeted indicators on decent work in rural and urban areas that can be used to advance national development agendas. But what do we know about rural workers and their participation in the labour market or, more broadly, about decent work in rural areas as compared to urban areas? The internationally agreed decent work measurement framework and recently adopted standards by the International Conference of Labour Statisticians (ICLS) on measuring paid and unpaid forms of work are the starting point for the measurement and monitoring of decent work.

However, currently there are different criteria applied by countries to define rural areas. The paper presents the case that the lack of a harmonized international statistical definition of rural and urban areas combined with a major data gap for even a basic set of decent work indicators in many countries limits the possibility of providing meaningful analysis on decent work in rural areas at the national, regional or global levels and presents recommendations on the way forward to address the challenges.

Keywords: Decent work, labour market, labour statistics, International Conference of Labour Statisticians (ICLS), rural areas, rural workers

PAPER

1. Introduction

Achieving sustainable development is the key challenge of our time. Countries have adopted a set of ambitious goals and specific targets that seek to end poverty, protect our planet and ensure prosperity for all by 2030. The largest concentration of the world's poor, about 800 million poor women, children and men, live in rural areas, many of whom work as subsistence farmers, herders, fishers, and artisans (Rural Poverty Portal, IFAD). Making real progress towards the Sustainable Development Goals (SDGs) will require a concerted effort to promote decent work in rural areas, particularly among developing countries. While rural poverty is a complex issue, achieving full and productive employment and decent work in rural areas is recognized as a principle means of tackling it.

Launched in 1999, the concept of decent work is understood as a need of people in all societies regardless of level of development. It is defined as opportunities for women and men to obtain decent and productive work, in conditions of freedom, equity, security and human dignity. The Decent Work Agenda has received widespread international endorsement. During the 2005 United Nations World Summit, Heads of State and Government expressed their strong support for a fair globalization and for making the goals of full and productive employment and decent work for all, including for women and young people, a central objective of their policies and national development strategies.

The International Labour Organization's (ILO) Declaration on Social Justice for a Fair Globalization adopted in 2008 by ILO Member States represents a road map for the promotion of a fair globalization based on decent work, and is intended as a tool to accelerate progress in the implementation of the Decent Work Agenda at the country level (ILO 2008). It acknowledges the universality of the Decent Work Agenda in which all ILO Members will pursue policies based on the four strategic objectives – international labour standards and fundamental principles and rights at work, employment creation, social protection, and social dialogue and tripartism. These objectives are seen as inseparable, interrelated and mutually supportive.

The Declaration calls upon the ILO to assist Member States in their efforts towards its implementation and states that "ILO Members may consider the establishment of appropriate indicators or statistics, if necessary with the assistance of the ILO, to monitor and evaluate the progress made." To facilitate such technical assistance, in 2008 the ILO convened a tripartite meeting of experts to establish a measurement framework to monitor progress towards decent work.

In 2008, the Framework on the Measurement of Decent Work (FMDW) was presented to the International Conference of Labour Statisticians (ICLS) and to the ILO Governing Body both of which have encouraged an ILO work programme to further develop and test the framework. The FMDW has since been successfully piloted in different countries and nearly 20 decent work country profiles have been developed on the basis of the framework. The newly adopted SDG targets and indicators that relate to employment and decent work, particularly under Goal 8 "Promote inclusive and sustainable economic growth, employment and decent work" offer a fresh opportunity to redouble efforts towards monitoring decent work, including in rural areas, in order to address extreme poverty of many developing countries.

2. The Framework on Measuring Decent Work (FMDW)

The FMDW is intended to assist countries to assess progress towards decent work and to offer comparable information for analysis and policy development. It offers the possibility of disaggregating most statistical indicators by rural and urban area to analyse differences by geographic area and includes a specific indicator to measure the discrimination of rural workers. It is a model of international relevance that allows the adaptation to national circumstances and priorities and that has the potential to evolve dynamically over time. The framework can be applied to all countries, although it is recognized that adequate technical support is required for countries with limited statistical capacity.

The FMDW covers ten dimensions or substantive elements as follows: (1) employment opportunities; (2) adequate earnings and productive work; (3) decent working time; (4) combining work, family and personal life; (5) work that should be abolished; (6) stability and security of work; (7) equal opportunity and treatment in employment; (8) safe work environment; (9) social security; and (10) social dialogue, employers' and workers' representation. These substantive elements are closely linked to the four strategic objectives of the Decent Work Agenda noted above and represent the structural dimensions of the framework under which both statistical and legal framework indicators on decent work are organized. There is an additional substantive element related to the economic and social context for decent work whose indicators are not intended to measure decent work per se but rather serve to provide data users information that relates to the characteristics of the economy and population. The substantive elements and corresponding statistical and legal framework indicators are presented in the Annex.

The statistical indicators were identified by looking through the eyes of people, that is, from the perspective of how decent work is perceived by individual people. They are quantitative indicators that can be derived from official national data sources. The legal framework indicators are qualitative in nature and are primarily based on legal, policy or programme texts and other related information. While statistical indicators make up the vast majority of the indicators in the FMDW, the legal framework indicators are equally important. The two sets of indicators are mutually reinforcing and thus both considered essential for monitoring progress towards decent work in a given national economy.

There is a layered approach to the statistical indicators as follows. Main indicators represent a parsimonious core set of indicators to monitor progress towards decent work. Additional indicators are to be used where appropriate, and where data are available. Future indicators are currently not feasible, but are to be included as data become more widely available. Gender equality is a cross-cutting element in the Decent Work Agenda, thus it is recommended that the indicators be disaggregated by sex whenever possible.

Many of the decent work statistical indicators are best calculated using estimates derived from a labour force survey (LFS). The primary objective of a LFS is to obtain reliable estimates about the labour force of a given population based on a sample of households. This instrument permits the estimation of the number of persons employed as well as the size of the working age population and can be designed to provide both stock and flow estimates. It generally covers all workers, including all self-employed persons and often allows disaggregation of data by demographic variables such as sex, age group and in some cases, ethnic group. Moreover, it often allows breakdowns by status in employment, occupation group and economic activity group. Other sources are used to complement the estimates from labour force surveys such as other topic-specific household surveys (like child labour surveys) and other household surveys, employment-related establishment surveys, and administrative records.

The measurement scope of the FMDW extends to all persons in a given country who are or potentially could be engaged in productive work in the broadest sense. It includes both persons in the labour force and persons outside the labour force. Its scope goes beyond the working age population since child labour is included. Moreover, because one of the main pillars is the objective of social protection for all, including workers and non-workers, children and adults, the population scope on this topic covers the entire population in a given country. It covers all usual residents and therefore covers migrant workers and non-migrants and workers of all ethnic and indigenous origins.

3. Concept definitions: What is meant by work, employment, rural, and rural workers?

The ICLS and concept definitions of work and employment

Since 1923, the ILO has been responsible for organizing the International Conference of Labour

Statisticians (ICLS). The ICLS is held every 5 years and seeks to promote the development and use of statistical concepts, definitions, and methods. ICLS standards are the world reference for producing statistical information on employment and unemployment and a wide range of other decent work-related subjects. In 2013, the 19th ICLS adopted a new international statistical standard, the "Resolution concerning statistics of work, employment and labour underutilization" (referred to hereafter as the Resolution) (ILO, 2013). The Resolution adopted in 2013 establishes a new framework on work statistics, defining the concept of work as comprising "any activity performed by persons of any sex and age to produce goods or to provide services for use by others or for own use".

Work is defined irrespective of its formal or informal character or of the legality of the activity. It excludes activities that do not involve producing goods or services (e.g. begging and stealing), self-care (e.g. personal grooming and hygiene) and activities that cannot be performed by another person on one's own behalf (e.g. sleeping, learning and activities for own recreation). According to the Resolution, the concept of work covers all activities within the general production boundary as defined in the System of National Accounts 2008 (SNA 2008). According to the Resolution, work can be performed in any type of economic unit as distinguished by the SNA 2008, namely: (i) market units (i.e. corporations, quasi-corporations and household unincorporated market enterprises, the latter encompassing, as a subset, informal sector units); (ii) non-market units (i.e. government and non-profit institutions serving households); and (iii) households that produce goods or services for own final use.

The Resolution identifies five mutually exclusive forms of work, distinguishing them on the basis of the intended destination of the production (for own final use; or for use by others, i.e. other economic units) and the nature of the transaction (i.e. monetary or non-monetary transactions, and transfers). These include:

a) **own-use production work** comprising production of goods and services for own final use (an unpaid form of work) - (note that own-use production of goods includes as a subset category, subsistence food production);

b) **employment work** comprising work performed for others in exchange for pay or profit;

c) u**npaid trainee work** comprising work performed for others without pay to acquire workplace experience or skills;

d) **volunteer work** comprising non-compulsory work performed for others without pay;

e) **other work activities** (including such activities as e.g. unpaid community service and unpaid work by prisoners, when ordered by a court or similar authority, and unpaid military or alternative civilian service).

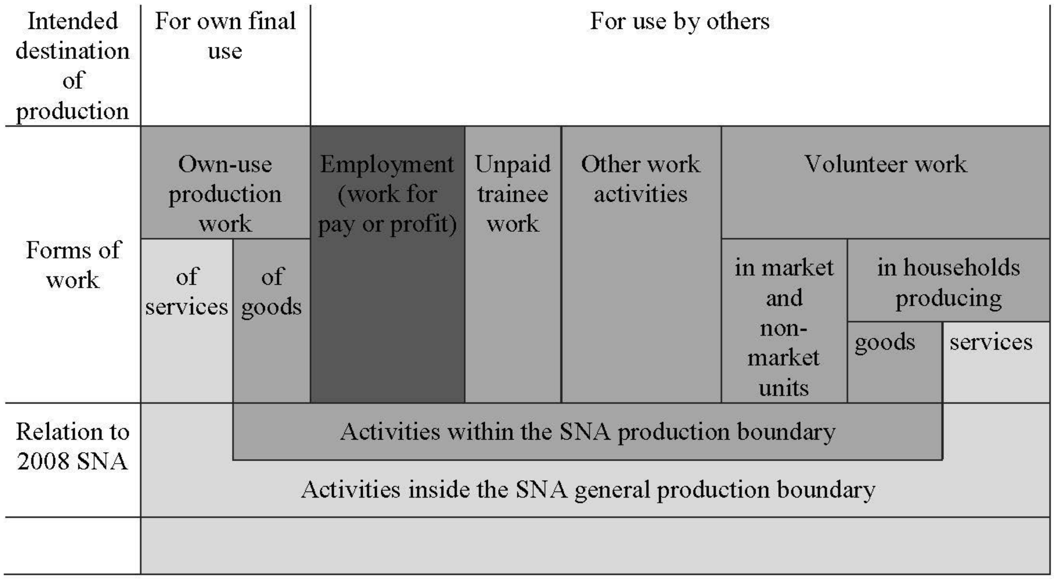
Own-use production of goods, employment, unpaid trainee work, a part of volunteer work and "other work activities" are within the SNA 2008 production boundary, while own-use production of services and the remaining part of volunteer work are beyond the SNA production boundary but inside the SNA general production boundary. In the previous ICLS standards on measuring employment and unemployment adopted in 1982, employment corresponded to persons engaged in activities within the SNA production boundary, and thus for example included subsistence farming activities. Figure 1 below presents the conceptual framework for work statistics.

The current definition of employment (work for pay or profit) is thus much narrower than it was under the previous standards and excludes own-use production of goods (including subsistence workers) and other unpaid forms of work. This change is expected to have a notable impact on various headline indicators in the future as countries begin to implement the standards in their household surveys (including LFS). Thus for example, countries which have in the past included persons engaged in subsistence food production activities in employment may well see increases in the unemployment rates, particularly in rural areas. Until now, rural unemployment rates have been consistently lower than urban unemployment rates in many developing countries, but this situation will likely reverse with the implementation of the 19th ICLS Resolution. It is thus important that countries produce parallel series (using the old and new standards) for at least 12 months and carry out an appropriate communications strategy with data users to inform them of the changes in methodology and any changes in the time series.

Definition of rural and urban areas

The definition of rural and urban areas as used in labour statistics or other statistical domains is a complex issue, since there are no existing international statistical guidelines that would allow coherent, harmonized reporting. Currently, a broad array of different criteria is applied in national definitions of rural/urban areas reflecting a myriad of geographic and socio-economic realities in countries across the globe. This situation presents serious challenges when attempting to make cross-country comparisons of labour statistics by rural/urban area or even regional or global estimates of different indicators, for example, labour force participation rates, gender pay gaps, youth unemployment rates,

Figure 1 – Conceptual framework for work statistics

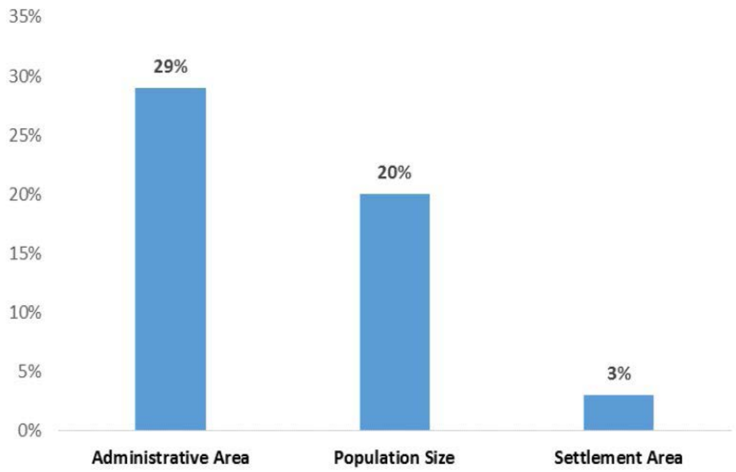


Source: ILO, 2013

or child labour rates, to name just a few.

The ILO has developed an inventory of country-level statistical definitions of rural and urban areas for 214 countries/territories which confirms that the definitions are highly heterogeneous (Robles, Kashef and Castillo, 2016). Countries often define urban areas and provide no specific definition of rural areas. The fact that rural areas in many countries are defined de facto by urban areas is telling, since it signals that urban areas are the main target, and rural areas, a residual category. A majority of countries (52%) base their definitions on a single criterion, most often administrative area, population size or type of settlement area (Figure 2). It is interesting to note that predominance of agricultural activities is not commonly used as a single criterion.

Figure 2 – Percentage of countries applying a single criterion to define rural/urban areas by the main criterion



Source: ILO, 2016. Values are given as a percent of 214 countries, 52 percent of which applied a single criterion

Forty-eight percent of countries use multiple criteria to define rural/urban areas, that is, they combine criteria such as administrative area, population size and/or density, predominance of agricultural/ non-agricultural activities, and availability of infrastructure services and amenities, among others to distinguish between rural and urban areas. Where multiple criteria were found to define rural/ urban areas, the vast majority (60 percent) of countries use administrative area and other criteria, mainly population size and/or density. Predominance of agriculture/non-agriculture activities together with other criteria are used in 15 percent of the countries, mainly in Europe, Central Asia and Africa. Availability of infrastructure services and amenities along with other criteria are applied in 12 percent of the countries.

Some key similarities and differences in the rural/urban definitions across regions should be mentioned. In Latin America, Asia and Europe, administrative area is the most common criterion, followed by population size. Both Latin America and Asia apply predominance of agriculture/non-agriculture activities as a third most commonly used criterion. In Africa, population size is the most commonly applied criterion, followed by administrative area, predominance of agricultural/non-agricultural activities, and availability of infrastructure services and amenities.

The highly heterogeneous criteria used to define rural/urban areas in different countries and regions around the world is an issue that needs to be addressed. In order to have meaningful cross-country comparisons of different statistical indicators disaggregated by rural/urban areas, the international statistical community should establish an internationally recognized definition of rural and urban. A recently published FAO working paper proposes a conceptual framework and territorial definitions to support better coherence and comparisons of rural statistics (Offutt, 2016).

Definition of worker and rural worker

While the ICLS recently adopted a statistical definition of the concept of work, it didn't explicitly define "worker". However, since according to the 19th ICLS Resolution work refers to the productive activities carried out within the SNA general production boundary, a worker by extension can be understood as any person that is engaged in one or more of the five forms of work defined in the Resolution during a given reference period. A rural worker can then be defined for statistical purposes as a worker engaged in any job or work activity that is located in a rural area during a given reference period. This issue requires special attention in survey measurement, since often the geographic location of the household or housing unit in a household survey is assumed to be the same as the geographic location of the person's job(s) or work activity(ies). However, individual workers may be living in one geographic area and working in another. This is depicted in Figure 3 below, where cells 2 and 3 reveal situations where a worker's household is located in one geographic area but the job or work activity is in another.

Figure 3 – Worker's household location versus job or work activity location

	Urban household	Rural household
Urban-based job or work activity	Urban household and urban-based job or work activity 1	Rural household and urban-based job or work activity 2
Rural-based job or work activity	Urban household and rural-based job or work activity 3	Rural household and rural-based job or work activity 4

Source: ILO

In order to best identify the geographic location of the job/work activity, specific questions should be introduced in the questionnaire that allow identification of the geographic location according to the national definition of rural and urban areas. Such a question(s) should be appropriately tested prior to full-scale implementation in a household survey. The ILO is currently field testing a question on this in model LFS questionnaires that are part of a pilot LFS programme intended to support countries to implement the 19th ICLS Resolution on work statistics.

4. What do available data reveal about decent work and the labour market situation of rural workers?

When reviewing data currently available in international labour statistics repositories such as ILOSTAT, it is evident that substantial data gaps exist for even several main decent work indicators. When seeking decent work indicators disaggregated by rural/urban areas or additional disaggregations, for example, by rural/urban areas and by sex or age, data are even scarcer. The most commonly available indicators disaggregated by rural/urban areas for a large set of countries are basic labour market indicators related to employment, unemployment and labour force. Table 1 below presents the very limited country coverage of decent work indicators disaggregated by rural/urban areas available in ILOSTAT. This table reveals that the only substantive elements of the FMDW for which statistics are readily available are (1) Employment opportunities (denoted EMPL) with six variables/indicators, and (2) Social security (SECU) with seven indicators. Thus, for eight of the ten substantive elements, there are too few countries producing the corresponding statistical indicators to allow their inclusion in the database. Whilst there are also some indicators available under the substantive element of Economic and social context for decent work (CONT), these do not allow the direct monitoring of decent work.

The ILO Department of Statistics has recently begun to analyse the few available labour market indicators disaggregated by rural/urban areas. It should be noted that the available statistics reflect definitions on employment, unemployment and labour force that correspond to international standards adopted by the 13th ICLS in 1982. The scarce availability of quality labour statistics, the lack of implementation of the 19th ICLS Resolution on work statistics, and the lack of a commonly applied international definition of rural/urban areas makes analysing the labour market situation in different countries an enormous challenge. The lack of harmonization in concept definitions and methods limits the possibility of constructing regional or global estimates, or even averages for a small set of countries.

Table 1: Country coverage of decent work indicators by rural/urban areas and further disaggregations by sex and age (in number of countries)

TOPIC	Indicator	RUR/URB	RUR/URB + SEX	RUR/URB + AGE (Youths and Adults)	RUR/URB + SEX + AGE (Youths and Adults)
CONT	Estimates and projections of the total population	195	195	195	195
CONT	Working-age population	116	110	35	34
CONT	Poverty gap at national poverty line	67			
CONT	Poverty gap at rural poverty line	67			
CONT	Poverty headcount ratio at national	98			
CONT	Rural poverty headcount ratio at rural poverty line	97			
EMPL	Labour force	113	110	38	36
EMPL	Labour force participation rate	93	88	31	31
EMPL	Employment	122	117	36	35
EMPL	Employment-to-population ratio	99	92	31	31
EMPL	Unemployment	113	108	35	34
EMPL	Unemployment rate	112	102	32	32
SECU	Active contributors to an old age contributory scheme as % of employment	21	21		
SECU	Share of population above statutory pensionable age receiving a contributory old age pension	20	20	NA	NA
SECU	Legal health coverage	159			
SECU	Out-of-pocket expenditure	118			
SECU	Coverage gap due to financial resources deficit	147			
SECU	Coverage gap due to health professional staff deficit	161			
SECU	Maternal mortality ratio per 10 000 live births by geographical coverage	142			

Source: ILOSTAT. Note: Countries are counted if they present at least one data point for the indicator from 1980 until 2015

The analysis below seeks to present the changes during the period 2012-13 in just three available labour market indicators—labour force participation rate, employment to population ratio, and unemployment rate—in a few selected countries to show the key differences between urban and rural areas using existing concept definitions. It exemplifies the challenges to analysing the indicators as available today disaggregated by rural/urban areas, where cross-country comparisons are not possible.

Labour market situation in selected countries, 2012-13

During 2012-13, global growth was slow in the wake of the 2008 global financial crisis. According to the IMF, during 2013 advanced economies began to expand again but needed to continue restructuring the weakened financial sector and promote job growth (IMF, 2013).

Emerging market economies faced the challenges of slowing growth and a more difficult global financial situation.

Table 2 below presents labour market data for seven countries for which the trends and rural/urban differences are noteworthy during the period. The set of indicators cannot be compared across countries, since there are serious data comparability issues involving measurement of the labour market concepts and definitions of rural and urban areas.

As noted previously when describing the currently applied (13th ICLS, 1982) standards on the measurement of employment and unemployment, due to the current broad measurement of employment, all but one country present lower unemployment rates in rural areas as compared with urban areas in both years. The exception is Sri Lanka that reported a slightly higher rural unemployment rate in 2012 as compared with the urban rate, but this situation reversed in 2013.

With the forthcoming implementation of the 19th ICLS Resolution on work statistics, many countries will show the reverse situation, that is, rural unemployment rates are expected to be higher than urban unemployment rates. Moreover, with the implementation of the Resolution, countries will have a broader set of labour underutilization indicators to choose from to complement the unemployment rate, allowing for a more refined analysis and more targeted policy interventions in both urban and rural areas.

Table 2: Key labour market information for selected countries (percentages)

Countries	Labour force participation RUR/URB + AGE (Youths and Adults)				Employment-to-population ratio				Employment-to-population ratio			
	Rural		Urban		Rural		Urban		Rural		Urban	
	2012	2013	2012	2013	2012	2013	2012	2013	2012	2013	2012	2013
Armenia	73.3	72.5	57.1	58.3	69.4	68.2	42.5	44.6	5.3	6.0	25.5	23.4
Dominican Republic	62.8	53.4	66.1	57.5	54.3	45.8	56.0	48.6	13.6	14.2	15.3	15.4
Egypt	50.0	49.9	46.8	46.7	45.0	44.6	39.2	39.0	9.9	10.7	16.3	16.5
Indonesia	70.5	67.4	65.3	66.1	67.2	64.0	60.3	61.3	4.7	5.1	7.7	7.3
Iran, Islamic Republic of	40.0	39.7	36.5	36.9	36.2	36.7	30.9	31.4	8.2	7.0	13.8	11.8
Serbia	48.0	50.1	45.7	47.3	38.3	40.9	33.4	35.6	20.1	18.4	26.9	24.9
Sri Lanka	48.0	55.3	43.7	49.0	46.1	52.9	42.1	46.4	4.0	4.2	3.7	5.3

Source: ILOSTAT

Another point to note from the data in Table 2 is that a particular labour market indicator for a rural area will sometimes move in the opposite direction when compared with the indicator for an urban area, reflecting specific labour market demand and supply conditions in the different geographic areas. This is exhibited in the cases of Armenia and Indonesia, where the rural unemployment rates increased during the period (reflecting a decline in rural labour demand that exceeded the decline in rural labour supply) while the urban unemployment rates declined (reflecting an increase in urban labour demand that exceeded the increase in the labour supply).

Finally, some of the indicators in Table 2 present very large differences between rural and urban areas. In Armenia for example, there is a 20.2 and 17.4 percentage point gap between the rural and urban unemployment rates in 2012 and 2013, respectively. Serbia, Iran and Egypt present somewhat smaller but still notable differences between urban and rural unemployment rates in both years. Iran and Serbia report low values of employment-to-population ratios, while Serbia, Dominican Republic and Egypt report high values of unemployment rates. Disaggregations by sex, age, ethnicity and other factors are highly important for understanding some of these values in rural areas, but such data are not always available.

5. Conclusions

Policymakers increasingly require more refined analysis based on targeted decent work indicators and greater levels of disaggregation by sex, age, ethnicity and other variables in addition to geographic area, and this demand is expected to grow considerably in the coming years due to the launch of the Sustainable Development Goal (SDG) indicators. Yet, despite the existence of robust conceptual frameworks and international recommendations related to the measurement of decent work and work statistics, there remain many obstacles that prevent the production of timely, high quality statistics on decent work and productive employment disaggregated by rural and urban areas. The international statistical community should act quickly and create opportunities to meet the challenges, including considering new strategies and partnerships. There are a number of interrelated measures and steps that should be considered in this process, that include the following:

1. Countries need to build capacity as regards the latest statistical standards on work statistics and other ICLS standards, in order to implement the standards in their labour statistics system and produce high quality statistics. This should be accomplished through technical assistance.

2. ILO Guidance and toolkits that support the implementation of the international standards need to be developed and shared with countries.

3. An international statistical definition on rural/urban areas should be developed in collaboration with national statistical offices and international agencies. Countries should be encouraged to continue to use national definitions as appropriate, but would use the international definition for international reporting and cross-country comparisons.

4. A statistical conceptual framework on rural workers should be developed that is consistent with the latest ICLS standards and considers decent work indicators specifically for rural workers that go beyond the existing set of decent work indicators.

5. Capacity-building activities (training) should be strengthened around the topic of rural labour statistics and analysis, including topics of gender mainstreaming in rural labour statistics, youth and ethnicity in rural labour statistics, and other selected topics pertinent to rural development and poverty reduction.

6. Partnerships among donors and various international agencies with a mandate on rural labour statistics should be strengthened in order to support countries on rural labour statistics production and analysis.

ANNEX I

Table A. Measurement of decent work based on guidance received at the Tripartite Meeting of Experts on the Measurement of Decent Work (September 2008)

Substantive element of the Decent Work Agenda	**Statistical Indicators**	**Legal Framework Indicators**
Numbers in parentheses in the first column below refer to ILO strategic objectives: 1. Standards and fundamental principles and rights at work; 2. Employment; 3. Social protection; 4. Social dialogue.	Selection of relevant statistical indicators that allow monitoring progress made with regard to the substantive elements. M – Main decent work indicators A – Additional decent work indicators F – Candidate for future inclusion / developmental work to be done by the Office C – Economic and social context for decent work (S) indicates that an indicator should be reported separately for men and women in addition to the total.	L – Descriptive indicators providing information on rights at work and the legal framework for decent work. Description of relevant national legislation, policies and institutions in relation to the substantive elements of the Decent Work Agenda; where relevant, information on the qualifying conditions, the benefit level and its financing; evidence of implementation effectiveness (as recorded by ILO supervisory bodies); estimates of coverage of workers in law and in practice; information on the ratification of relevant ILO Conventions.
Employment opportunities (1 + 2)	M – Employment-to-population ratio (S)* M – Unemployment rate (S) M – Youth not in employment, education, or training, 15-24 years (S)* M – Informal employment rate (S)* A – Labour force participation rate (1) [to be used especially where statistics on Employment-to-population ratio and/or Unemployment rate (total) are not available] A – Youth unemployment rate,15-24 years (S) A – Unemployment by level of educational attainment (S)* A – Employment by status in employment (S) A – Proportion of own-account workers and contributing family workers in total employment (S)* [to be used especially where statistics on informal employment are not available] A – Share of wage employment in non-agricultural employment (S) F – Labour underutilization (S) Memo item: Time-related underemployment rate (S) grouped as A under "Decent Working time"	L – Government commitment to full employment L – Unemployment insurance

Adequate earnings and productive work (1 + 3)	M – Working poverty rate (S)* M – Employees with low pay rate (below 2/3 of median hourly earnings) (S)* A – Average hourly earnings by occupation group (S)* A – Average real wages (S) A – Minimum wage as a percentage of median wage A – Manufacturing wage index A – Employees with recent job training (past year / past 4 weeks) (S)	L – Statutory minimum wage*
Decent Working Time (1 + 3)*	M – Employment in Excessive Working Time (more than 48 hours per week) (S)* A – Employment by weekly hours worked (hours in standardized hour bands) (S)* A – Average annual working time per employed person (S)* A – Time-related underemployment rate (S) F – Paid annual leave (developmental work to be done by the Office; additional indicator)	L – Maximum hours of work L – Paid annual leave
Combining work, family and personal life (1 + 3)	F – Asocial / unusual hours (developmental work to be done by the Office) F – Maternity protection (developmental work to be done by the Office; main indicator)	L – Maternity leave (including weeks of leave, and rate of benefits) L – Parental leave*
Work that should be abolished (1 + 3)	M – Child labour rate [as defined by ICLS resolution] (S)* A – Hazardous child labour rate (S)* A – Rate of worst forms of child labour (WFCL) other than hazardous work (S)** A – Forced labour rate (S)** A- Forced labour rate among returned migrants (S) **	L – Child labour (including public policies to combat it) L – Forced labour (including public policies to combat it)
Stability and security of work (1, 2 + 3)	M - Precarious employment rate ** A - Job tenure** A - Subsistence worker rate** A – Real earnings of casual workers** (S) Memo item: Informal employment is grouped under employment opportunities.	L – Termination of employment* (incl. notice of termination in weeks) Memo item: 'Unemployment insurance' is grouped under employment opportunities; needs to be interpreted in conjunction for 'flexicurity'.
Equal opportunity and treatment in employment (1, 2 + 3)	M – Occupational segregation by sex M – Female share of employment in senior and middle management* A – Gender wage gap A – Share of women in wage employment in the non-agricultural sector A – Indicator for Fundamental Principles and Rights at Work (Elimination of discrimination in respect of employment and occupation) to be developed by the Office. A – Measure for discrimination by race / ethnicity / of indigenous people / of (recent) migrant workers / of rural workers where relevant	L – Equal opportunity and treatment* L – Equal remuneration of men and women for work of equal value*

	and available at the national level to be developed by the Office. F – Measure of dispersion for sectoral / occupational distribution of (recent) migrant workers F – Measure for employment of persons with disabilities. Memo item: Indicators under other substantive elements marked (S) indicator should be reported separately for men and women in addition to the total.	
Safe work environment (1 + 3)	M – Occupational injury frequency rate, fatal* A – Occupational injury frequency rate, nonfatal* A – Time lost due to occupational injuries A – Labour inspection (inspectors per 10,000 employed persons)	L – Employment injury benefits* L – Occupational safety and health (OSH) labour inspection
Social security (1 + 3)	M – Share of population above the statutory pensionable age (or aged 65 or above) benefiting from an old-age pension (S) * M – Public social security expenditure (percentage of GDP) A – Healthcare expenditure not financed out of pocket by private households A– Share of economically active population contributing to a pension scheme (S) * F – Share of population covered by (basic) health care provision (S) (to be developed by the Office; additional indicator) F – Public expenditure on needs based cash income support (% of GDP) F – Beneficiaries of cash income support (% of the poor) F – Sick leave (developmental work to be done by the Office; additional indicator) [Interpretation in conjunction with legal framework and labour market statistics.]	L – Old-age social security or pension benefits (public/private)* L – Incapacity for work due to sickness / sick leave L – Incapacity for work due to invalidity Memo item: 'Unemployment insurance' is grouped under employment opportunities.
Social dialogue, workers' and employers' representation (1 + 4)	M – Trade union density rate (S) * M – Employers' organization density rate (ED) (S)* M – Collective bargaining coverage rate (S) M/F – Indicator for Fundamental principles and rights at work (Freedom of association and collective bargaining) to be developed by the Office; main indicator A – Days not worked due to strikes and lockouts*	L – Freedom of association and the right to organize L – Collective bargaining right L – Tripartite consultations
Economic and social context for decent work	C – Children not in school (percentage by age) (S) C – Estimated percentage of working-age population who are HIV-positive C – Labour productivity (GDP per employed person, level and growth rate)	L – Labour administration** Developmental work to be done by the Office to reflect environment for Sustainable enterprises, incl. indicators for (i) education, training and lifelong learning, (ii)

	C – Income inequality (90:10 ratio) C – Inflation rate (Consumer Price Index, CPI) C – Employment by branch of economic activity C – Education of adult population (adult literacy rate, adult secondary-school graduation rate) (S) C – Labour share of Gross Value Added (GVA)* C (additional) – Real GDP per capita (level and growth rate)* C (additional) – Female share of employment by economic activity (ISIC tabulation category)* C (additional) – Wage / earnings inequality (90:10 ratio)* C (additional) – Poverty measures **	entrepreneurial culture, (iii) enabling legal and regulatory framework, (iv) fair competition, and (v) rule of law and secure property rights. Developmental work to be done by the Office to reflect other institutional arrangements, such as scope of labour law and scope of labour ministry and other relevant ministries.

*Wording modified by ILO in the pilot phase; **Indicator added by ILO in the pilot phase (2009-2013).

Table B. Sustainable Development Goal (SDG) Indicators related to Monitoring Decent Work

SDG Goal	Indicator number	Indicator name
Goal 1. End poverty in all its forms everywhere	1.1.1	Proportion of the population below the international poverty line
	1.a.2	Proportion of total government spending on essential services
	1.3.1	Coverage of social protection floors
Goal 5. Achieve gender equality and empower all women and girls	5.5.2	Proportion of men and women in managerial positions
Goal 8. Promote sustained, inclusive and sustainable economic growth, full and productive employment and decent work for all	8.2.1	Annual growth of real GDP per employed position
	8.3.1	Proportion of Informal employment in non-agriculture employment
	8.5.1	Average hourly earnings of female and male employees
	8.5.2	Unemployment rate
	8.6.1	Proportion of youth not in education, employment or training
	8.7.1	Proportion and number of children engaged in child labour
	8.8.1	Frequency rates of fatal and non-fatal occupational injuries
	8.8.2	Increase in compliance of labour rights
	8.b.1	Total government spending in social protection and employment porgammes as a proportion of national budgets and GDP
Goal 10. Reduce inequality within and among countries	10.4.1	Labour share of GDP
	10.7.1	Recruitment costs borne by employee as a proportion of yearly income
Goal 16. Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels	16.10.1	Number of verified cases of killing, kidnapping, enforced disappearance, arbitrary detention and torture of journalists, associated media personnel, trade unionists and human rights advocates in the previous 12 months

Note: Other SDG indicators not listed above may also be also relevant for monitoring progress towards decent work. The above list includes only those for which the ILO is closely involved or a direct custodian. While the language formulation in the above indicators may differ slightly from that used in the decent work indicators, nearly all of the listed SDG indicators are also decent work indicators. Note also that while SDG indicator 8.3.1 related to informal employment excludes agriculture, the corresponding decent work indicator (EMPL-4) does not exclude agriculture.

A05

A framework for measuring rural women's empowerment within the context of decent work: focus on economic and social advancement[1]

DOI: 10.1481/icasVII.2016.a05d

ABSTRACT

The objective of the paper is twofold: (i) to provide an assessment of existing measures of rural women's economic and social empowerment within the decent work framework, and (ii) to propose the first part of a new measurement framework to better capture the nexus between women's empowerment and decent work within rural areas in developing countries where agricultural is an important part of the economy. This partial measurement framework proposes an indicator set on time use as a way to measure an aspect of rural women's empowerment, complementing the conventional approaches to measuring employment and decent work in the rural economy.

Keywords: Gender and sex-disaggregated indicators, rural, agriculture, Decent Work, women's empowerment

PAPER

1. Introduction

Gender-sensitive labour indicators disaggregated by rural/urban areas are crucial to better understanding how roles, rights, and opportunities shape men and women's access to decent work in rural areas in developing countries. They can assist in identifying disparities in rural men and women's participation in decent work, as well as in pinpointing differences in men and women's constraints in participation in decent work. Over the last decade, the development of international standards and guidelines has resulted in a greater number of gender-sensitive and sex-disaggregated statistics. However, despite the progress made, a gender-sensitive statistical measurement tool to explore the nexus between women's greater empowerment and decent work within the rural areas in a developing country context where many rural households are engaged in agricultural production has not yet been fully developed. The objective of the paper is twofold: (i) to provide an assessment of existing measures within the decent work framework of women's economic and social empowerment in developing countries particularly with a focus on rural areas, and (ii) to propose the first part of a new measurement framework to better capture the nexus between women's empowerment and decent work within this context. The full measurement framework aims to incorporate a set of core indicators to monitor rural women's empowerment, complementing the conventional approaches to measuring employment and decent work in the rural,agricultural context.Because of space, this paper presents only the first part of the full measurement framework, and within this partial framework it specifically focuses on a set of indicators measuring work time. The paper is structured as follows: Section 2 links the concept of women' empowerment with the concept of decent work and discusses the gender dimensions of work within the rural areas in a developing country context where many rural households are engaged in agricultural production. Section 3 assesses the decent work indicators and how well they capture women's social-economic empowerment (or constraints to empowerment) with work within this context and provides the first part of set of core indicators to monitor rural women's empowerment. Section 4 discusses data collection for the set of indicators measuring work time. Section 5 concludes.

Setting the stage: defining empowerment in terms of work and understanding the gendered dimensions of work within the rural areas in a developing country context where many rural households are engaged in agricultural production

The term empowerment encompasses a broad range of concepts, which generally comprises of, at least in part, the idea of having an environment or the conditions for which an individual can achieve his or her goals and having the ability to make decisions over one's life (Malhotra, Schuler and Carol 2002). Within the context of decent work–where the concept of work, according to the Resolution on work, employment, and labour underutilization adopted by the 19th International Conference of Labour Statisticians (ICLS) in 2013, is defined as any activity performed by persons of any sex or age to produce

[1] Contribution to the ICAS VII: Rough draft on gender and rural women's empowerment in relation to DW/rural employment.

goods or provide services for use by others or for own use —empowerment means that there are equal work opportunities for women and men in conditions of freedom, equity, security, and dignity (ILO 1999). This concept of decent work, as developed by the ILO and endorsed as a global goal, goes beyond a simple analysis of labour market outcomes such as unemployment reduction and employment creation. According to the Declaration on Social Justice for a Fair Globalization adopted in 2008 by ILO Member States, it incorporates four mutually intra-dependent strategic pillars: (I) employment creation and enterprise development, (II) social protection, (III) standards and rights at work, and (IV) governance and social dialogue (ILO 1999)[2]. Following a Tripartite Meeting of Experts in 2008 with the aim to provide guidance on how to measure decent work, a Decent Work Measurement Framework was established and structured along 10 core substantive elements of decent work. Such substantive elements --ranging from čemployment opportunitiesč to čadequate earnings and productive workč and čsocial dialogue, workers' and employers' representationč-- were attached to one or more of the four strategic pillars of the Agenda. Seventy-one statistical indicators and twenty-one legal framework indicators are currently contained in the Decent Work Measurement Framework as a way to measure progress within these substantive elements.The selected decent work indicators serve as a tool for a) assisting constituents to assess progress towards decent work and b) to offer comparable information for analysis and policy development. Building from this framework, the Food and Agriculture Organization (FAO 2016) developed a conceptual framework which incorporates rural women's empowerment in terms of work directly as well as all aspects outside of work but that affect work in a gendered way (e.g. health facilities and infrastructure, education, gender training, etc.) The FAO 2016 framework—which overlaps in parts but also extends beyond Decent Work agenda—has three empowering components as a way to conceptualise women's empowerment within the framework of decent work. These are 1) Social and Economic Advancement; 2) Power and Agency; and 3) Dignity and Value. The Social and Economic Advancement component focuses specifically on individual's engagement in work within and outside employment with a focus on rural and agricultural work. It also focuses on education and the skills development needed to access gainful employment activities within this context. It aims to measure men and women's work time, returns to wage work and differences in employment and skills development. The Power and Agency component focuses on access, control over, and influence of community and individual resources as well as engagement in social and economic decisions related in agriculture production and other productive activities in the household. It also focuses on control over and input into the use of income earned from the household's productive activities. It aims to measure ownership of physical and financial resources important in this context, decision-making over the use of productive assets and income earned form productive activities, and leadership in the community. The Dignity and Value pillar underlines the quality of life and work perceived by the individual and as measured by his or her surrounding environment. It aims to measure the freedom to choose and satisfaction with work, conditions of employment, forced labour, and child labour.

While the FAO 2016 paper provides a comprehensive framework for conceptualizing rural women's empowerment in decent work, this paper provides a core set of indicators within this first pillar (social and economic empowerment) focusing specifically on measures of men and women's engagement in work. The setting is on developing countries where agriculture is an important part of the countries' economies, there is a large rural population, poverty remains largely rural, and many rural households engage in agricultural production. For the purpose of this paper we define agriculture as the production of crop and animal products, as well as hunting, trapping, fisheries and aquaculture, forestry and related activities. Rurality is defined in contrast to urban areas, referring to areas outside of urban agglomeration. These areas may lack sufficient infrastructures that connect rural to urban areas and thus may be cut off from more developed urban markets. The population density in rural areas is lower than urban areas, but what exactly constitutes rurality as defined by national statistical offices varies across country (United Nations 2014)[3]. Within this context, members of small-holder households in agriculture often engage in multiple livelihood activities as a way to try to minimise their vulnerability to variability and cyclicality of income throughout the year due to seasonality and uncertainty in agriculture production. These activities may include self-employment activities in agriculture, earnings or in kind from temporary or casual wage labour, petty trading, street vending, or rent from leasing land.Income diversification is recognized as an important survival strategy for poor households particularly in rural Africa, and many studies of households in developing countries have found that income diversification is positively associated with greater welfare in rural households, particularly when the diversification is in activities outside of agriculture (see for instance, Ersado 2006; Block and Webb 2001Davis, et al. 2010).

In addition to income earning activities, own-use production, including subsistence farming, is

[2] The Decent Work Agenda (1999) is a policy framework endorsed by ILO Member States for conceptualising how to achieve decent work at the national level, which has received endorsement at the highest political and international levels. The 2008 Declaration on Social Justice for a Fair Globalisation indicates that member States should consider the ―establishment of appropriate indicators or statistics, if necessary with the assistance of the ILO, to monitor and evaluate progress made...[towards decent work]‖(ILO 2008 Paragraph II.B.ii).

[3] The United Nation (UN) statistical division has proposed a minimum set of criteria for international comparability. Rural areas are generally classified in accordance with "the size of locality or, if this is not possible, the smallest administrative division of the country." In other words, rural areas comprise a less dense population even if country specific characteristics usually make these areas different from country to another (United Nations 2008).

particularly important to the well-being and survival of poorer rural households, where own-use production is the production of household goods and services for the household's consumption or family living in other households[4]. It includes unpaid caregiving services and household maintenance such as cleaning, laundry, agricultural production for consumption, food preparation, gathering food, and providing for children or elderly. When dealing with shocks or income shortfalls, households may substitute market goods and services with goods and services provided by household members. Since incomes tend to fluctuate, there can be a large amount of fluidity between the consumption of goods and services produced for home consumption and goods and services purchased in the market. In poor rural households engaged in agriculture, it is often the combination of income from employment work activities and own-use production work in collaboration with other household members that sustains the household. The same activity in own use production (e.g. harvesting maize, or food preparation, etc.) can be considered a form of employment if the work is paid or the goods are intended for sale. There are a gendered aspects to these work activities. Evidence from the literature suggests that women perform a large majority of the household's own-use production work; although it varies by context (see, among others, Antonopoulos 2009, Bardasi and Wodon 2006, Budlender 2008; Ilahi 2000). Additionally, contributing family work is a widespread form of employment among women, particularly among the extremely and moderately working poor (ILO 2014). Data from the ILO global employment trend (2014), for instance, suggests that 59 percent of the female labour force in South Asia, 35 percent in Southeast Asia and the Pacific, 35 percent in Sub-Saharan African, and seven percent in Latin America are contributing family workers in the household's business. While contributing family workers are included in the definition of employment (with the ICLS 19th Resolution), remuneration of the work is paid to another household or family member. Indirect remuneration is subject to individual with control of the revenue. Women's greater engagement in work for which they are not directly paid (such as own-use production work and contributing family labour) compared to men results, in some contexts, in women working a greater number of hours than men, and a greater likelihood of facing time poverty, where time poverty is defined as not having adequate time for rest and relaxation. Bardasi and Wodon (2005), for instance, find that women work more hours than men on average in Guinea for 2002-2003 and that time poverty rates are much greater in rural areas than in urban areas. Women's greater engagement in own-use production work and contribution family labour than men also affects how and to what degree women can engage in employment activities for which they are paid directly. Women, for example, may be more likely to combine own-use production and other non-remunerated activities with remunerated work, taking on multiple work tasks at the same time. Floro (1995) argues that overlapping activities are particularly applicable to women in poorer households that do not have the access to resources that would allow them to purchase market substitutes. Additionally, studies suggest that the concentration of women from low-income households in informal paid work is in part related to the greater ability to combine unpaid household work and paid work (Mitra 2005; Chen et al. 2005; Kucera and Roncolato 2008; Roncolato and Radchenko forthcoming). This is because the informal nature of many self-employment jobs, such as street vending or trading, often allows greater flexibility in terms of time dedicated to other activities.

Assessment of current Decent Work indicators for measuring rural women's Social and Economic empowerment in work and proposal for a conceptual framework for measuring rural women's empowerment within decent work

The concept of Decent Work is a means to identify countries' major priorities in terms of labour market outcome achievements as well as a better understanding of productive work overall of both men and women. Recognizing that men and women may not have the same opportunity and treatment in work, and the women may face different constraints around family and engagement in work, many of the Decent Work indicators are sex disaggregated and there are a number of gender relevant indicators including occupation segregation, wage gap, maternity protection, and work time arrangements. While these indicators are important, many are not as easily applicable in a context described above where many individuals may engage in multiple income-earning activities, self-employment activities are the norm, and own-use production work is vital to sustaining the household compared to contexts where individuals are mostly engaged in one or two primary jobs in the formal market. The gender wage gap indicator (EQUA-3), for example, is calculated based on average hourly earnings from employers, which is less applicable in this context where work with earnings from employers is only a small percent of

[4] Specifically, if it is unpaid, the 19th ICLS Resolution considers own-use production work as
a. Producing and/or processing for storage agricultural, fishing, hunting and gathering products that are not intended for sale or profit ;
b. Collecting and/or processing for storage mining and forestry products, including firewood and other fuels;
c. Fetching water from natural and other sources;
d. Manufacturing household goods (such as furniture, textiles, clothing, footwear, pottery or other durables, including boats and canoes);
e. Building, or effecting major repairs to, one's own dwelling, farm buildings, etc.
f. Household accounting and management, purchasing and/or transporting goods;
g. Preparing and/or serving meals, household waste disposal and recycling;
h. Cleaning, decorating and maintaining one's own dwelling or premises, durables and other goods, and gardening;
i. Childcare and instruction, transporting and caring for elderly, dependent or other household members and domestic animals or pets, etc.

Table 1: Proposed work indicators for measuring rural women's empowerment within the context of decent work under the economic and social empowerment component of the FAO (2016) conceptual framework

	Area	Indicators	Already in the DW framework
1.1	Employment and labour force participation	• Men's employment-to population ratio, Women's employment-to population ratio • Men's labour force participation rate; Women's labour force participation rate	Yes (EMP-1 and EMP-5)
1.2	Informal employment, including the agricultural sector	• Proportion of men informally employed; Proportion of women informally employed	Yes (EMP-4)
1.3	Own account workers and contributing family workers	• Proportion of employed men who are own-account workers; Proportion of employed women who are own- account workers • Proportion of employed men who are contributing family workers; Proportion of employed women who are contribution family workers	Yes (EMP-9)
1.4	Work contribution	• Average total number of hours per day men dedicate to remunerated and non-remunerated work in agriculture Average total number of hours per day women dedicate to remunerated and non-remunerated work in agriculture • Average total number of hours per day men dedicate to all remunerated and non-remunerated work; Average total number of hours per day women dedicate to all remunerated and non-remunerated work	No

the work done by men and women. Profits from and time worked in self-employment activities, which often overlap with other activities and are difficult to separate from own-use production, makes the data difficult to capture in this context. Similarly, measures of maternity protection and work time arrangements within employment are less applicable in a setting where much of employment work is informal. Occupational segregation (EQUA-1) measures men and women's difference in occupations in their main job. While important, the occupational categories are broad (ISCO sub-major groups) and less informative than the EMP indicators when disaggregated by sex. Indeed, when compared to the employment-to-population ratio (EMP-1), the other labour force indicators disaggregated by sex: informal employment rate (EMP-4), employment status in employment (EMP-8), and proportion of contributing family labours in total employment (a part of EMP-9) allow for a greater understanding of men and women's differences in employment work as well as engagement in employment that does not provide direct exchange for the work within this context. Previously these indicators included individuals engaged in own-use production of goods (but not services) as a main job in the definition of employment. This changed with the 19th International Conference of Labour Statisticians (ICLS Resolution I, 2013), which distinguishes between work for pay or profit,or employment, and unpaid forms ofwork across five forms of work:1) own-use production work, 2) employment, 3) unpaid trainee work, 4) other work activities, 5) volunteer work. The new concept includes only formal and informal wage employment, self-employment activities, and contributing family labour in the definition of employment. The exclusion of own-use production makes the employment indicators more comparable across countries. Within this context, however, to capture the full extent of men and women's work, the Decent Work framework also needs to include measures of own-use production work and time worked in employment and non-employment work activities. Based on current definitions, the Decent Work time use indicators only focus on time associated with employment activities, not all work activities. The Subsistence Worker Rate (STAB-3), which is the proportion of employed persons who are subsistence workers—where subsistence workers are subsistence farmers, fisheries, hunters, and gathers—needs to be modified to be in line with the new definitions. Even with a modification, a proportion indicator only captures who engages in the work and not the extent to which individuals engage in the type of work.

Additionally, it does not capture all forms of own-use production work.

Under the Social and Economic Advancement component of the FAO 2016 framework,Table 1 presents our proposed set of core indicators that we believe may better capture a decent work framework for the measurement of rural women's socio-economic empowerment in developing countries where small household agriculture in an important part of the economy. The set of indicators is based on both the FAO conceptual framework as well as the ILO decent work Agenda and Decent Work indicators already part of the framework. The indicators proposed are at the country-level. Since rurality differs by country, it is difficult to compare across countries if the focus is only on rural areas. However, we recommend countries also disaggregate by rural/urban areas.

Indicators 1.1, 1.2 and 1.3 are already part of the Decent Work Measurement framework. The employment indicators (under 1.2 and 1.3) provide information on the type of the employment and whether the type of jobs men and women engage in lack basic social or legal protections or employment benefits. Greater empowerment is proxied though fewer women (and men) in informal type work of those employed. The criteria adopted to construct the proportion of employed rural population working under informal labour arrangements follow the resolution adopted by the 17th International Conference of Labour Statisticians. According to the ILO (2012), informal employment is a job-based concept capturing the extent to which employed persons lack basic social protections in a given economy[5]. These indicators are often limited to individuals' main jobs. The 17th International Conference of Labour Statisticians recommendations suggest to countries to compile statistics on multiple jobholders, but countries often do not have the resources to incorporate this into Labour Force Survey questionnaires.

The final indicator set (under 1.4) captures women and men's time spent in all work in agricultural activities and total work time spent in all activities (agriculture and non-agriculture). The indicator set in not currently included in the current Decent Work indicators. Similar to the indicators proposed in the Global Strategy for Improving Agricultural and Rural Statistics "Guidelines for collecting data for sex-disaggregated and gender-specific indicators in national agricultural surveys" (FAO forthcoming) we propose including (1) the average time spent in all agricultural activities by men and women and (2) the average time spent in all work activities in general by men and women. Specifically these are $\left\{\frac{\sum_i T_{Ai}}{X_T}, \frac{\sum_j T_{Aj}}{Y_T}\right\}$ and $\left\{\frac{\sum_i T_{wi}}{X_T}, \frac{\sum_j T_{wj}}{Y_T}\right\}$, where X_T is the total number of adult women in the time use sample, Y_T is the total number of adult men in the time use sample, and T_A is the time spent by the ith female or jth male in work in agricultural production, and T_w is the time spent by the ith female or jth male in all work. We aggregate own-use production and employment in agricultural work and all work, because in this context often the boundaries between own-use production work and employment work are not distinct. For example, it can be difficult to distinguish activities where the crops are primarily for sale versus activities where the crops are for home consumption, since so often these are dual-purpose, particularly in smallholder agriculture. Even aggregated, the indicator set captures the extent of rural women's work as compared to men in this context in a way all the other Decent Work indicators focused only on employment work do not.

Recommendations for data collection of the new indicator set measuring work time

To capture time use data, many labour force surveys as well as agricultural surveys tend to use stylised time methods where time in a specific activity is estimated over a week or month. Data collected in this way are best used when activities take place on a regular basis and when general trends, rather than the actual time spent, are sought (Juster, Ono and Stafford 2003). The preferred approach for collecting time use data is through experimental sampling method for time use data collection, where an individual records their own activities at random times throughout a specified time period. This approach tends to be less prone to systematic measurement error than recall methods, but more burdensome to the respondents and more costly to implement than stylized approaches. As a middle ground—following the Global Strategy Guideline—we propose using a 24-hour recall module that can be included as part of labour force surveys. Unlike other stylised methods where the time period is much longer, the 24-hour recall method reduces methodological biases and allows for the detail needed

[5] From a statistical standpoint, the employment in the informal sectors can be computed according to the characteristics of the enterprises owned by the own-account worker and employers. According to the ICLS, the informal nature of their jobs follows directly from the characteristics of the enterprise, which they own. Three main criteria are employed in defining the jobs performed in the informal agricultural sectors: 1) produced goods are meant for sale or barter; 2) the size of the farm in terms of employment falls below a certain threshold–determined according to national circumstances— 3) farms are not registered under specific forms of national legislation. The informal employment is captured by summing up the total number of informal jobs performed under informal arrangements and not regulated labour relationships. This is the case of contributing family workers who, by definition, inherently hold informal jobs. Accordingly, the ILO statistical definition of ―informal employment— (ILO, 2003) classifies jobs held by contributing family workers as a priori informal, irrespective of the formal or of informal nature of the sector in which they work. The classification does not apply to employees, since the informal nature of the performed job mainly reflects the absence of national labour legislation, social protection or employment benefits that apply to their jobs. In practice individuals within the rural population may engage in multiple forms of employment, the labour force statistics collected, however, are usually based only on individual's primarily and sometimes secondary occupations.

to capture differences in time spent in different work activities (Kan and Pudney 2008). An example module in the appendix merges the time use modules in the American Time Use Survey (ATUS) and the Women's Empowerment in Agriculture (WEAI and pro-WEAI) Surveys. To collect information on the selected respondent's activities, the enumerator asks the respondentfor activities from 4 a.m. the previous day until 3:59 a.m. the day of the interview using pre-codes to record activities. Using the data from this module, the mean population estimates can be inferred by collecting time use data from one randomly selected respondent per household in a subsample of households (and weighted as needed based on the probability of an individual within his or her household) (Frazis and Stewart 2012). A drawback to the 24-hour approach, however, is that we are often interested in time use over a longer period of time than a single day. If data is collecting for many households over a period of time (such as a particular season), inferences will be made on men and women's average time use over that full season. To be comparable across years the module will need to implemented at the same time period every year. Ideally, the module would be implemented quarterly (or at least twice a year) as a way to capture seasonality. Future drafts will include examples of set of time use indicators using data from districts in Uganda.

2. Conclusion

This paper proposes the first part of set of core work indicators with the socio-economic component of the FAO 2016 women's empowerment framework to monitor rural women'sempowerment in the context of decent work within rural areas in developing countries where agricultural is an important part of the economy. This paper is the first of three papers. The other two will cover the Power and Agency and Dignity and Value components of the FAO 2016 women's empowerment framework.

MEASURING THE SOCIAL AND ECONOMIC IMPACT OF CONFLICTS AND POLITICAL INSTABILITY ON AGRICULTURE

Session Organizer
T. Brück | IGZ | Großbeeren | Germany

ABSTRACT

Violent conflict has significant effects on the welfare, resilience and behaviour of individuals, households and communities. These impacts deserve close study at the micro-level, both as a new field of academic inquiry and as an aid to development and poverty reduction policy. Policy practitioners have increasingly realized the importance of understanding, compensating for, and overcoming the constraints caused by violent conflict.

Subsistence agriculture is one of the key livelihood strategies of extremely poor people affected by violent conflict, including those forced to flee. In rural areas, conflict often puts an end to formal economic activities (e.g., export-oriented agriculture), destroys productive assets (e.g., livestock), and restricts access to formal markets and traders. In response, resilient households resort to various informal, small-scale, labour-intensive activities including subsistence agriculture. This can prove particularly valuable for refugees in protracted humanitarian emergencies, given the restrictions on their movement and their inability to access to much land. For example, planting very small vegetables gardens is one of the most labour intensive and least land intensive forms of agriculture, which can even be undertaken even inside a refugee camp.

However, relatively little is known about how households struggling to survive protracted violence and displacement get by economically, what shapes their (agricultural) livelihoods and what determines their food security. This is true both of socio-economic determinants and of the natural science of smallholder agriculture in conflict and fragile settings.

Standard agricultural surveys in conflict-affected countries only sporadically feature questions related to the causes and consequences of violence, leaving treatments ad-hoc and incomparable across different settings. This makes it hard to build a systematic and comparable understanding of how violence has affected different people, communities and population groups, and constitutes a key gap in agricultural policies in conflict-affected settings. To gather better data on the impacts of conflict and instability, well-designed surveys need to acknowledge the prior existence of violent conflict in formal questionnaires and survey designs. A recent publication by the World Bank helps to address this need (Brück, T. et al, 2013. „Measuring Conflict Exposure in Micro-Level Surveys". LSMS-ISA Sourcebook, World Bank, Washington, D.C.) as do the many papers published by the Households in Conflict Network (www.hicn.org).

Building on these insights, this session will review recent efforts to measure violence, conflict, instability and fragility at the micro-level in the agricultural sector in low, middle and high income countries. Particular preference will be given to papers developing and testing new methodologies for data collection on conflict dynamics or individual behaviour and welfare outcomes in rural settings and to papers using such data analytically to understand the performance of agriculture and rural development in times of violent conflict.

ABSTRACT

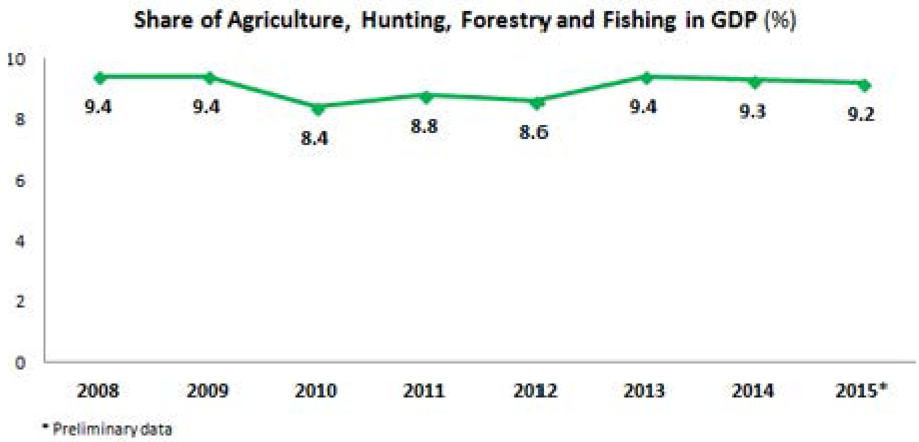
According to the recent census results in Georgia, as of October 1, 2014, there are 642.2 thousand holdings in the country: of which 640.0 thousand households and 2.2 thousand legal entities. 30.9% of holders are women. Among the regions, the largest number of holdings is observed in Imereti (19.6%), Kakheti (15.1%) and Samegrelo-Zemo Svaneti (13.3%). The diagram below illustrates regional distribution of holding numbers.

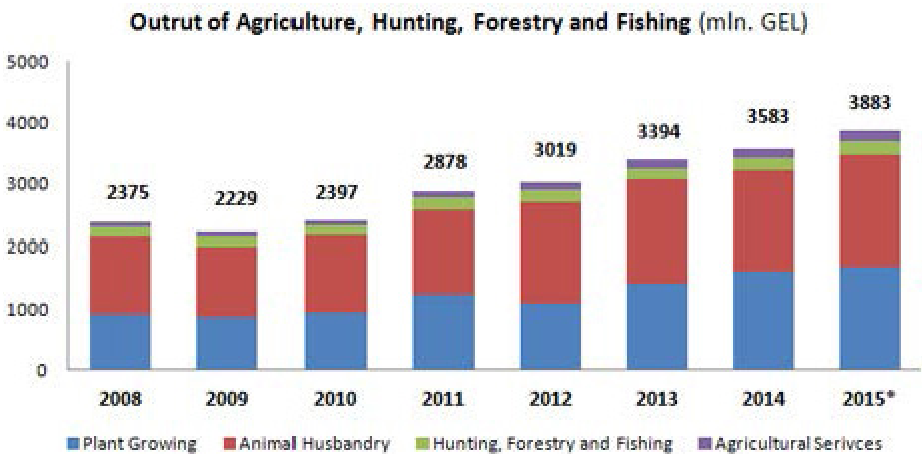
Keywords: Keyword 1, Keyword 2, Keyword 3 (character 12 pt, double-justified)

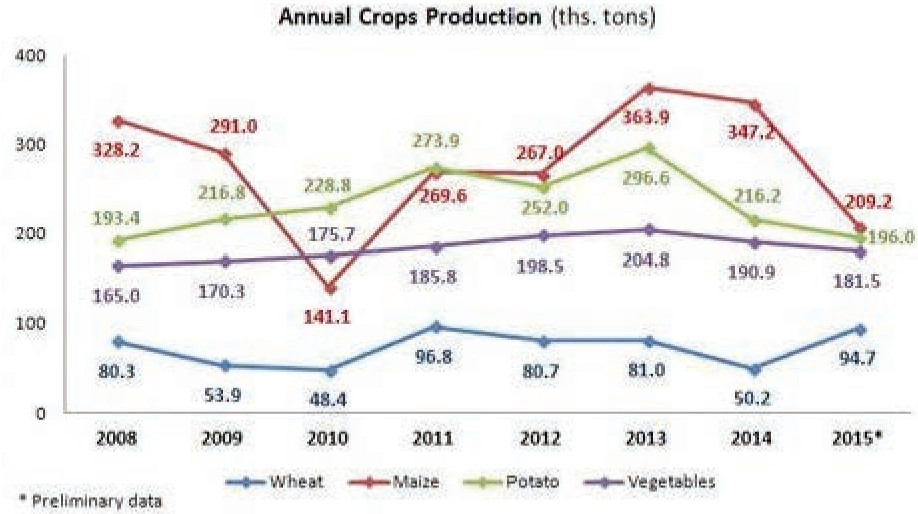
PAPER

1. Agricultural Census Data in Georgia

Major portion of holdings are operating small-sized land. In particular, more than three fourth of holdings (77.1%) are operating agricultural land of size less than 1 ha and their total area constitute 21.5% of whole operated agricultural land. 40.1% of agricultural land operated by holdings are located in Kakheti, 15.5% - in Kvemo Kartli, and 9.7% - in Samtskhe-Javakheti. The census has covered all agricultural holdings in the country (on the territory controlled by the Government of Georgia) and it was done according to the methodology developed by the Food and Agriculture Organization.





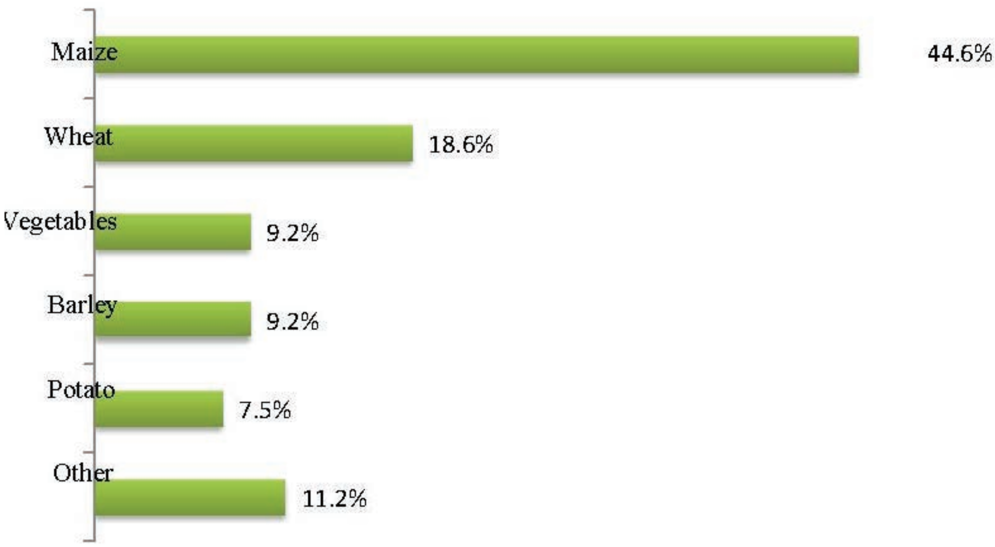


2. Food Security as challenge for Georgian Farmers

Georgian food producers, farmers and Agricultural Cooperatives should be in response of a growing number of outbreaks associated with consumption of fresh fruits and vegetables. All our efforts are on a development of the a science-based regulatory frameworks to address the production of all fruits and vegetables in organic manner according existing guidance documents and regulations; and, consistent with a mission to promote uniform food safety laws, rules and regulations.

Opportunities in Food microbiology research are the gateway to sustaining and improving agriculture and food production in Georgia, quality, and safety. Multidisciplinary research must be undertaken to capitalize on advances in different disciplines, such as genomics, nanotechnology, and computational biology. Research into the interactions of animal and plant hosts with pathogens and beneficial microbes is essential to preventing disease and encouraging mutuality interactions. On a more holistic scale, interactions occurring among organisms within a microbial community require study so that a healthy balance between the highly managed ecosystems of industrial agriculture and the unmanaged ecosystems of the Food Security can be achieved.

Figure 1 - Structure of Land under Temporary Crops by Particular Crops (as of October 1, 2014)



As of October 1, 2014, there is 377.4 thousand ha of arable land operated by holdings, of which 85.5% is operated by households and 14.5% - by legal entities. An average area of arable land operated by holdings is 0.7 ha. 86.9% of holdings are operating arable land of size less than 1 ha. 70.3% (265.4 thousand ha) of arable land area is covered by temporary crops1. This indicator is 77.2% (249.2 thousand ha) for households and 29.5% (16.2 thousand ha) - for legal entities. 49.4 thousand holdings are operating the land under temporary crops of size 1 ha and more, 3.5 thousand holdings - 5 ha and more, and 1.6 thousand holdings - 10 ha and more. 44.6% of land under temporary crops is covered by maize, 18.6% - by wheat, 9.2% - by vegetables, and 9.2% - by barley. The diagram below shows the structure of land under temporary crops by particular crops.

Table 1: Livestock and Poultry Numbers and Average Values (as of October 1, 2014)

Indicator	Unit of measurement	Holdings of all categories	Households	Legal entities
Livestock and poultry numbers				
Cattle	Thousand heads	1,005.4	997.0	8.5
Sheep and goat	Thousand heads	989.3	962.0	27.3
Pig	Thousand heads	213.1	195.3	17.8
Poultry	Thousand heads	8,216.0	5,441.3	2,774.7
Number of holdings with livestock/poultry				
Cattle	Thousands	271.9	271.7	0.1
Sheep and goat	Thousands	23.7	23.7	0.0
Pig	Thousands	93.9	93.9	0.0
Poultry	Thousands	364.9	364.8	0.1
Average number per holding[2]				
Cattle	Heads	3.7	3.7	60.4
Sheep and goat	Heads	41.7	40.6	700.7
Pig	Heads	2.3	2.1	424.1
Poultry	Heads	22.5	14.9	32,264.0

Tables: The highest number of cattle is observed in Samegrelo-Zemo Svaneti (195.2 thousand heads), Imereti (168.8 thousand heads) and Kvemo Kartli (140.7 thousand heads). 14.1 thousand holdings have 10 and more cattle, while 0.5 thousand holdings have 50 and more. The diagram below shows regional distribution of cattle numbers.

DOI: 10.1481/icasVII.2016.a06b

ABSTRACT

Rural dwellers cherish social relationships and are passionately engaged in such interactions even as they carry out agricultural practices on which they depend for livelihood. The situation can readily be jeopardized by conflicts. Violent communal conflict (VCC) is usually unpredictable, could retard development, perpetuate poverty and household food nutrition and health, insecurities, and widen gender inequalities. Individuals and groups, including gender categories are usually affected differently irrespective of the causes of VCC. Empirical data on causes and effects of VCC on gender categories will be valuable to inform individual, community and policy decisions.

This study assessed gender perspective to effects of violent communal conflicts on selected rural communities in Edo and Ondo States of Nigeria. Specifically it by gender; described the socio-economic characteristics of the respondents; ascertained gender roles in key household activities; identified causes and severity of VCCs experienced; and examined the effects of VCC on social and livelihood activities; ascertained the coping/survival strategies used; and identified perceptive solutions to conflict.

A two-stage sampling procedure was adopted; firstly the purposive selection of three communities that experienced VCC within 2010-2014 in each State and secondly, the random selection of sixty (60) households / respondents per community to give a total of 360 respondents. Data were collected using structured questionnaire while focus group discussion (FGD) and key informants were used to triangulate information. Data analysis was by descriptive and inferential statistics.

The study revealed that male youth constituted 20. 7%, adult males (40.6%), female youth (10.4%) and adult females (28.2%) that majority of the respondents were males (61.4%), married (68.6%), and with a mean age of45.8years. About 24.5% had no formal education,71.5%were indigenes and family size was5-9 persons. About 67.7% held two leadership positions, with 63.1% engaged in agricultural enterprises in a mean farm size of 2.09ha. It was found that VCCs were mostly caused by power/ leadership tussle (65.7%). Gender roles slightly changed with increase in activities of females. Gender categories differed significantly with respect to effect of VCC on social relations (F=9.743; p=0.000) and livelihood (F=13.705; p=0.000). Wilcoxon signed-rank test shows that the difference before and after conflict is statistically significant for bread winning (z= -9.603), ownership of land (z= -9.368), use of land (z= -7.673) and use of credit (z= -7.802).

The VCC adversely affected gender categories differently but more severe on the females. Bread winning and agricultural indicators such as credit access, land ownership and use were negatively affected after VCC. Appropriate policy support for compensation, peace-building and conflict prevention are recommended.

Keywords: Communal conflicts, socio-economic variables, gender categories

PAPER

1. Introduction

1.1 Background to the Study

Communal connotes shared social interaction which entails interpersonal contact, reciprocal response and an inner adjustment of behavior to the actions of others (Ekong, 2010). Conflict is a form of social interaction in which the actors seek to obtain scarce reward by eliminating or weakening other contenders, (Ekong, 2010). It degenerates into violent situations when excessive physical force and weapons are used. Yesufu, (2005) observed that in rural Nigeria, conflicts may arise where there is difference of opinion, exploitation, and challenge to security between groups. In conflicts, security and livelihood activities are disrupted and high level of poverty, food and nutrition insecurities and communal living and individuals could be affected.

Gender is an acquired identity that is learned, changes over time, and varies widely within and across cultures. It is relational and refers not simply to women or men but to the relationship between them, (USAID, 2007). It is could be seen as development issue since it limits potentials and opportunities. These also dictate their access to and control of resources. Gender inequalities arise from deep-rooted and durable social norms. According to Kabeer, (2012), barriers range from social norms that constrain women's choices and actions, to discriminatory legal and regulatory frameworks tend to restrict opportunities to engage economic and social engagements. In cases where changes in roles have been experienced over the years, corresponding access and control of resources could not be guaranteed (Kabeer, 2010).

Bolarinwa, Abdulsalam-Saghir and Oyekunle (2013) in Nigeria, found adverse impact of conflicts on farmers' livelihood (crops, domesticated and wild life animals), lost productive land. In another study, Bolarinwa, et al.,(2013) found that communal conflict management styles, employed by farmers often lead to destruction of life and properties in core conflict areas. Yesufu, (2005) observed that the frequency of religious and communal clashes, riots, conflicts and violence since 1980, has reached endemic proportions. He suggested the need for self-appraisal, correcting the inherited primordial, religious and cultural, and colonial structures. Nwonu, et al., (2013) found that both the Boko Haram crisis and the Niger Delta crisis have adverse impact on the country's international image and tourism development, consequently on youths' unemployment rate.

1.2 Statement of Problem

Conflicts are antagonistic social interactions and have been of frequent occurrence globally and particularly Nigeria in recent times. It is necessary to provide evidence and understanding of indicators involved in communal conflicts at micro level (Bruck and Justino, 2013) to improve academic research on the issues to better inform policy and interventions. Edo and Ondo States recorded various VCCs which disrupted communal life particularly because of the rural sector's dependence on agriculture and other primary occupations. Conflict could affect the gender groups differently due to varying roles, opportunities, resources, empowerment/capabilities and barriers the society ascribes to the positions occupied by individuals.

1.3 Objectives of the Study

This study assessed gender perspective to effects of violent communal conflicts on selected rural communities in Edo and Ondo States, Nigeria. Specifically it by gender;

1. described the socio-economic characteristics of the respondents;

2. identified causes and severity of VCCs experienced;

3. ascertained gender roles in key household activities before and after VCC;

4. examined the effects of VCC social and livelihood activities;

2. METHODOLOGY

2.1 Study Area

This study was conducted in Edo and Ondo States located at the south western agro-ecological zone of Nigeria. Edo State has an area of 6,873 square miles, 6° 30oN 6°E as its coordinates and an estimated population of over 3,497,502. Ondo State is made up of 18 local government areas. The state lies between longitude 4o 30o N and 6 o East of the Greenwich meridian, 50 450and 80 150 North of the Equator. It has a land area of 14788.723 square kilometers (km2) and a population of 3,441,024 comprising of 1,761,263 males and 1,679,761 females (National Population Commission, 2006).

Edo and Ondo States are made up of 18 Local Government Areas each. They have tropical climate characterized by two distinct conditions of wet and dry seasons. The people are mostly subsistence farmers, public servants, traders and artisans. Major crops produced are rubber, oil palm, cocoa, yam, cassava, maize, rice and plantain. There is also significant animal husbandry, fisheries and forestry activities.

2.2 Sampling Technique

A two-stage sampling process was adopted involving firstly purposive selection of three communities in Edo and Ondo States which experienced VCC in the last five years. They are;

Edo-Egbaen, Okhoromi, Eghirhe communities, Western Post news July 18, 2014; December 31, 2014(http://westernpostnigeria.com/boundarydisputeclaims-livesinedo)

Second stage was the random selection of 60 households per community to give a total of 360 respondents. FGD was used in Edo State but key informants were involved in Ondo communities due to lingering court action in Arigidi communities. Vanguard News August 21, 2011 (www.vanguardngr.com/2011/02/ondo-sets-up-commission-of-in...)

The pre-test was carried out in Okhoromi community which is not included in the study. Test-retest method showed reliability with r=0.893.

Fine tuned instrument content.

2.3 Data collection

Data were collected using structured questionnaire. Focus group discussion (FGD) involving four (4) focal groups (adult male, adult female, male and female youths) was used in Edo communities while key informants were used to complement the questionnaire in Ondo communities due to lingering hostilities. However, questionnaire from 13 respondents were incorrectly filled and so were excluded in the final data analyses.

2.5 Data Analysis

Data analysis involved the use of descriptive statistics and inferential statistics such as using SPSS.

2.6 Measurement of Variables

Gender roles/division of labour in households: level of involvement was measured using a 3point likert type scale of: Highly involved (3), Little involved (2) and Not involved (1). A mean score ⚹2 =involved.

Income from livelihood activities-Average annual income (N)/household.

Severity of VCC indicator items-Actual occurrence/quantity of relevant items were obtained and categorized into 3pt scale while others were measured on a 3-point likert type scale of very serious=3, serious=2 and not serious=1 for 23items minimum=23, maximum=69

Perceived Effect on social and livelihood indicators- was measure on a 3-point scale for 15 items of social indicators to give scores; minimum=15 and maximum=45. Livelihood indicator items were 20 to give scores; minimum=20 and maximum=60.

Extent of usage of coping/survival strategies was measured on a 3point scale: regularly/highly used=3, occasionally/moderately used=2, not used=1;

Perceptive measures for VCC resolution- was measured on a 3point scale: regularly/highly used=3, occasionally/moderately used=2, not used=1

3. RESULTS AND DISCUSSION

3.1 Socio-economic characteristics of respondents by gender

Table 1 shows the socio-economic characteristics of the respondents. Male youths constituted 20. 7%, Adult males (40.6%), female youth (10.4%) and adult females (28.2%) that majority of the respondents were males (61.4%), married (68.6%), mean age was 45.8years with more over 50 years (51.6%), 24.5% had no formal education and reasonable proportion had tertiary education (35.5%), majority were indigenes (71.5%), family size of 5-9 persons (67.7%) held two leadership positions, engaged in agricultural enterprises (63.1%) and mean farm size of 2.99ha.

Findings show that males were more in rural communities. High proportion of educated respondents could imply that unemployed youths were resident. The findings also show that more of older male and female an indication that adults populate the communities. Female represented households had less education, farm size but engaged more in agriculture related enterprises.

3.2 Causes of Violent Communal Conflict

Table 2 shows that major cause of conflict was power/leadership tussle (89.6%) followed by land dispute (53.6%). The finding on power is in line with global trend whereby countries have been plunged into crises due to struggle for leadership. Land/boundary disputes affect major source of livelihood for most rural dwellers. Herdsmen versus crop farmers conflicts are not widespread.

3.3 Severity of conflicts

Table 3 shows minimum and maximum responses to the severity items. On the average, five persons died, 120 injured, 123 were displaced, and 28 lost their means of livelihood among other indicators. These are indications of adverse effect on the people.

Table 2: Causes of violent communal conflict

*Causes of VCC	Frequency	Percentage
Land	186	53.6
Political	64	18.4

3.4 Gender Roles before and after

Roles of males before and after

Fig 1 shows male gender roles in key household activities before and after VCC. The results show that some activities which were considered exclusively women's were undertaken by men before and after VCC experience though at lower extent than female. These include fetching water, sweeping, cooking, and washing clothes. This is an indication of modern values infiltrating the communities. The performance of some of the roles changed/increased after VCC experience.

Roles of females before and after VCC

Fig 2 shows female gender roles in key household activities before and after VCC. The results show that some activities which were considered exclusively men's were undertaken by women before and after

Figure 1 - Roles of male before and after

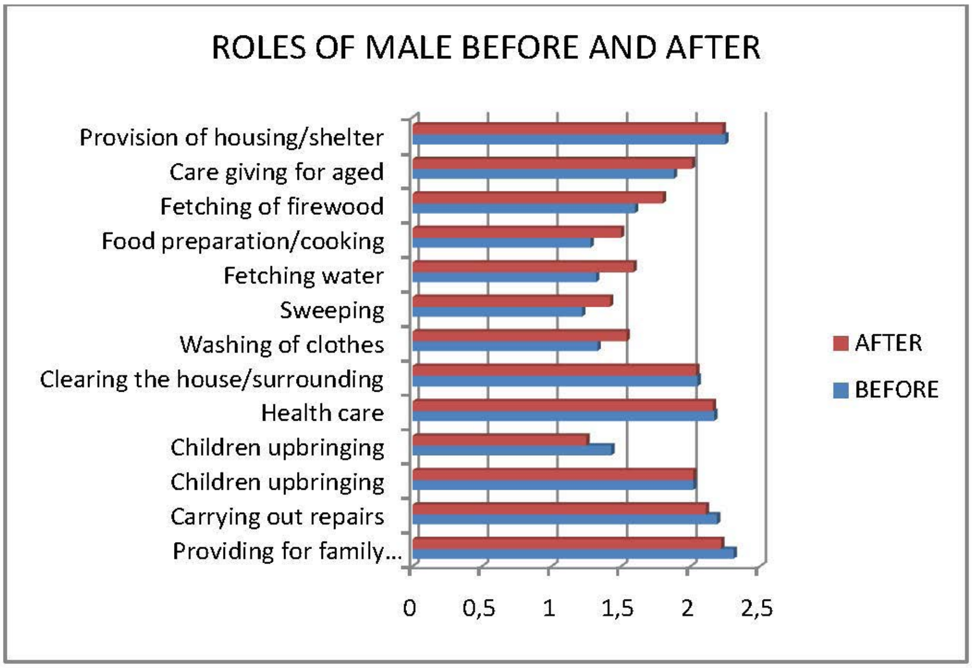

Figure 2 - Roles of female before and after

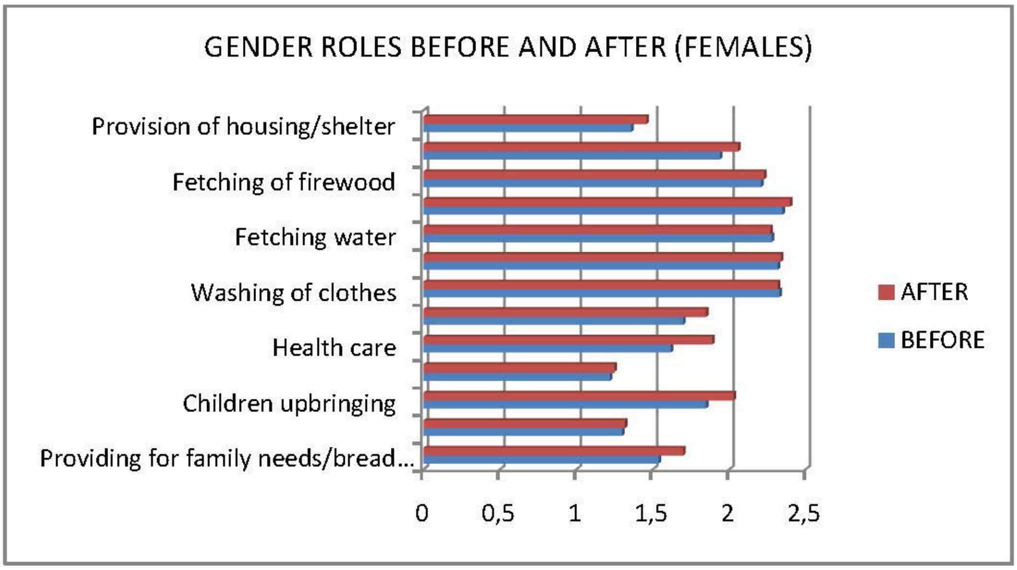

VCC experience. Theses include provision of shelter and bread winning. Women's performance of roles was high for all the roles before and after VCC experience. Higher performance after VCC was revealed for almost all and no decline in performance of any. This is an indication that females carried additional burdens after VCC. It could be that their spouses died or were maimed or relocated. The performance of some of the roles changed/increased after VCC experience.

3.5 Effects of Violent Conflicts

3.5.1 Perceived effects of VCC on social activities by gender

Table 5a shows that respondents' social lives were affected in several ways as the result of VCC. The effects of items 1-3 were common to the gender categories: poor participation in community activities (X =2.21-2.51) highest for female youth, disruption of peace (2.56), social insecurity (X =2.50). In addition to these female youth perceived effect on disruption of worship (X =2.22), loss of human dignity/ confidence (X =2.89), suspicion (X =2.03) especially for female youth.

Some positive social effects were perceived by the females; clearer definition of issues in contention (X =2.42), group cohesion and solidarity (X =2.31), alertness to members interests (X=). The findings confirm the vulnerability of females which agrees with Kanono (2015) which found that women were

*≥2.00=serious effect/seriously affected.

The females indicated more effects on livelihood activities than males. This is also an indication vulnerability of females than males. Males were affected mostly in areas.

3.6 Difference between gender categories with respect to the effects of VCC (ANOVA)

From Table 6a, there were significant differences between gender categories with respect to effect of social and livelihood activities with F=9.743; p=0.000 and F=13.705; p=0.000 respectively. The Post Hoc test shows that the perceived effects for male youth and male adult were similar, but different from the effect on female youth and female adult which were also similar.

3.7 Difference between selected socio-economic variables of respondents before and after VCC

Table 7 shows that or the first variable, providing for family needs, the result shows the effect after the event. It shows that 119 people had their situation turned negative as a result of the clash hence could perform less of this duty of providing for their family needs. Only one respondent had situation turned positive while 227

variables: ownership of land, use of land, use of labour and use of credit. The findings are indications that those engaged in agriculture related enterprises were adversely affected by VCC.

4. CONCLUSIONS

Violent communal conflicts affected social relations and livelihood activities of the respondents. The effects were different from one gender category to another. Agriculture related variables were adversely affected by VCC. The female youth and adult felt the brunt more.

5. RECOMMENDATIONS

1. Community outreaches should be mounted and available communication channels used to appeal to members and enlighten on ills of violent conflicts.

2. Appropriate policy support for compensation, peace-building and participatory conflict prevention and resolution are recommended.

DOI: 10.1481/icasVII.2016.a06c

ABSTRACT

There has been an appreciable decrease in fish catch from inland waters due to conflicts from environmental pollution, religious and tribal clashes; as well as at the household level based on differences in gender roles. Lack of enforcement of fisheries laws and data collection have also resulted in failure to coordinate and restrain the many users, thereby affecting livelihood of fisher folks and food security. However, evidence of conflict on their livelihood and on fish catch and production has not been documented. The study was therefore aimed to identify various forms of conflict, perception of fisher folks and impact on the fishing and fish farming households in Nigeria; and factors influencing conflict. Multistage stratified sampling method was used to select households involved in fishing and fish farming from two States each in the North East (NE) and South South (SS) political zones of Nigeria. Fishing and fish farmers were proportionally and randomly sampled from lists obtained from Agriculture Development Program and Ministry of Agriculture and Natural Resources in each state based on known conflict Local Governemt Areas. Both primary and secondary data were used for the study. Qualitative primary data were collected through In-Depth Interviews with heads of Fisheries Department and leaders of livelihood groups along the capture fisheries and aquaculture value chains. Structured questionnaires were administered to a sample size of 96 and 44 for fisher folks and fish farmers respectively in NE, while 93 and 117 were sampled among fisher folks and fish farmers respectively in SS; being a total of 350 households. Descriptive statistics and logit model were used for the analysis. Various forms of conflicts, effects on fisher folks" livelihood and food security in fishing communities were documented. Types of perception, vulnerabilities, and methods of adaptation to the various forms of conflict were documented. Implication of conflict and migration on the household and fisheries activities as major sources of livelihood were discussed. Types of conflict and productivity of fish differed with political zones. In conclusion, conflict activities had adverse effects on livelihoods and food security of fishing and fish farming households.

Keywords: Perception, Vulnerabilities, Adaptation, Food security

PAPER

1. Introduction

Fisheries resources are a major source of food especially as animal protein for humans and provide employment and economic benefits. According to Food and Agriculture Organisation (2016), in 2013, fish accounted for about 20 percent of animal protein intake in developing countries; Nigeria inclusive. Fisheries can therefore play a role in eradicating extreme poverty and hunger especially in the South-South where most households within the region depends on fishing and fish marketing (Kingdom and Alfred-Ockiya, 2009). Based on the immense role fisheries play to the food security and development of a country such as Nigeria, it is imperative to know that it is being affected by the complex, multi-lingual, multi-cultural diversities of the people. In recent years, these have triggered different forms of conflicts ranging from ethno-religious conflicts to cultural conflicts to political conflicts and to conflict in resource use (Danfulani, 2009). Conflicts take place in fisheries when groups or individuals seek the same resource using different methods or try to utilize the same space for their activities with either party seeking dominance (FAO, 2003). Therefore, conflicts over access and control of fisheries and aquatic resources are a global phenomenon. However, they have particular importance in Nigeria where a significant portion of the population depends on capture fisheries for food and livelihoods. Conflict has led to violence, but avoiding and shunning conflict is also problematic. This is because unresolved problems may flare up again, often with renewed vigour (Salayo et al., 2006). This has been the case in the North East (NE) and South-South (SS) Agro-ecological Zone (AEZ) of Nigeria where unresolved conflict activities have been noted to be a major factor affecting production of fish.

1.1 Problem Statement

Fish catch from inland waters have decreased over the years due to conflicts from environmental pollution, religious and tribal clashes. There has also been inadequate enforcement of fisheries laws and data collection which failed to coordinate and restrain the many users, thereby affecting livelihood of fisher folks and food security. Livelihoods are now threatened as a result of the depletion of aquatic lives, deforestation of farm lands and loss of biodiversity resulting from overexploitation of existing resources and the resultant pollution (Egbe, 2012). Though there is no specific statistics as to how much conflict has dwindled fish production in the agro-ecological zones but according to Davies (2008) the livelihood of fisher folks which was once solely dependent on fisheries resources, accounting for more than 85% annual income, is now combined with other occupation such as arable farming and trading among several others. These livelihoods play complimentary and supplementary role in stabilizing the economy of fishing communities (Fregene, 2005).

1.2 Justification for Study

The presence of many inland water bodies in the NE and SS provide sources of livelihood from fishing and fish farming. Moreover, FAO (2008) reports that the fisheries sector is valuable and important for employment, livelihood support, poverty reduction, food security as well as foreign exchange earnings. The sector employs men in the main fishing activity/pond construction, while women are involved with the on-shore postharvest activities such as processing, storage and trading. Due to various conflict activities in the region, the fisheries sector has become vulnerable and the livelihoods of most fishers are threatened. However, evidence of conflict on their livelihood and on fish catch and production has not been documented.

1.3 Objectives and Hypothesis of Study

The study was therefore aimed to identify various forms of conflict, perception of fisher folks and impact on the fishing and fish farming households in Nigeria; vulnerabilities, adaptation and factors influencing conflict.

$\mathbf{H_{01}}$= None of the demographic and socio-economic factors have any significant relationship on enhancing conflict activities.

2.0 Methodology

2.1 Sampling Procedure

Multistage sampling method was used to select two geopolitical zones in which conflict activities were more prominent among fish folks and fish farmers. In the NE, Borno and Taraba States were selected, while Delta and Edo States in SS zones. Households involved in fishing and fish farming were proportionally and randomly sampled from lists obtained from Agriculture Development Program and Ministry of Agriculture and Natural Resources in each state based on known conflict affected Local Governemt Areas (LGAs). Structured questionnaires were administered to a sample size of 96 and 44 for fisher folks and fish farmers respectively in NE, while 93 and 117 were sampled among fisher folks and fish farmers respectively in SS; being a total of 350 households. Both primary and secondary data were used for the study. Qualitative primary data were collected through In-Depth Interviews with heads of Fisheries Department and leaders of livelihood groups along the capture fisheries and aquaculture value chains.

2.2 Data Analysis

Descriptive statistics was used was to describe household characteristics. Logit model will be used to analyze factors enhancing conflicts.

3.0 Results and Discussion

3.1 Socio-economic Characteristics

Presented in Table 1 are forms and perceptions of conflicts in NE and SS AEZs of Nigeria. In the NE AEZ, the predominant form of conflict is religious (57.1%), while 25.7% indicated no activity of conflict. The dominant forms of conflict in the SS AEZ range from politics (19.0%) to oil pollution (13.3%) and land ownership (5.7%) which are collectively 'resource control' form of conflict; but 41.4% observed none. The perception of conflict indicated as very severe was 83.6%) in NE, but in the SS AEZ main perception of conflict were severe 40.0% and very severe (18.6%). This is in line with the findings of El-Bushra et al (2013) who reported that land disputes such as competition over access to oil-bearing land and to compensation for environmental impact of oil and gas including political manipulation of elections are the major cause of conflict in the south-south AEZ. Arong and Egbere (2013) also reported that oil spills have destroyed the aquatic ecosystem leading to decline of fisheries resource.

The major form of livelihood in the NE was fishing (68.6%) while 31.4% were engaged in fish farming as an alternative (Table 2). In the SS AEZ the major form of livelihood was fish farming (55.7%) and fishing (44.3%). It was observed that people were leaving fishing due to polluted waters resulting in little or no yield. Historically, fishing and agriculture have been the two main occupations in the region. However,

Very severe	86	61.4	31	22.1	117	83.6	13	6.2	26	12.4	39	18.6

after Nigeriaǧs independence in 1960, conflicts between local communities, oil companies, and the federal government started to emerge. As a result of this, communities have come into conflict with oil companies and with the security forces over a range of issues including payments, land acquisition, and environmental damage (Niger Delta Development Commission, 2005). Fishermen were also engaged in fish related activities such as fish processing, fish transportation etc. (Akinrotimi et al., 2007).

The major vulnerability in the NE AEZ was division and crisis caused by the Islamic sect (60%) and the inaccessibility to credit facilities (34.3%). In the SS, the major vulnerabilities was due to inaccessibility to natural resources (42.4%) as a result of either pollution or over-exploitation and the corrupt practices of leaders who seek to amass the wealth and resources for themselves without giving thought to the sustainability of livelihood (41.0%). The major coping strategy in NE AEZ was migration (75%) whereas in the SS AEZ was livelihood diversification. The implication of conflicts on livelihoods of households in the study area was that people were displaced from their homes and forced to undertake other livelihood activities not peculiar to them. As a result this has invariably caused fish production to dwindle in the study area. In view of this, the United Nations Development Project (2007) argues that men and women in the Niger Delta (South-South) feel politically disenfranchised and disadvantaged when compared to the other geopolitical zones of Nigeria. They are frustrated that they cannot legitimately benefit from the oil resources. Therefore, there is a clash of interest among individual, companies and the host communities. For instance, being designated as a "host community" to an oil facility comes with benefits, but historically this practice has exacerbated grievance and fighting among communities and has also led to disputes over "oil" boundaries. Insecurity and volatility in the region have disrupted livelihoods, damaged the ecosystem and created a challenging environment for social and economic development (Environmental Impact Assessment, 2003).

3.2 Test of Hypothesis

Results of the binary logistic regression (Table 3) showed that number of tribes (p←0.05), the type of livelihood and the major cause of conflict (p←0.01) were significant factors enhancing conflict in the NE. In the SS, education (p←0.05) and the major cause of conflict (p←0.01) contributed significantly to conflict activities. This is similar to the findings of Kamilu et al., (2012) who found that the conflict situation in Taraba state cut across level of religion, exposure education, occupation and personal characteristics. In terms of natural resource conflict, El-Bushra et al 2013 reported that in Nigeria, conflict between indigenous and incoming fishermen over sustainable fishing methods in the NE, while in the SS, land disputes such as competition over access to oil-bearing land and to compensation for environmental impact of oil and gas The Hosmer and Lemeshow test revealed that the logit model regression had an overall goodness of fit. The Cox and Snell R^2 and Ngelkerke R^2 for the northeast showed that the model explained 42% and 62% respectively of the variation in the dependent variable whereas in the south-south 33% and 41% respectively are explained in the variation of the dependent variable.

4.0 Conclusion

Conflict activities vulnerabilities and coping strategies differed among the North East and South-South Agro-

PAPER

1. Introduction on Somali Agriculture

Somalia has got potential agricultural resources that can feed its people (10.8m) and even produce surplus for export. It consists of agricultural land (44mha), forestry land (6.7mha), surface water (179.8km^3/annum) and potential underground water unidentified, livestock population (→36m heads), sea and inland fishery resources (3333km long coast) and forestry sectors. Gross Agricultural Products, GAP, contributed in average 62% to the national GDP for the period of 1977-1987. 25% of the GAP is of plant origin whilst 75% comes from the livestock sector. Agriculture commodities represent the only exports for Somali economy. Nearly 70% of the people live in rural areas, being agriculture their main source of livelihood. This statistics clearly indicates how important the agricultural sector is to the national economy. According to the data from the Ministry of Agriculture in 1989, prior to the outbreak of the civil conflict, the tilled area distributed as 564,600ha of rain-fed and 113,000ha of irrigated land; and around 360,300ha was under fallow. Crop production in Somalia is dependent mainly on the rain-fed system while the irrigated area reached at its best 200,000ha. Thus, adoption of water harvesting techniques in rain-fed agriculture, efficient use of the available water for irrigation, delivery of proper agricultural services and availability of farm labor constitute the major determinant factors for the success of crop production.

Upon the outbreak of civil conflicts in the capital and its surroundings in late 1990, wild destruction and looting of public properties including factories, premises, vehicles, machineries, utilities and the like has happened. Looting of heavy and light arms, weapon and ammunition from the military camps is considered the major reason for the continuous civil conflicts. It encouraged the criminals to rob mercilessly the public and private belongings. As a result, the delivery of all social services including education, health and security suspended. The unemployment rate reached its peak due to release of tens of thousands of public employees. During this period, the contribution of the private sector to the national economy was negligible. Consequently, the living condition of the people was badly affected. The impacts of the conflict on the different agricultural sectors will be discussed in the following sections.

2. Methodology

There is no official statistics on the related issues available; but, as secondary data, we reviewed contents of the websites of FAO, IDP, WB, and UNHCR; and fortunately we received the last technical report from the Ministry of Agriculture in 1989. In addition, we organized a discussion with a selected focus group of 13 farmers who have practiced farming before and after the outbreak of the civil conflict. During the meeting, we have discussed all possible conflict factors impacted on crop production; and the results are shown below.

3. Impacts of the conflict on crop production activities

Displacement and migration trend

One of the worst consequences of the civil conflict is the fearful dilemma it created in the people. When killings, robbery, and thievery rates increased, as a coping mechanism, millions of people resorted to flee from their homes to relatively peaceful places in the country; and the number of displaced people reached 1.1m people in 2013 with a distribution pattern of 893,000 in South and Central Somalia, 129,000 in Puntland and 84,000 in Somaliland. Based on the size of support they expect from the relief agencies or their relatives and friends, some people have migrated to abroad. They have been mainly located in the neighboring countries like Kenya, Ethiopia, Djibouti and Yemen; while the others are scattered all over the world. According to World Bank report, the number of Somali refugees also reached 1.1 million people in 2013. The absence of the IDPs and the migrants from their families can not only be regarded as a loss since they have significantly supported their families back, few received high degrees, gained experience and/or earned money from self-employment or employment from other institutions. But, out of that number, 2.2m of IDP and migrants, they compose of a workforce of 1.2m people (56% of 2.2m, ILO model). Being agriculture the major source of employment for the Somali people, in their presence in the country, sizable proportion of that number could have joined to the ongoing agricultural activities in the country.

Increased use of drugs (Qat)

Qat (Catha edulis) is a drug plant grown in Kenya, Ethiopia and Yemen. It was medically proved that it is harmful to human health. This drug is believed to have been introduced to Somalia from the neighboring countries, the producers, for decades back. The annual imports of this poisonous plant cost hundreds millions of dollars. In the past, the government banned Qat twice but failed due to the evasive tactics used by the black marketers. In response, the government imposed heavy taxes on the imports to minimize the quantity and the number of chewers. Now Qat is very cheap, available and widely consumed. Nearly all of the chewers are men; and under the influence of the drug, they always have problems with themselves, their families and environments. Due to income constraints, chewers sometimes beg and skimp on their family needs. During the civil conflicts, Qat chewing reached to the farming areas; and since the addicts hardly abstain from consuming, they resorted to sell their assets, farms, animals. Their productivity and their health status declined. Farmers believe that the absence of effective government is the main factor behind the widespread of Qat chewing habits. There is a widely accepted perception that Qat is incentive for on-going fighting.

Untimely food aid distributions

Prior to the outbreak of the civil conflict, there has been large number of refugee population. They were supported by the government with the support from UN agencies such as WFP. Food commodities were distributed properly to the needy people. In addition, sometimes when seasons fail and the expected harvests fall short, the deficit was filled from commercial imports and food aid. In the economic language when the supply of a product increases, the prices decline. So, the government, by protecting the local producers, set food distribution timing strategy; and taxes were imposed on the cheap imports for price adjusting. Marginal profit was allowed for the farmers' encouragement. But currently agriculture is not the priority area of the government; and farmers are at loss in bumper seasons due to purposeful coincidence of food aid distribution at harvesting time. It is worth-mentioning that the farmers gain profits during poor seasons because there is no food aid distributed and the food prices soar. This does not mean that farmers are happy with the hunger of their people, but the relief agencies concerned are dormant during his period and there is no effective government institutions that can communicate effectively with the concerned partners to purchase the surplus of the harvests in some regions for the benefit of the others. In case the local supply could not meet the gap, food aid imports should be sought from abroad. This could have encouraged and motivated the local producers.

Loss of banana export markets

Somalia is known to produce good quality banana which has been exported to Europe and Gulf markets for nearly a century. It is the only crop exported to abroad; and it constituted 20% of the GAP. Banana production which is a very lucrative industry is considered as one of the most labor intensive agricultural projects. Prior to the outbreak of the civil war, there was a strong banana business run by Somalifruit Company which was shared by Italian Businessman (51%) and Somalia (49%). The company managed about 7000 hectares, thousands of skilled and non-skilled labor force, large network of transportation vehicles, refrigerated marine fleet, substantial agriculture supporting services, banana processing facilities, packaging factory among others. Suspension of such project has caused the release of thousands of technicians and farm labor. Nearly the entire banana industry collapsed. As a result, the unemployment rate of the farming communities rose. Reopening of this business has been tried in 1994, but aggressive competition between farmers of Somalfruit and Sombana (Dole Food Companies) has ended up to the closure of this business. In light of FAO data 2013, the area of the banana shrank from 6000ha to 1900 ha which is equivalent to 216% whilst there was light yield improvement of 15.8% which moved from 17.7t/ha to reach 20.5t/ha for the average years of 1986/90 to 2010/2013 respectively. The area shrinkage can be attributed to lack of export markets, high wages from farm labor shortages, high transportation cost from rough roads, road blocks and the like.

Lack of agriculture supporting services

Crop production practices and civil war incidences are only confined in the southern regions of Somalia. The farming communities are peaceful and unarmed; but competition of the resources by the rival groups is considered the main reason for the concentration of the incidences in these zones. In Somalia, small farmers produce nearly all types of the crops, except the fruit crops which are grown by the commercial farmers. Their production system is traditional with less improved seeds, no use of fertilizers, chemicals and other inputs. During the government period, farmers paid reduced fees for land preparation services to ONAT, the government agency. Currently all of the machinery services are offered by the private sector for profit basis. Prior to the outbreak of the civil conflict, government institutions offered extension services to all farmers. For instance, they were told when to irrigate their farms to avoid water salinity, trained animal power were sometimes freely distributed, competitions for crop productivity were organized annually, for the sake of farmers, market price was controlled properly for the protection of the farmers. Due to the developments on the ground, all of the said services are currently lacking.

Weak judiciary system

On the other hand, in the past, when animals grazed farms accidently or purposefully, the crop farmers received legal support from the police forces against the owners of the herd; and they got compensations commensurate with the damages incurred; but currently irresponsible herders with guns attack farms; and there is no reliable security forces to seek support. These incidences often happen when some neighboring farms harvested and the remaining others postpone harvesting till the crops dry very well for economic reasons. Thus, the latter groups are often attacked by livestock herders; and consequently clashes often erupt. It is worth mentioning that in the past, farmers grew tillering sorghum varieties in the first season, Gu'; and at harvest they did not razed the plants at soil level, but left 10-20cm above the soil in an effort to ratoon in the next rains, the second season. New earlier crop with less input facilities have been harvested next. But, in light of the recurrent clashes with the livestock herders, that agronomic package cannot be adopted.

Lack of quality control institutions

The world is full of unethical people who always run after their interests. They do not care of the crimes they commit. This kind of people is found anywhere in the world including Somalia. Those people can only be managed by strong government institutions. We, in Somalia, during the chaos period, have suffered a lot from this kind of mischievous acts. Those criminals imported poor quality/expired food commodities, fake medicines, poor agrochemicals and fertilizers, machineries, electronics and the like; and large number of people suffered from their evil acts. Lack of such institutions has lead to emergence of such gangs. These harmful products are quite cheap, and the poor has no choice since his purchasing power is very limited. On the other hand, the local production is uncompetitive with the price of the alternative cheap/low quality food imported from abroad. Thus, the local producer and the citizens as a whole are at loss without the government protection.

4. Conclusion

Despite the fact that getting solutions to the problems mentioned by the farmers come under the government responsibilities, but since we have been out of the scene for more than quarter of a century and the challenges are too complex, getting back to the normal track will not be easy. At this end, we call for the global partners to feel sympathy for the suffering Somali people and extend them the maximum technical and financial support they can to restore peace; otherwise, nothing can be achieved.

B07

MEASURING PRODUCTIVITY IN AGRICOLTURE, FISHERY, AND FORESTRY

Session Organizer
C. Carletto | The World Bank | Rome |Italy

ABSTRACT

Despite the key role of the agricultural sector in the economy of many countries, serious weaknesses persist in the measurement of agricultural outcomes and in our understanding of the factors hampering agricultural growth, particulary among smallholders. While governments and donors alike target agriculture for large-scale investments with ambitious goals of raising agricultural productivity multi-fold, large gaps remain in the way we measure returns to key activities like agriculture, particularly among smallholders. Similarly, even greater challenges emerge in the measurement of returns from activities such as fishery and forestry which are central to the livelihood of a large share of poor people. The much heralded Data Revolution and the ensuing use of advanced technologies and new data sources promises to be an opportunity to fill some of the existing knowledge gaps through the development and testing of novel and more cost-effective ways to measure productivity in agriculture, fishery and forestry. Particularly, the use of satellite imagery, remote sensing, mobile phones and various types of sensors are already routinely used in many countries but often their applicability to developing countries contexts – characterized by complex smallholder farming systems and low capacity – has yet to be fully proven. For this session, we invite submissions of theoretical and empirical research proposing innovative uses of technologies and new methods for the cost-effective measurement of productivity of smallholders in developing countries involved in crop and livestock production, fishery and forestry. Especially, we encourage submissions of original applications that contribute to solving particularly thorny issues that continue to challenge agricultural statisticians such as, but not confined to, the measurement of productivity of root and continuous crops, production under intercropping and returns to livestock rearing. We would also welcome innovative examples of integration of new data sources like Big Data with more traditional instruments like surveys and census data to improve on the way we measure productivity among smallholders.

ABSTRACT

We conducted a survey to evaluate the growth of goats and sheep under communal grazing, and to determine the relationship between weight, heart girth, shoulder height, and body condition score in Kweneng, Central and Kgalagadi districts, Botswana. The same animals were measured on two separate occasions, approximately one month apart, to allow growth rates to be recorded. Significant differences in growth rates between the three case study districts were found for both goats and sheep. Amongst the goats measured, gains in height and weight were significantly greater in the Kweneng district, while gains in heart girth measurement were greatest in the Central district. In the case of sheep, weight gain was significantly higher in the Central and Kgalagadi districts, increases in girth measurement were significantly higher in the Central district, and shoulder height gain was significantly greater in the Kweneng district. Statistical tests were used to determine the relationships between animal weight and the other measures taken for goats and sheep. Heart girth in both goats and sheep was shown to be a significant predictor of weight across all three districts. Likewise, shoulder height proved to be a statistically significant predictor of animal weight for both goats and sheep, across each district. The data therefore suggest that heart girth and shoulder height have potential to act as proxy measurements of weight in both goats and sheep, potentially providing smallholder farmers with a cost-effective way of estimating small-stock productivity.

Keywords Tswana goats, Tswana sheep, growth performance, heart girth.

PAPER

1. Introduction

Small-stock such as goats and sheep play a vital role in the livelihood of smallholder farmers in rural Botswana. The goat population in Botswana was estimated to be 1.6 million in 2013, and the sheep population at just under 300,000 (Statistics Botswana, 2015). Just about all goat and sheep production in Botswana takes place in the traditional smallholder sector, with commercial livestock production focusing mainly on cattle (Burgess 2006). The indigenous Tswana breed accounts for the majority of goats and sheep owned by farmers. Goats and sheep are raised mainly for domestic consumption of meat, milk, hides, for income generation, and for other social activities like payment of dowry (Aganga & Aganga 2015).

Small-stock in Botswana are mostly commonly managed in communal grazing areas, where fencing is not permitted (Nsoso et al. 1999). Most local farmers allow their goats, sheep and cattle to browse on tree forages in the rangelands. They may also periodically cut tree branches or harvest tree pods, to use as feed supplements (Aganga & Autlwetse 2000).

However, most smallholder farmers in Botswana invest relatively little in supplementary feeding, labour, and disease and parasite control for their goats and sheep. Although in the case of supplementary feed this may be partly due to irregularity of fodder production arising from variable weather conditions (Burgess 2006), the result of this lack of investment is to hinder the productivity of small-stock. Lack of availability of accurate scales makes it difficult for smallholder goat and sheep producers to gauge the productivity of their animals (ESGPIP 2009). In this study, we therefore sought to evaluate the growth performance of goats and sheep under a communal grazing system, and to determine the relationship between weight, heart girth, shoulder height, and body condition score, by repeated measurement of these characteristics in a sample of animals. A key objective of the study was to determine the extent to which heart girth, shoulder height and body condition score may be used as proxy measures of goats and sheep weight.

2. Materials and Methods

2.1 Study Area

The study was conducted from September through to November 2015 in Kweneng and Kgalagadi districts in the south and south-west of Botswana, and Central district in eastern Botswana. The climate in the Kweneng district is classified as semi-arid, and is influenced by the local steppe. Average annual temperature is 19.6°C, and average annual rainfall is 455 mm (Climate-Data.Org 2016). In the Central district the climate is semi-arid. Average annual temperature is 20.4°C, and average annual rainfall is 452 mm (Climate-Data.Org 2016). The Kgalagadi district is classified as having a desert climate.

2.2 Description of goats and sheep

The Tswana goats are a large horned, multicoloured, medium size breed, with lopping ears, a short course hair structure, and are predominantly bearded and horned (Katongole et al. 1996, Podisi, 1999). Tswana sheep have a well developed fat tail, hairy coat, and are usually white or black and white in colour (Nsoso et al. 1999).

2.3 Small-stock management and data collection

Goats and sheep measured during the project, across all farms and in all three districts, were ear tagged for repetitive collection of data during the study period. All goats and sheep in sampled farms aged "one year and below" were selected for the study. Farmers usually released the goats and sheep between 1000hrs and 1100hrs to forage in communal grazing areas. The small-stock were returned to the „kraals" (fenced enclosures) in the evening. In each farm, initial measurements (weight, girth and shoulder height) were taken before the goats or sheep were released for grazing. A second series of measurements were taken approximately four weeks after initial measurement, to allow a determination of growth rate to be made.

2.4 Statistical analysis

In order to determine the growth rates of livestock for each animal the first measurement of each of these characteristics was subtracted from the second measurement, resulting in three figures for change in weight, heart girth measurement and shoulder height measurement respectively. In order to determine the relationship of different measures of sheep and goat size, analysis of variance (ANOVA) of fixed effects was carried out using the General Linear Model (GLM) procedures of the Statistical Analysis System software package (SAS, 2010). The fixed effects considered were animal type (sheep or goat) and district (Kweneng, Central or Kgalagadi). Initial animal weight was used as a covariate variable. The response variable analysed were weight, heart girth measurement, shoulder height measurement, and body condition score[1]. Simple regression analysis was used to determine the relationship of weight, heart girth, shoulder height, and body condition score. A linear trendline was fitted to each scatterplot. All tests were considered significant at a $P<0.05$ level.

3. Results and Discussion

Data analysed for both goats and sheep showed that district and sex interactions with the variables were not significant, although growth rates measured amongst female goats and sheep alike were smaller than amongst male goats and sheep. Likewise, there was a poor relationship between weight and body condition score, as a potential proxy estimate of animal weight. Consequently, these results are not reported.

Feed availability for grazing animals play a significant role in determining growth performance. Grazing animals like cattle, goats and sheep will usually selectively graze in communal areas when released. Therefore, if forage quantity is limited then selection of the best forages or plant parts by the animal is limited (Zalesky 1997). In an accompanying study of sample communal pastures in the three case study districts (Kgosikoma, unpublished data), Kgalagadi district had the highest grass biomass, at 154kg/ha for good species and 187.50kg/ha for intermediate species. The Kweneng district had the least grass biomass, at 1.48kg/ha for good grass species, and 7.26kg/ha for intermediate grass species. Grass palatability was also most likely to be estimated as intermediate or poor in this district. The population of small shrubs (<0.5m to <1m in height) was highest in Kweneng at 1700 plants/ha and lowest at Kgalagadi with 150 plants/ha. Larger shrubs (>1m to <2m in height) were present in more dense populations in the Central and Kweneng districts, at 700 plants/ha.

[1] Body condition score (BCS) is used as an assessment of the fat reserves of livestock, and involves a physical assessment of fat coverage around the lumbar vertebrae, breastbone, and rib cage (eXtension.org 2009; New South Wales, Department of Agriculture, Agrifact A2.23). A scale of 1 to 4 was used for this research. BCS scores of 1.0 to 2.0 indicate a management or animal health problem. BCS scores of 2.5 to 4.0 indicate a healthy animal in most cases (eXtension.org 2009).

3.1 Growth rates of goats and sheep

The monthly weight gain of goats in the Kweneng district was significantly greater than the other districts (2.19kg; Table 1). The monthly weight gains for goats in the Kgalagadi and Central districts were not significantly different, at 1.97kg and 2.01kg respectively (Table 1). In previous controlled experiments carried out in Botswana (Aganga et al. 1998, Aganga et al. 2000, Aganga et al. 2001) the monthly weight gain of Tswana goats ranged from 0.9kg to 2.4kg, based on a diet of Buffalo grass supplemented with browse species. In these experiments, goats whose diets were supplemented with either lucerne or lablab gained 2.1kg monthly. These results were comparable to the results of our study. In rangelands, goats tend to prefer woody species over grass species. Mphinyane et al. (2015) reported that the diet of goats comprised 72% „browse" consumption in summer, with this proportion increasing to 82% in spring. The higher growth performance of goats in the Kweneng district suggests that a browse-dominant diet appears to be rich in minerals and protein (Le Houerou, 1980, Aganga et al. 2000), and is generally a more significant source of minerals and protein during dry seasons and drought periods (Dambe et al. 2015). According to Devendra (1980) goats are opportunistic foragers, and can maintain a high quality diet under different ecological zones. This was reflected at the Kgalagadi district where the plant population per hectare was the lowest of the three case study districts (↓ 300 plants/ha). Despite this, the goats managed to survive from ample grass that was denser in this district in communal grazing areas than in the other two case study districts surveyed for the study.

Table 1 - Monthly growth parameters of goats browsing natural pastures in communal areas across three districts of Botswana

	Kweneng[1]	Kgalagadi[2]	Central[3]	P-value
Height gain (cm)	3.21±0.21	1.98±0.16	1.89±0.20	*0.0001*
Girth gain (cm)	3.31±0.23	1.99±0.18	6.01±0.21	*0.0001*
Weight gain (kg)	2.19±0.08	1.97±0.06	2.01±0.08	*0.019*

[1] Number of observations in Kweneng; 372. [2] Number of observations in Kgalagadi; 620. [3] Number of observations in Central; 439. ± refers to standard error of the mean (S.E.M).

Height gain was significantly greater amongst goats in the Kweneng district than in the other two districts (3.21cm; Table 1). Browse utilization is dependent on accessibility for foraging animals. Livestock can only fully utilise browse material from plant heights that are within their reach (Le Houerou 1980). Hence, goats in the Kweneng district may have displayed better weight gain because they were able to access browse material from the greater diversity and quantity of shrubs that were within reach, compared to the other two districts where shrub density was not as great. The monthly weight gain of sheep was significantly higher in the Mahalapye and Kgalagadi districts (Table 2; 2.75kg and 2.91kg respectively; Table 2). In Kgalagadi, this may be attributable to the high grass biomass of 341kg/ha for good and intermediate species combined. In Mahalapye, sheep may have benefited from a combination of seedlings (<0.5m) which had a population count of 1200/ha, and grass biomass of 30kg/ha for good and intermediate species combined. Sheep in the Kweneng district gained the least weight, perhaps because most of the shrubs in the area were not within their reach. In this regard the sheep may only have benefited from fallen tree leaves as they drop naturally from trees, and by that stage the feed value of the leaves may have reduced (Dambe et al. 2015).

Table 2 - Monthly growth parameters of sheep browsing natural pastures in communal areas across three districts of Botswana

	Kweneng[1]	Kgalagadi[2]	Central[3]	*P-value*
Height gain (cm)	2.97±0.2	1.65±0.49	1.53±0.37	*0.033*
Girth gain (cm)	-0.15±0.62	0.82±0.25	5.52±0.43	*0.0001*
Weight gain (kg)	1.53±0.29	2.75±0.12	2.91±0.22	*0.0002*

[1] Number of observations in Kweneng; 63. [2] Number of observations in Kgalagadi; 378. [3] Number of observations in Central; 109. ± refers to standard error of the mean (S.E.M).

Similarly, since cattle and sheep are primarily grazers, both livestock species are more likely to be negatively impacted by drought or extended dry periods, because herbaceous plants are more sensitive to periodic moisture stress than wood plants (Mphinyane et al. 2015). Unlike goats in the Kweneng district, sheep gained relatively less weight, since their inability to forage from a bipedal stance from higher plants (as goats do) meant they did not have access to much of the woody plant material on communal grazing lands in this district. Nonetheless, height gain was significantly greater (3.21cm; Table 1) amongst sheep in the Kweneng district than the other two districts, showing that there was not necessarily a correlation between the extent of height gain and weight gain across the three districts.

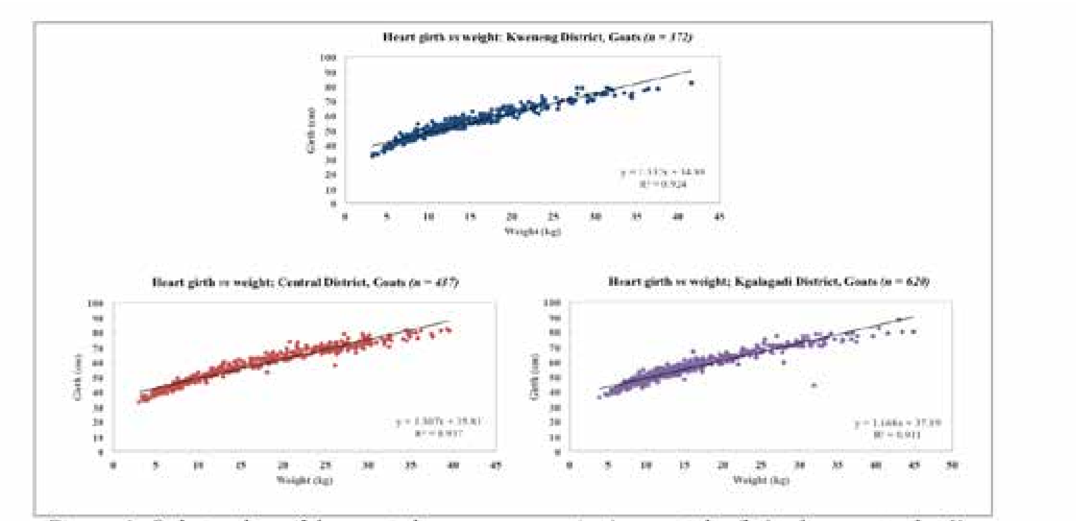
B07

3.2 Relationships of growth measures

3.2.1 Relationship of heart girth measurement to weight

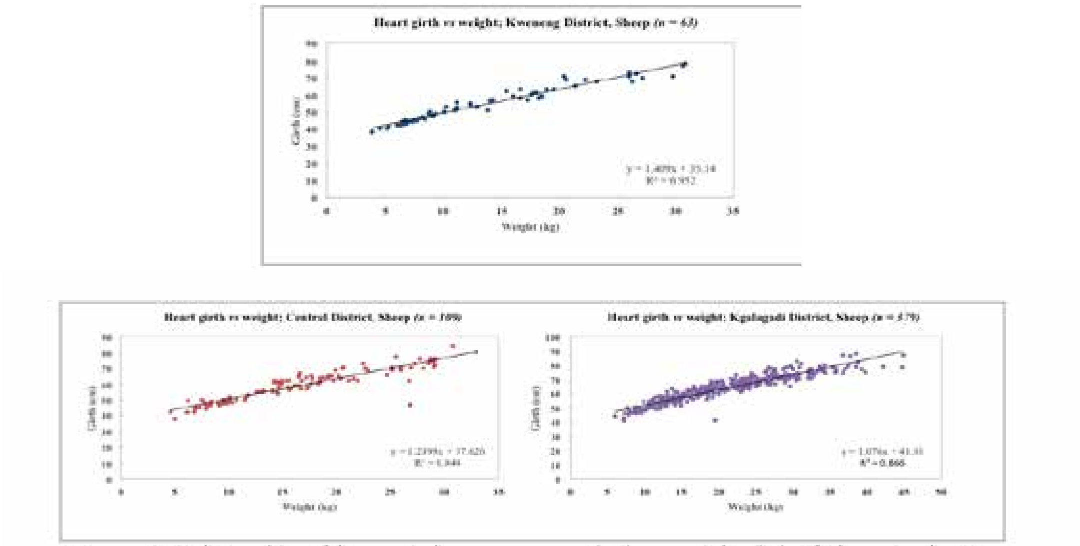
Data on body condition score showed no statistically significant relationships with weight in both goats and sheep, and consequently the results are not presented. Heart girth measurement in goats appears to be a statistically significant predictor of weight in the Kweneng, Central and Kgalagadi districts (R2=0.92, R2=0.95 and R2=0.91 respectively; Figure 1). As this Figure shows, heart girth measurement accounted for a large amount of the variability associated with animal weight across the sample of goats measured.

Figure 1 - Relationship of heart girth measurement (cm) to weight (kg) of goats in the Kweneng, Central and Kgalagadi districts, Botswana



As was the case with goats, heart girth measurement in sheep was highly correlated to weight in Kweneng, Central and Kgalagadi districts (R2=0.95, R2=0.85 and R2=0.87 respectively; Figure 2). Once again, heart girth measurement accounted for a large amount of the variability associated with animal weight across the sample population.

Figure 2 - Relationship of heart girth measurement (cm) to weight (kg) of sheep in the Kweneng, Central and Kgalagadi districts, Botswana



3.2.2 Relationship of shoulder height measurement to weight

As was the case with heart girth measurement, the shoulder height of goats in the sample showed a strong correlation with weight in Kweneng, Central and Kgalagadi districts (R2=0.82, R2=0.87 and R2=0.72 respectively; Figure 3).
In sheep, shoulder height also proved to be a strong predictor of weight in Kweneng, Central and Kgalagadi districts (R2=0.76, R2=0.79 and R2=0.62 respectively; Figure 4.).

Figure 3 - Relationship of shoulder height measurement (cm) to weight (kg) of goats in the Kweneng, Central and Kgalagadi districts, Botswana

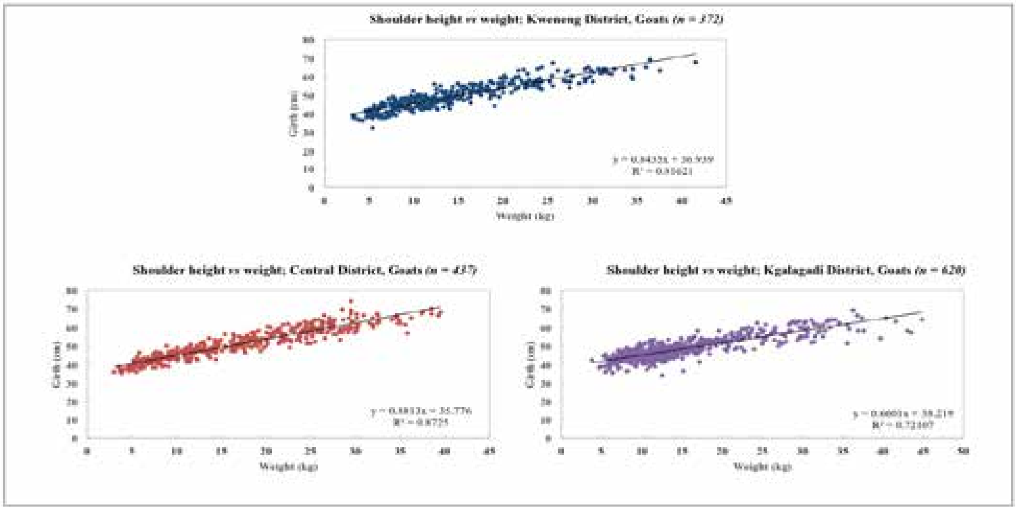


Figure 4 - . Relationship of shoulder height measurement (cm) to weight (kg) of sheep in the Kweneng, Central and Kgalagadi districts, Botswana

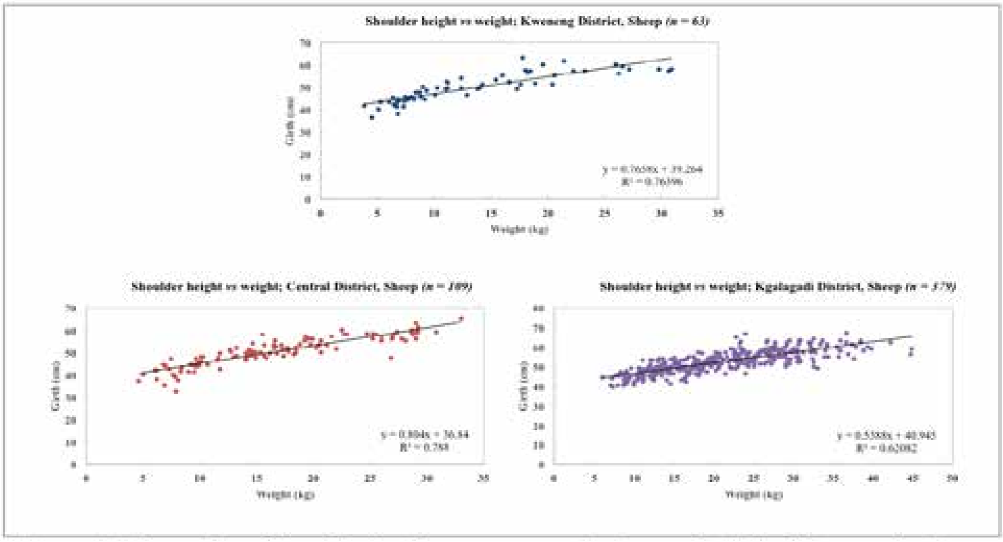

4. Conclusions

The results suggest that goats performed well in the Kweneng district, as a result of a high population density of browse species (particularly small shrubs). Previous research has suggested that small shrubs are the preferred source of feed for goats in Botswana during the dry season (Omphile et al. 2004). Sheep tended to perform well in Kgalagadi and Central districts, due to the relatively high grass biomass observed in these districts. Both heart girth measurement and shoulder height measurement appeared to be consistent and statistically robust predictors of weight in all the three districts in this study. As has been suggested in previous studies conducted elsewhere (e.g. ESGPIP 2009, Cam et al. 2010, Musa et al. 2012), heart girth appeared to be a better proxy measure of weight than shoulder height, however both can be used in a complementary fashion to estimate the weight of goats and sheep under communal grazing.

Future research in determining the potential for linear measurements to act as proxy measures for small-stock weight may involve expanding data collection to fully-grown animals, or those over 12 months of age, providing a sample of animals of known age could be identified. Likewise, data on breed may be collected for each animal measured to allow potential differences in weight, heart girth and shoulder height measurements by breed to be identifed.

Acknowledgements

We would like to thank the Food and Agriculture Organization of the United Nations for funding this research as part of the project Improving methods for estimating livestock production and productivity. In Botswana, we gratefully acknowledge the support of the Department of Agricultural Research (DAR), including provision of transport as well as technical and logistical support from DAR researchers, technical officers and extension officers during fieldwork activities.

ABSTRACT

Cotton, a multiple picking crop, is grown in nine states in India. The existing procedure of estimation of average yield of cotton is based on crop cutting experiment approach, which utilizes data on all pickings, is cumbersome and cost prohibitive. The double sampling approach can be gainfully employed in this case by collecting data on picking which has highest correlation with the total picking yield on a larger sample and the total picking yield data on a smaller sample. Accordingly, a stratified two-stage two phase sampling design has been proposed for selection of representative sample and an appropriate estimation procedure, based on double sampling regression estimator, has been developed for estimation of average yield of cotton at district level. Utilizing the data of survey conducted in the Aurangabad and Amravati district of Maharashtra State and Adilabad and Guntur district of Andhra Pradesh wherein third picking data is collected on a larger sample and total picking yield data on a smaller sample,expression for optimum number of villages for larger and smaller sample have been obtained by minimizing cost subject to fixed percentage standard error of the estimates. The results show that the average yield of cotton can be estimated with at most 5% standard error, if 137 preliminary sample villages are selected for third picking and 48 sub-sample villages are selected for the remaining pickings from each selected district while the corresponding sample size for an estimator which make use of entire picking data is 51 villages. Recommendations have been made with regard to which picking data can be used as auxiliary variable, in the double sampling regression estimator, for 9 cotton growing states in India.

PAPER

Cotton is an important fibre yielding crop of global importance. It is also known as the "White Gold" or the "King of Fibres". It is grown, world over, in tropical and subtropical regions of more than 80 countries. It is an internationally sensitive commodity. Occupying an area of around 35.72 million ha, cotton is cultivated mainly in U.S.A. (11%), China (15%) and India (34%). Current estimates of world production are about 27.25 million tonnes annually, accounting for around 2.5% of the world's arable land. China is the world's largest producer of cotton, but most of this is used domestically. India occupies highest area under cotton (12.18mha) and is the second largest country, after China, as far as production is concerned (35.20 mt). In India, the States of Gujarat (34.09%) Maharashtra (20.45 %), and Andhra Pradesh (13.92%) are the leading cotton producing states having a predominantly tropical wet and dry climate.

The yield estimation of cotton in India is carried out using crop cutting experiment technique. A limitation of the crop cutting experiment technique is that it requires observation on yield data of all the pickings of sampled fields. In case, data of one or two pickings of some of the selected fields are not available, not only precision of the yield estimate will suffer but estimate of average yield will be biased. Moreover, it is very difficult to capture data for all the pickings (up to 8 pickings in some states) creating practical difficulties in implementation of the procedure. Practical feasibility of crop cutting experiment technique for multiple picking crops like cotton is a matter of concern in India. Another important consideration is cost aspect of crop yield estimation survey. The cost on conduct of crop cutting experiment involving multiple picking crops increases manifold when data are to be collected on all the pickings. Therefore, there is a need to develop an alternative technique which is easier to implement as well as capable of providing unbiased estimates of average yield of cotton with desired precision.

2. Existing procedure for estimation of average yield of Cotton

The existing estimation procedure followed, under the General Crop Estimation Surveys (GCES), for estimation of average yield of Cotton is as under:

At the stratum level, the average yield of the crop is obtained as a simple arithmetic mean of plot yields (net) within a stratum.

Let

Y_{hij}= The plot yield (net) in gms/plot of the jth plot in the ith village in the hth stratum

n_{hi}= Number of experiments conducted in the ith village of hthstratum

m_h= Number of villages in which experiments are conducted in the hthstratum

n_h= Number of experiments conducted in the hthstratum

L = Number of strata in a district

a_h= The area (net) under the crop in the hthstratum

d = The driage ratio

f = The conversion factor for converting the green yield per plot into the yield of dry marketable produce per hectare

The average green yield for the h^{th} stratum is obtained as

$$\bar{y}_h = \frac{1}{n_h}\sum_{i=1}^{m_h}\sum_{j=1}^{n_{hi}} y_{hij}$$

and the district level average yield of the dry marketable produce per hectare is given by

$$\hat{\bar{Y}} = d.f.\frac{\sum_{h=1}^{L} a_h \bar{y}_h}{\sum_{h=1}^{L} a_h}$$

The sampling variance of $\hat{\bar{Y}}$ is obtained as

$$\hat{V}(\hat{\bar{Y}}) = \frac{d^2.f^2\left[W\sum_{h=1}^{L}\frac{a_h^2}{n_h} + (B-W)\sum_{h=1}^{L}\frac{a_h^2\sum_{i=1}^{m_h} n_{hi}^2}{\lambda_h n_h^2}\right]}{\left[\sum_{h=1}^{L} a_h\right]^2}$$

where

$$\lambda_h = \frac{n_h^2 - \sum_{i=1}^{m_h} n_{hi}^2}{n_h - (m_h - 1)},$$

$$B = \frac{\sum_{i=1}^{m_h}\frac{\left(\sum_{j=1}^{n_{hi}} y_{hij}\right)^2}{n_{hi}} - \frac{\left(\sum_{i=1}^{m_h}\sum_{j=1}^{n_{hi}} y_{hij}\right)^2}{n_h}}{\sum_{h=1}^{L}(m_h - 1)},$$

the mean square between villages and

$$W = \frac{\sum_{h=1}^{L}\left[\sum_{i=1}^{m_h}\sum_{j=1}^{n_{hi}} y_{hij}^2 - \sum_{i=1}^{m_h}\frac{\left(\sum_{j=1}^{n_{hi}} y_{hij}\right)^2}{n_{hi}}\right]}{\sum_{h=1}^{L}(n_h - m_h)},$$

the mean square within villages

The percentage standard error of $\hat{\hat{Y}}$ is given by

$$\%S.E.(\hat{\hat{Y}}) = \frac{\sqrt{\hat{V}(\hat{\hat{Y}})}}{(\hat{\hat{Y}})} \times 100$$

3. Sampling design used for selection of sample

Stratified multistage random sampling design is generally adopted for carrying out General Crop Estimation Survey (GCES) with taluks/revenue inspector circles as strata, revenue villages within a stratum as a first stage unit of sampling, survey number/field within each selected village as a sampling unit at the second stage and experimental plot of a specified shape and size as the ultimate unit of sampling.

Sampling design for GCES

Strata – Taluk

↓

First stage sampling unit – Revenue Village

↓

Second stage sampling unit – Survey Number/Field

Ultimate unit of sampling – Experimental Plot

(Specified shape and size)

Total numbers of experiments at district level are finalized as per following norms: (i) 130 to 150 experiments are planned at district level (65 to 75 villages having two experiments per village) if area under experimental crop in a district is above 80,000 hectares.

(ii) 100 to 120 experiments are planned at district level (50 to 60 villages having 2 experiments per village) if area under experimental crop in a district is between 20,000 to 80,000 hectares.

(iii) 40 to 80 experiments are planned at district level (20 to 40 villages having two experiments per village) if area under experimental crop in a district is below 20,000 hectares.

The number of villages allotted to a district is distributed among the strata, within a district, roughly in proportion to the area under the crop in stratum. Generally, Crop insurance scheme is implemented at taluk/circle level in India. To determine compensation to be paid to the farmer in the event of crop loss, average yields are calculated on 18/12 crop cutting experiments at taluk/circle level respectively. The number of villages is increased up to 9/6, if the distributed villages to the strata within a district are less than 9/6 at taluk/circle level respectively. Hence, due to implementation of crop insurance scheme, number of crop-cutting experiments planned at district level increased up to 700.

In each taluk/circle, in Maharashtra, a number of villages are selected every year for crop cutting experiments as per above norms at the time of district level-training programs conducted every year in Kharif, Rabi and Summer season. The list containing the names of the selected villages are made available by State Statistical Authority, Department of Agriculture, Maharashtra State, Pune to the concerned officers.

In each selected village, two fields growing the particular crop are selected according to the random sampling method. For the above purpose, two survey numbers are first selected out of all survey numbers for experimental crop in the village according to the said method.

In each selected survey number, where there are more than one field sown with the crop, one such field nearest to the South-West corner of the selected survey number should be selected. In each field thus selected, one plot of specified size is to be located at random.

4. Proposed procedure of estimation of crop yield of cotton

A detailed examination of the data pertaining to five districts of Andhra Pradesh (A.P.) and five districts of Maharashtra showed that the yield of cotton at different pickings were highly correlated with the total yield. Hence, it may not be statistically efficient to collect data in respect of all the pickings from the same sample of fields since the additional information gained would be only marginal. Therefore, it would be desirable to examine the possibility of using other sampling design such as double sampling which may not only be more efficient but also operationally more convenient resulting in more reliable data for estimation of crop yield of multiple picking crop like cotton.

Table 3.1 - Picking-wise correlation with total yield in Maharashtra for the year 2006-07

District	Pick-1	Pick-2	Pick-3	Pick-4	Pick-5	Pick-6	Pick-7	Pick-8
Aurangabad	0.55	0.65	0.82	0.84	0.83	0.74	0.51	0.24
Jalgaon	0.44	0.73	0.82	0.86	0.83	0.70	0.49	-0.40
Jalna	0.65	0.77	0.86	0.86	0.77	0.73	0.60	0.77
Buldhana	0.66	0.69	0.82	0.81	0.72	0.61	0.44	0.30
Yavatmal	0.58	0.76	0.87	0.91	0.86	0.75	0.51	0.35

Table 3.2 - Picking-wise correlation with total yield in Andhra Pradesh (A.P.) for the year 2005-06

District	Pick-1	Pick-2	Pick-3	Pick-4	Pick-5	Pick-6	Pick-7
Adilabad	0.59	0.61	0.82	0.82	0.81	0.48	0.16
Guntur	0.30	0.60	0.86	0.81	0.71	0.50	0.30
Khammam	0.65	0.81	0.87	0.56	0.66	0.37	-0.24
Karimnagar	0.65	0.80	0.80	0.45	0.43	0.41	-
Warangal	0.70	0.81	0.81	0.23	0.27	0.26	0.20

Results of both the tables reveal that 3^{rd} and 2^{nd} pickings in A.P. and 4^{th}, 3^{rd}, 5^{th} and 6^{th} pickings in Maharashtra have high correlation with total yield. It is, therefore, desirable to use the yield of picking having highest correlation with total yield as auxiliary variable. Thus, there is an opportunity to use double sampling approach in this situation.

Estimation procedure using double sampling approach under stratified two stage samplingdesign framework The estimation procedure for estimation of average yield of cotton using double sampling approach under stratified two stage sampling design framework is as under:

Let

L = number of strata (mandals/taluks) in a district

N_h = total no. of fsu's (villages) in h-th stratum (h=1,2,...,L)

n_h' = no. of fsu's selected randomly in h-th stratum for observing yield for the p-th picking (p=1,2,...,P)

n_h = size of sub-sample selected randomly in h-th stratum for observing yield for the remaining pickings

m' = no. of ssu's (fields) selected for observing yield for the p-th picking in i-th village of h-th stratum (i=1,2,..., nh')

m = size of sub-sample for observing yield for remaining pickings of these m' ssu's

$y_{hij}(p)$ = yield of cotton in j-th field of i-th village (j=1,2,..., m') in h-th stratum corresponding to p-th picking.

An estimator of average yield corresponding to p-th picking, $\bar{y}_{nm}(p)$ for a district is given by

$$\bar{y}_{nm}(p) = \frac{1}{n_0 m}\sum_{h=1}^{L}\sum_{i=1}^{n_h}\sum_{j=1}^{m} y_{hij}(p) \quad \text{where } n0 = \sum_{h=1}^{L} n_h$$

An estimator of average yield, $\bar{y}_{nm}$ for a district is given by

$$\bar{y}_{nm} = \sum_{p=1}^{P} \bar{y}_{nm}(p)$$

This is a biased estimate of the population average discussed by Panse *et al.* (1966). However, investigations by Sukhatme and Panse (1951) into the magnitude of the bias from the data collected in district crop-cutting surveys has shown that the bias is negligible. A double sampling regression estimator of average yield of cotton under the proposed framework can be written as

$$\bar{y}_{ld}(2) = \bar{y}_{nm} + \hat{\beta}[\bar{y}_{n'm'}(p) - \bar{y}_{nm}(p)]$$

where $\bar{y}_{n'm'}(p) = \frac{1}{n_0' m'}\sum_{h=1}^{L}\sum_{i=1}^{n_h'}\sum_{j=1}^{m'} y_{hij}(p)$, $\quad n_0' = \sum_{h=1}^{L} n_h'$

$$\hat{\beta} = \frac{(\frac{1}{n_0} - \frac{1}{n_0'})s_{by(p)y} + \frac{1}{n_0'}(\frac{1}{m} - \frac{1}{m'})s_{wy(p)y}}{(\frac{1}{n_0} - \frac{1}{n_0'})s^2_{by(p)} + \frac{1}{n_0'}(\frac{1}{m} - \frac{1}{m'})s^2_{wy(p)}}$$

where

$$s_{by(p)y} = \frac{1}{L}\sum_{h=1}^{L}\frac{1}{(n_h-1)}\sum_{i=1}^{n_h}(\bar{y}_{hi.(p)} - \bar{y}_{h..(p)})(\bar{y}_{hi.} - \bar{y}_{h..})$$

$$s_{wy(p)y} = \frac{1}{n_O(m-1)}\sum_{h=1}^{L}\sum_{i=1}^{n_h}\sum_{j=1}^{m}(y_{hij(p)} - \bar{y}_{hi.(p)})(y_{hij} - \bar{y}_{hi.})$$

where $\bar{y}_{hi.}(p) = \frac{1}{m}\sum_{j=1}^{m} y_{hij}(p)$ and $\bar{y}_{h..}(p) = \frac{1}{n_h}\sum_{i=1}^{n_h}\bar{y}_{hi.}(p)$,

$$s^2_{by(p)} = \frac{1}{L}\sum_{h=1}^{L}\frac{1}{(n_h-1)}\sum_{i=1}^{n_h}(\bar{y}_{hi.}(p) - \bar{y}_{h..}(p))^2$$

An estimator of $MSE(\bar{y}_{ld}(2))$ is given by

$$\hat{MSE}(\bar{y}_{ld}(2)) = \left\{\left(\frac{1}{n_0} - \frac{1}{N_0}\right)s^2_{by} + \frac{1}{N_0 m}s^2_{wy}\right\}(1 - r^{*2}) + r^{*2}\left\{\left(\frac{1}{n_0'} - \frac{1}{N_0}\right)s^2_{by} + \left[\frac{1}{N_0 m} - \frac{1}{n_0'}\left(\frac{1}{m} - \frac{1}{m'}\right)s^2_{wy}\right]\right\}$$

where $N_0 = L\bar{N}$, and $\bar{N}$ is the harmonic mean of N_{hs}. This is the usual estimator in sub-sampling design.

$$s^2_{by} = \frac{1}{L}\sum_{h=1}^{L}\frac{1}{(n_h-1)}\sum_{i=1}^{n_h}(\bar{y}_{hi.} - \bar{y}_{h..})^2$$

$$s^2_{wy} = \frac{1}{n_0(m-1)}\sum_{h=1}^{L}\sum_{i=1}^{n_h}\sum_{j=1}^{m}(y_{hij} - \bar{y}_{hi.})^2$$

$$r^{*2} = \frac{q^2_{y(p)y}}{q_{y(p)y(p)}q_{yy}}$$

with

$$q_{y(p)y} = (\frac{1}{n_0} - \frac{1}{n_0'})s_{by(p)y} + \frac{1}{n_0}(\frac{1}{m} - \frac{1}{m'})s_{wy(p)y}$$

$$q_{y(p)y(p)} = (\frac{1}{n_0} - \frac{1}{n_0'})s^2_{by(p)} + \frac{1}{n_0}(\frac{1}{m} - \frac{1}{m'})s^2_{wy(p)}$$

$$q_{yy} = (\frac{1}{n_0} - \frac{1}{n_0'})s^2_{by} + \frac{1}{n_0}(\frac{1}{m} - \frac{1}{m'})s^2_{wy}$$

Validation of proposed methodology for estimation of average yield of cotton

For the validation of proposed methodology, surveys were planned for data collection in Amravati and Aurangabad districts of Maharashtra State while in Andhra Pradesh (A.P.) State planning was done in Adilabad and Guntur districts. In Maharashtra State, two additional fields were selected in 114 villages selected for CCE in Aurangabad district and 118 villages selected for CCE in Amravati district while in A.P., two additional fields were selected in 77 villages selected for CCE in Warangal district and 75 villages selected for CCE in Guntur district.

In addition to CCE data for the third picking from two additional fields from the selected CCE village of the selected districts of both the states, the regular CCE data of selected districts of both the states was also required for validation of the proposed double sampling procedure under stratified two stage sampling design framework.

The estimate of average yield of cotton along with % S.E. for the year 2012-13was obtained using proposed double sampling approach under stratified two stage sampling design framework. In order to compare the results, the estimate along with % S.E. was also obtained using existing GCES procedure.

For implementation purpose the selected CCE villages in the district have been treated as preliminary sample villages (n') for the third picking yield and a sub-sample of 40% and 30% CCE villages (n) were selected by SRSWOR from the preliminary sample villages for the remaining pickings and out of the four fields (m') for the third picking, in each of these sub-sample villages, two fields (m) were selected for observing yield pertaining to the remaining pickings from CCE plot. The estimate of average yield of cotton along with % S.E. was obtained for both the districts of Maharashtra State and both the districts of A.P. State. The results of the district wise analysis are presented in the Tables 4.1 to 4.4.

Table 4.1 - Estimates of average yield of cotton (Kg/ha) along with % S.E. using different approaches for Aurangabad district of Maharashtra State for the year 2012-13

Existing procedure			
No. of sampled villages	Average yield (Kg/ha)	% S.E.	Total no. of pickings involved
Total GCES villages (83)	202.027	5.49	1328
Double sampling regression procedure under stratified two stage sampling design framework			
n'=83 (for one picking) n=33 (40% of n') (for remaining pickings)	189.711	5.32	794
n'=83 (for one picking) n=26 (30% of n') (for remaining pickings)	188.966	6.39	696

A close perusal of the above table reveal that under the Double sampling regression procedure involving stratified two stage sampling design framework,the estimates of average yield of cotton was obtained with less than 3% standard error for Aurangabad district which is fairly reliable.

The estimate is almost at par with the estimate obtained using existing procedure. Further, as the sample size decreases i.e. from 40% to 30%, percentage standard error increases for both the proposed procedures. The alternative procedure is operationally more convenient than the existing GCES procedure and is expected to reduce the workload of the field staff significantly which in turn will lead to good quality CCE data from these limited number of plots.

It may be seen from the above table that in case of the proposed alternative procedure the estimate of average yield of cotton is obtained with less than 3% standard error for Amravati district which is fairly reliable. Further, as the sample size decreases i.e. from 40% to 30%, percentage standard error increases.

The analysis of data in respect of Guntur district reveals a similar trend as earlier i.e. the proposed estimator scores over the estimator currently used in terms of the criterion of percentage standard error. It may be observed from the Table that the estimate of average yield of cotton in case of existing GCES procedure is obtained based on data on 65 villages. But double sampling regression procedure under stratified two stage sampling design framework requires CCE villages data for all the mandals in the district. In most of the mandals only two villages data was available and at least two villages data is necessary for the analysis. Hence, there was not much scope for sub-sampling and accordingly, the 40% and 30% sub-sampling of villages could not be done. The results are presented based on the maximum possible reduced number of villages i.e. 52 villages. The improved performance of double sampling approach based estimator is evident.

Table 4.2 - Estimates of average yield of cotton (Kg/ha) along with % S.E. using different approaches for Amravati district of Maharashtra State for the year 2012-13

Existing procedure			
No. of sampled villages	Average yield (Kg/ha)	% S.E.	Total no. of pickings involved
Total GCES villages (111)	637.055	2.81	1776
Double sampling regression procedure under stratified two stage sampling design framework			
n'=111 (for one picking) n=43 (40% of n') (for remaining pickings)	529.168	2.85	1046
n'=111 (for one picking) n=34 (30% of n') (for remaining pickings)	511.038	2.92	920

Table 4.3 - Estimates of average yield of cotton (Kg/ha) along with % S.E. using different approaches for Guntur district of A.P. State for the year 2012-13

Existing procedure				
No. of sampled villages	Average yield (Kg/ha)	% S.E.	Total no. of pickings involved	
Total GCES villages (65)	629.399	3.95	910	
Double sampling regression procedure under stratified two stage sampling design framework				
n'=65 (for one picking) n=52 (for remaining pickings)	608.882	3.61	884	

Table 4.4 - Estimates of average yield of cotton (Kg/ha) along with % S.E. using different approaches for Warangal district of A.P. State for the year 2012-13

Existing procedure				
No. of sampled villages	Average yield (Kg/ha)	% S.E.	Total no. of pickings involved	Percentage reduction in cost
Total GCES villages (59)	371.034	1.63	708	
Double sampling regression procedure under stratified two stage sampling design framework				
n'=59 (for one picking) n=48 (for remaining pickings)	371.891	5.69	716	
Double sampling Regression procedure under stratified two stage sampling design framework				
n'=59 (for one picking) n=48 (for remaining pickings)	345.751	5.15	598	

The results of analysis of data in Warrangal district are bit different than earlier i.e. although the percentage standard errors are within permissible limits, the existing estimator scores over the proposed estimator in terms of the criterion of percentage standard error of the estimator. This highlights the need to compare the proposed estimator over the existing estimator using optimum sample sizes determined by minimizing expected cost for a fixed value of percentage standard error of the estimator.

5. Estimation of sample size (no. of villages to be selected in a district for the survey)

The guiding principle in the determination of optimum sample size is either to fix variance of the estimator and minimize cost or to fix cost and minimize variance of the estimator. We, in this paper, aimed at minimizing the cost by fixing the variance of the estimator. The optimum number of villages to be sampled in a district was determined by fixing the percentage standard to 5 and 7.

In order to estimate sample size in case of double sampling regression procedure, a simple cost function given by

$$C = c\, n_0\, m + c'\, n'_0\, m'$$

was considered, where

c = costs involved in conducting crop cutting experiment for all the pickings of a selected plot (e.g. travel, equipment, harvesting and drying, stationery) and

c' = costs involved in conducting crop cutting experiment for one picking (3rd picking) of a selected plot (e.g. travel, equipment, harvesting and drying, stationery)

= {1/(Total no. of pickings)} x c

By minimizing the cost subject to a fixed variance V_0, the optimum values of n_0 were obtained from the following relations

$$\frac{n_0}{n'_0} = \sqrt{\frac{c'(1-r^{*2})}{cr^{*2}}} = \theta$$

and

$$n_0 = \{(1-r^{*2}) + \theta r^{*2}\}\left(s_{by}^2 + \frac{1}{m}s_{wy}^2\right) \Big/ \left[\hat{V}_0 + \frac{s_{by}^2}{N_0}\right]$$

The proposed regression estimator, involving auxiliary information, was accordingly compared with the estimator which does not make use of auxiliary information on the basis of optimum sample sizes determined by minimizing the cost function subject to a fixed value of the percentage standard error (the optimum sample sizes were determined by fixing the percentage standard error to 5 and 7).

The estimated sample size and desired percentage standard error of the district level estimates of average yield of cotton for Maharashtra and A.P. states are presented in theTable.

Table 5.1 - Sample size (no. of villages per district) for district level estimates of average yield of cotton for 5% standard error

State	Districts	Calculated S.E. (%)	No. of villages (n)	No. of prel. sample villages (n')	Desired S.E. (%)	Estimated sample size (n_0)	c'/c	r	Estimated sample size (n'_0)
Double sampling regression procedure under stratified two stage sampling design framework									
Maharashtra	Aurangabad	6.39	26	83	5.00	48	0.125	0.7109	137
	Amravati	2.92	34	111		11	0.125	0.7867	30
Andhra Pradesh	Guntur	3.61	52	65		34	0.143	0.7681	102
	Warangal	5.69	48	59		45	0.167	0.7992	127
Recommended optimum sample size i.e maximum of estimated sample size						48			137

The optimum sample size is maximum of the estimated sample size used for estimation of average yield of cotton in both the States.

A close perusal of Table 5.1 reveal that the district level average yield of cotton can be estimated with less than or equal to 5% standard error, if 137 preliminary sample villages are selected for third picking and 48 sub-sample villages are selected for the remaining pickings from each selected district. Therefore, the recommended sample size i.e. no. of preliminary sample villages and sub-sample villages to be selected from a district are 137 (one hundred thirty seven) and 48 (forty eight) respectively. Further, the percentage standard error of the double sampling regression estimator is directly related to "r" i.e. greater the "r" value smaller the percentage standard error of the estimator.

Table 5.2 - Sample size (no. of villages per district) for district level estimates of average yield of cotton for 7% standard error

State	Districts	Calculated S.E. (%)	No. of villages (n)	No. of prel. sample villages (n')	Desired S.E. (%)	Estimated sample size (n_0)	c'/c	r	Estimated sample size (n_0')
Double sampling regression procedure under stratified two stage sampling design framework									
Maharashtra	Aurangabad	6.39	26	83	7.00	25	0.125	0.7109	71
	Amravati	2.92	34	111		6	0.125	0.7867	17
Andhra Pradesh	Guntur	3.61	52	65		18	0.143	0.7681	55
	Warangal	5.69	48	59		25	0.167	0.7992	70

The results of analysis of Table 5.2 reveals that at district level, the average yield of cotton can be estimated with less than or equal to 7% standard error, if 71 preliminary sample villages are selected for third picking and 25 sub-sample villages are selected for the remaining pickings from each selected district. Therefore, the recommended sample size i.e. no. of preliminary sample villages and sub-sample villages to be selected from a district are 71 (eighty one) and 25 (twenty five) respectively with minimum two sub-sample villages per mandal/taluka of the district as per requirement of the proposed alternative sampling methodology. As earlier, greater the r value, smaller the percentage standard error of the estimator.

The optimum values of sample size in the context of simple linear estimator (existing estimator) are given below

Table 5.3 - Sample size (no. of villages per district) for district level simple estimates (GCES estimates) of average yield of cotton for 5% standard error

State	Districts	Calculated S.E. (%)	No. of villages (n)	Desired S.E. (%)	Estimated sample size (n_0)
Maharashtra	Aurangabad	5.49	83	5.00	100
	Amravati	2.81	111		35
Andhra Pradesh	Guntur	3.95	65		41
	Warangal	1.63	59		6
Recommended optimum sample size i.e. maximum of estimated sample size					100

Table 5.4 - Sample size (no. of villages per district) for district level simple estimates (GCES estimates) of averageyield of cotton for 7% standard error

State	Districts	Calculated S.E. (%)	No. of villages (n)	Desired S.E. (%)	Estimated sample size (n_0)
Maharashtra	Aurangabad	5.49	83	7.00	51
	Amravati	2.81	111		18
Andhra Pradesh	Guntur	3.95	65		21
	Warangal	1.63	59		3
Recommended optimum sample size i.e. maximum of estimated sample size					51

Using the optimum values of sample sizes the percentage reduction in cost by using the double sampling regression estimator over an estimator which does not use auxiliary information are given in Table 5.5 and 5.6 by fixing the percentage standard error values to 5 and 7 percent respectively. Keeping in view the Indian scenario i.e. the manpower available, costs etc., the values of m and m' are fixed at 2 and 4 respectively.

Table 5.5 - Percentage reduction in cost using different approaches based on optimum sample size of villages required per district for obtaining district level estimates of average yield of cotton for Maharashtra and A.P. states for 5% standard error

Existing GCES procedure				
Optimum number of sample villages required per district		Average number of pickings based on four districts	Total number of pickings involved	Percentage reduction in cost
100		7	1400	
Double sampling regression procedure under stratified two stage sampling design framework				
Optimum no. of preliminary sample villagesrequired per district	Optimum no. of sub- sample villages required per district	Average number of pickings based on four districts	Total number of pickings involved	Percentage reduction in cost
137	48	7	1124	19.71

Table 5.6 - Percentage reduction in cost using different approaches based on optimum sample size of villages required per district for obtaining district level estimates of average yield of cotton for Maharashtra and A.P. states for 7% standard error

Existing GCES procedure				
Optimum number of sample villages required per district		Average number of pickings based on four districts	Total number of pickings involved	Percentage reduction in cost
51		7	714	
Double sampling regression procedure under stratified two stage sampling design framework				
Optimum no. of preliminary sample villages required per district	Optimum no. of sub- sample villages required per district	Average number of pickings based on four districts	Total number of pickings involved	Percentage reduction in cost
71	25	7	584	18.21

The results of analysis of Table 5.5 and 5.6 reveal that there is considerable reduction in cost using the double sampling procedure as compared to an estimator which does not make use of information on auxiliary variable. More and less the entire cotton area in the country has now been covered under Bt.

Cotton that requires only 2-3 pickings for the Crop Cutting Experiments. Therefore, in order to determine which picking should be used as an auxiliary variable, the CCE data of cotton pertaining to two major cotton growing districts namely,
Mansa and Muktsar Sahib of Punjab State and two districts namely, Hisar and Sirsa of Haryana State for the year 2012-13 was acquired. The data from both the states was available for four (4) pickings only. Picking-wise correlation with the total yield for the CCE data for all the four selected districts, two each Punjab and Haryana states, was obtained and are presented in the Tables 5.7 to 5.8.

Table 5.7 - Picking-wise correlation with total yield for plots in the selected districts of Punjab Statefor Desi and American Cotton (Combined) for the year 2012-13

State	Districts	Pick-1	Pick-2	Pick-3	Pick-4
Punjab	Mansa	0.652751	0.753949	0.80976	0.142816
	Muktsar Sahib	0.769401	0.731496	0.79637	0.364979

Table 5.8 - Picking-wise correlation with total yield for plots in the selected districts of Haryana Statefor the year 2012-13

State	Districts	Pick-1	Pick-2	Pick-3	Pick-4
Haryana	Hisar	0.467793	0.821971	0.651065	0.305694
	Sirsa	0.668537	0.679208	0.350899	0.004528

It can be inferred from the above two tables that 3rd picking has the highest correlation with total yield in both the districts of Punjab State while in Haryana State, 2nd picking has the highest correlation with total yield in both the districts. Thus, **3rd picking data is recommended for use as auxiliary variablein Punjab State while 2nd picking data is recommended for use in Haryana State** for estimation of average yield of cotton using double sampling regression estimator.

The CCE data of other cotton growing states was analysed to determine the picking having highest correlation with total yield. Accordingly, CCE data on cotton pertaining to two districts of each of the five states namely, Gujarat, Karnataka, Madhya Pradesh, Rajasthan and Tamil Nadu for the year 2012-13 was acquired. Picking-wise correlation with the total yield for the irrigated and unirrigated plots (combined) was obtained and results are presented in the Table 5.9.

Table 5.9 - Picking-wise correlation with total yield for irrigated and unirrigated plots (combined) in the selected districts of five States for the year 2012-13

State	District	Pick-1	Pick-2	Pick-3	Pick-4	Pick-5	Pick-6	Pick-7	Pick-8
Gujarat	Patan	0.6444	0.8942	0.9081*	0.8938*	0.7601*	0.4618*	0.2088*	**
	Mehsana	0.3514	0.6915	0.7967*	0.7423*	0.4863*	0.3832*	0.0559*	
Karnataka	Yadgir	0.6498	0.8384	0.8020*	0.2960*	0.0706*	**	**	**
	Haveri	0.6581	0.7973	0.8894*	0.8517*	0.4383	0.4931*	**	**
Madhya Pradesh	Khrgon	0.5849	0.8195	0.8398	0.8368	0.7248*	0.0473*	0.0467*	0.0529 *
	Dhar	0.5735	0.7948	0.8144	0.7048	0.5895*	0.5577*	**	**
Rajasthan	Ganganagar	0.6532	0.8647	0.6417*	0.7873*	**	**	**	**
	Hanumangarh	0.7626	0.6945	0.7225*	**	**	**	**	**
Tamil Nadu	Perambalur	0.4903	0.8081	0.8004	0.7257*	**	**	**	**
	Salem	0.3781	0.6307	0.8003	0.8301	0.7828	0.5595*	0.3492*	0.2481 *

Note: *Insufficient data available

**Data not available

The analysis reveals that 2nd picking has the highest correlation with total yield in both the districts of Gujarat and Karnataka States while in Madhya Pradesh State, 3rd picking has the highest correlation with total yield in both the districts. Further, in Rajasthan State, 2nd picking has the highest correlation with total yield in Ganganagar district and 1st picking has the highest correlation with total yield in Hanumangarh district followed by 2nd picking. Since the correlation coefficient for 2nd picking is significant in Hanumangarh district, t**herefore, 2nd picking is recommended to be used as auxiliary variablein Rajasthan State for the sake of uniformity**.

Similarly, in Tamil Nadu State, the correlation coefficient for 3rd picking is significant. **Therefore, 3rd picking should be treated as auxiliary variablein Tamil Nadu State**. The recommended picking, to be taken as auxiliary variable, in the nine states is given in Table 5.10.

Table 5.10 - Recommended picking to be used as auxiliary variable for analysis of cotton data usingdeveloped methodology in nine major cotton growing states of India

S. No.	State	Picking to be used as auxiliary variable
1	Andhra Pradesh	3rd Picking
2	Gujarat	2nd Picking
3	Haryana	2nd Picking
4	Karnataka	2nd Picking
5	Madhya Pradesh	3rd Picking
6	Maharashtra	3rd Picking
7	Punjab	3rd Picking
8	Rajasthan	2nd Picking
9	Tamil Nadu	3rd Picking

Conclusions

The present study has revealed very encouraging results as shown from the results of analysis and demonstrated the feasibility of estimating cotton production with limited number of pickings using the double sampling approach based regression estimator. In view of the above, it is recommended that the alternative sampling methodology using double sampling regression procedure under stratified two stage sampling design framework may be adopted in all the cotton growing states of the country for estimation of average yield of cotton which will not only provide reliable estimate of average yield of cotton but will significantly reduce cost of the survey and will also be operationally more convenient than the GCES procedure. Further, the workload of the field staff will be significantly reduced which in turn will lead to good quality CCE data from limited number of plots.

ABSTRACT

The objective of this research is to determine the effects of data aggregation on firm-level efficiency measures. Aggregation creates heteroscedasticity since the error variance of average cost decreases as total output increases. Inefficiency indexes from stochastic frontier functions estimated assuming both heteroscedasticity and homoscedasticity are compared with those from data envelopment analysis (DEA) using a Monte Carlo study. Stochastic frontier functions hold up rather well in the presence of data aggregation, but efficiency measurement from DEA diverges from true efficiency measurement. In particular, DEA is biased towards finding more inefficiency in small firms.

Keywords: aggregation, cost function, data envelopment analysis, stochastic frontier.

PAPER

1. Introduction

Since Farrell (1957) developed his efficiency index using a deterministic frontier function, efficiency measurements from a stochastic frontier model and data envelopment analysis (DEA) have been frequently used to estimate firm-level efficiency measures. Stochastic frontier functions were suggested by Aigner et al. (1977), who allowed deviations from the frontier to arise from random factors where the disturbance term was the sum of symmetric normal and half-normal random variables. Jondrow et al. (1982) introduced firm-specific inefficiency measurement. DEA was introduced by Charnes et al. (1978), who assumed constant returns to scale (CRS). This idea was extended to variable returns to scale (VRS) by Banker et al. (1984). DEA is a nonparametric method and therefore does not require distributional assumptions about error terms. Also, DEA can handle multiple outputs and inputs. On the other hand, the fundamental merit of using a stochastic frontier function is to measure inefficiency in the presence of statistical noise, but it is subject to potential bias if an incorrect error structure is assumed.

One concern about the error structure is possible heteroscedasticity. Caudill and Ford (1993) find biases in frontier estimation due to heteroscedasticity of the one-sided error and later Caudill et al. (1995) find that the rankings of firms by efficiency measures are significantly affected by correcting for heteroscedasticity. These followed Schmidt's suggestion (1986) that a one-sided error can be associated with factors controlled by the firm while the random component can be associated with factors outside the firm's control. Hadri (1999) finds heteroscedasticity of both error terms with the same data of Caudill et al. (1995). This past research, however, has not formally derived how aggregation leads to heteroscedasticity.

Greene (2003) argues that the most common occurrence of heteroscedasticity is, in general, when data are aggregated, which is called "groupwise heteroscedasticity". Dickens (1990) shows that using data weighted by the square root of group size is only appropriate if individual error terms are not correlated within groups. In empirical work, disaggregated data are often not available so that economic research is often done using aggregated data. For example, the Macdonald and Michael (2000) study of the hog slaughter industry and the Ollinger et al. (2005) study of the poultry processing industry are aggregated over packing plants owned by the same firm. Adkins and Moomaw (2003) study public schools aggregated across teachers, while the Featherstone et al. (1997) study of beef cow farms uses data aggregated over cows. These studies typically conclude that small firms are much more inefficient than large firms. When the average cost (or average utput) function with aggregated data is estimated, the error variance of average cost decreases as group size increases, which raises the question as to how much of this finding of small-firm inefficiency is due to not considering heteroscedasticty created from using aggregate data.

This article uses a Monte Carlo study to estimate the biases in inefficiency measurement that are created from aggregate data. We begin with a disaggregate model with random effects, and the aggregate model is obtained by summing the disaggregate observations. The log cost model is obtained by a first order Taylor approximation. The resulting model is heteroscedastic. A Monte Carlo study compares inefficiency measurement in the presence of this heteroscedasticity with parameter estimates that both consider and disregard heteroscedasticity. With the same data, inefficiency indexes from DEA are also computed in order to provide comparisons with the stochastic frontier function.

2. Theory

Consider the following disaggregated cost function with random effects:

$$(1) \qquad C_{ij} = \mathbf{x}_{ij}'\beta + u_j + w_{ij}, \quad i = 1, \ldots, n_j, \; j = 1, \ldots, J,$$

$$u_j \sim iid\, N(0, \sigma_u^2),\; w_{ij} \sim iid\, N(0, \sigma_w^2),\; \mathrm{cov}(u_j, w_{ij}) = 0,$$

where C_{ij} is the cost of the ith unit in the jth firm, $\mathbf{x}_{ij}$ is a vector of explanatory variables including input prices, $\boldsymbol{\beta}$ is a vector of unknown parameters to be estimated, u_j is the random effect of the jth firm, and w_{ij} is the unexplained portion of the cost of the ith unit in the jth firm.

Examples of such a disaggregated cost function include a firm with multiple packing plants, a farmer with many fields, and a school with many teachers. The unit refers to each packing plant, each field, or each teacher. Note that the units within a firm all have the same random effect. The heteroscedasticity comes from the effects of w_{ij} being diversified away in larger firms.

In a stochastic frontier cost function, the inefficiency is represented with a one-sided error term (Aigner et al. 1977). Thus, a stochastic frontier cost function can be defined as

$$(2) \qquad C_{ij} = \mathbf{x}_{ij}'\beta + u_j + w_{ij} + v_j,\; v_j \sim iid\left|N(0, \sigma_v^2)\right|, \mathrm{cov}(u_j, v_j) = 0,$$

$$\mathrm{cov}(w_{ij}, v_j) = 0,$$

where v_j is the inefficiency and a one-sided error with $\mathrm{E}(v) = \sigma_v\sqrt{2/\pi}$ and $\mathrm{Var}(v) = \sigma_v^2(1 - 2/\pi)$. Especially, $\sigma_v\sqrt{2/\pi}$ is known as an average inefficiency measurement by Aigner et al. (1977). The term ($\mathbf{x}_{ij}'\beta$) can be interpreted as the minimum expected cost. Note that each unit within a firm is assumed to have the same inefficiency, which is consistent with Schmidt's (1986) view that the inefficiency error represents factors under control of the firm.

The (total) stochastic frontier cost function is the sum over all units of the firm:

$$(3) \qquad \sum_{i=1}^{n_j} C_{ij} = \sum_{i=1}^{n_j} \mathbf{x}'_{ij}\boldsymbol{\beta} + n_j u_j + \sum_{i=1}^{n_j} w_{ij} + n_j v_j,$$

where n_j is the number of units produced by the *j*th firm.

A dot subscript is the common notation to denote that the variable has been averaged over the corresponding index. A (total) stochastic frontier cost function (3) using the dot notation is

$$(4) \qquad TC_j = n_j \mathbf{x}'_{\bullet j}\beta + n_j(u_j + w_{\bullet j} + v_j), \; j = 1,\dots,J, \; w_{\bullet j} \sim N(0, \frac{\sigma_w^2}{n_j}),$$

where TC_j is the total cost for the *j*th firm, and the dot subscript indicates that the variable has been averaged over units. $\mathbf{x}_{\bullet j}$ is the averaged vector of explanatory variables over units, and $w_{\bullet j}$ is the averaged unexplained error over units.

Here, heteroscedasticity related with units is shown, which is typically called groupwise heteroscedasticity (Greene, 2003). Dickens (1990) showed similar heteroscedasticity in the presence of firm specific error, which is similar to the random effect shown here.

Logarithmic cost functions (translog or double log) are typically used in empirical work (Melton and Huffman, 1995) due to several conveniences such as including multiple outputs, calculating elasticities easily, and adjusting for heteroscedasticity. Taking the natural log of equation (4) gives

$$(5) \qquad \ln TC_j = \ln n_j + \ln\left(\mathbf{x}'_{\bullet j}\beta + u_j + w_{\bullet j} + v_j\right),$$

which is the double log cost function. Then, since error terms are the only random variables, applying a first-order Taylor approximation of $\ln\left(\mathbf{x}'_{\bullet j}\beta + u_j + w_{\bullet j} + v_j\right)$ around the mean of the random and unexplained error, and the frontier of inefficiency error such as $u_j = 0$, $w_{\bullet j} = 0$ and $v_{\bullet j} = 0$ gives the following model[1]:

$$(6) \quad \ln TC_j \approx \ln n_j + \ln \mathbf{x}'_{\bullet j}\beta + \frac{1}{\mathbf{x}'_{\bullet j}\beta}\left(u_j + w_{\bullet j} + v_j\right).$$

The variance of all error terms is $\left(1/\mathbf{x}'_{\bullet j}\beta\right)^2\left(\sigma_u^2 + \sigma_w^2/n_j + \sigma_v^2\right)$, which shows a combination of dependent variable heteroscedasticity and groupwise heteroscedasticity.

The usual stochastic frontier model is a special case of (3) where $\sigma_u^2 = 0$ and $n_j = 1, \forall j$. To define the usual model, let $e = w + v$ where w is unexplained error and v is the random inefficiency term. The density function for this case developed by Weinstein (1964) is

$$(7) \quad f(e) = \frac{2}{\sigma} f^*\left(\frac{e}{\sigma}\right) F^*\left(\frac{\lambda e}{\sigma}\right), -\infty < e < +\infty,$$

where $\sigma^2 = \sigma_w^2 + \sigma_v^2$, $\lambda = \sigma_v/\sigma_w$, and f^* and F^* are the standard normal probability density function and the standard normal cumulative density function, respectively. Note that the density function of a stochastic frontier function is a special case of skew normal distributions (Dominguez-Molina et al. 2003, Genton 2004; Gonzalez-Farias et al. 2004).

Here, λ is an indicator of the relative variability of error terms. As Aigner et al. (1977) argues, $\lambda \to 0$ means $\sigma_v \to 0$ and/or $\sigma_w \to \infty$, or that inefficiency error is dominated by random error. With data aggregation, λ increases as firms become larger since the variance of unexplained error does not increase as rapidly with firm size.

---

[1] A second order Taylor approximation gives the following model:
$\ln TC_j \approx \ln n_j + \ln \mathrm{x}'_{\bullet j}\beta + \frac{1}{\mathrm{x}'_{\bullet j}\beta}\left(u_j + w_{\bullet j} + v_j\right) - \frac{1}{2}\left(\frac{1}{\mathrm{x}'_{\bullet j}\beta}\left(u_j + w_{\bullet j} + v_j\right)\right)^2$. This model is not considered here since the primary concern is to investigate heteroscedasticity easily in the stochastic frontier function. Also, first order Taylor approximation for an average cost function can be expressed as $\ln AC_j \approx \ln \mathrm{x}'_{\bullet j}\beta + \frac{1}{\mathrm{x}'_{\bullet j}\beta}\left(u_j + w_{\bullet j} + v_j\right)$, which has the same error structure.

Two measurements for the firm-specific inefficiency are given by Jondrow et al. (1982). Both are based on the conditional distribution of inefficiency error (v) given overall error (e). The first measure is given by

$$(8) \qquad \mathrm{E}(v|e) = \sigma_* \left[\left(\frac{\lambda e}{\sigma}\right) + f^*\left(\frac{\lambda e}{\sigma}\right) \Big/ F^*\left(\frac{\lambda e}{\sigma}\right)\right],$$

where $\sigma_*^2 = (\sigma_v \sigma_w / \sigma)^2$. The other variables are the same as in equation (7).

The second measure, which is based on the conditional mode, is given by

$$(9) \qquad \begin{aligned} \mathrm{M}(v|e) &= e(\sigma_v^2/\sigma^2) \quad \text{if } e \geq 0 \\ &= 0 \qquad\qquad\quad \text{if } e < 0. \end{aligned}$$

The log-likelihood function is derived from the density function in equation (7) by substituting the appropriate variances for the aggregated model:

$$(10) \qquad \sum_{j=1}^{J} \ln(f_j(e_j)) = \sum_{j=1}^{J} \ln \frac{2}{\sigma_j} f^*\left(\frac{e_j}{\sigma_j}\right) F^*\left(\frac{\lambda_j e_j}{\sigma_j}\right),$$

where $e_j = \frac{1}{\mathrm{x}'_{\bullet j}\beta}(u_j + w_{\bullet j} + v_j)$, $\sigma_j = \left(\frac{1}{\mathrm{x}'_{\bullet j}\beta}\right)\sqrt{\sigma_u^2 + \frac{\sigma_w^2}{n_j} + \sigma_v^2(1 - 2/\pi)}$, and $\lambda_j = \sqrt{\frac{\sigma_v^2(1-2/\pi)}{\sigma_u^2 + \sigma_w^2/n_j}}$.

Maximizing (10) gives maximum likelihood estimates for the stochastic frontier cost function with heteroscedasticty due to aggregation.

In the presence of data aggregation, two firm-specific inefficiency measurements like equation (8) and (9) are slightly modified. The first measurement can be expressed as

$$(11) \qquad \mathrm{E}(v_{*j}|e_j) = \sigma_{*j} \left[\left(\frac{\lambda_j e_j}{\sigma_j}\right) + f^*\left(\frac{\lambda_j e_j}{\sigma_j}\right) \Big/ F^*\left(\frac{\lambda_j e_j}{\sigma_j}\right)\right],$$

where $v_{*j} = v_j / \mathrm{x}'_{\bullet j}\beta$, $\sigma_{*j} = \left(\frac{1}{\mathrm{x}'_{\bullet j}\beta}\right)\sqrt{\frac{\sigma_v^2(1-2/\pi) \cdot \sigma_w^2/n_j}{\sigma_u^2 + \sigma_w^2/n_j + \sigma_v^2(1-2/\pi)}}$. The other variables are the same as in equation (10).

The second measure which is based on the conditional mode is given by

$$\text{(12)} \quad \begin{aligned} M(v_{*j} \mid e_j) &= e_j\left(\sigma_{*v}^2/\sigma_j^2\right) && \text{if } e_j \geq 0 \\ &= 0 && \text{if } e_j < 0, \end{aligned}$$

where $\sigma_{*v}^2 = \left(1/\mathrm{x}'_{\bullet j}\beta\right)^2 \sigma_v^2(1-2/\pi)$. The other variables are the same as in equation (10).

3. Data Envelopment Analysis (DEA)

Since input-oriented efficiency indexes with CRS and VRS were proposed by Charnes et al. (1978) and Banker et al. (1984), respectively, these two techniques have both been widely used (Fare et al. 1994) and therefore efficiency measurement with both CRS and VRS is discussed here.

Assuming M different outputs, N different inputs, and J different firms, the input-oriented model with VRS is

$$\text{(13)} \quad \begin{aligned} F_{\mathrm{j}}(\mathbf{x}_{\mathrm{j}},\mathbf{y}_{\mathrm{j}}) &= \min_{\theta_j,\boldsymbol{\lambda}} \ \theta_j \\ \text{s.t.} \ \ \mathbf{y}_{\mathrm{j}} \leq \mathbf{Y}\boldsymbol{\lambda}, \ \ \mathbf{X}\boldsymbol{\lambda} &\leq \theta_j \mathbf{x}_{\mathrm{j}}, \ \ \mathbf{j}'\boldsymbol{\lambda}=1, \ \ \boldsymbol{\lambda} \geq 0, \ \ j=1,\ldots,J \end{aligned},$$

where $F_{\mathrm{j}}(\mathbf{x}_{\mathrm{j}},\mathbf{y}_{\mathrm{j}})$ is the Farrell efficiency estimate (or technical efficiency) given a $N \times 1$ input vector ($\mathbf{x}_{\mathrm{j}}$) and a $M \times 1$ output vector ($\mathbf{y}_{\mathrm{j}}$) for the j^{th} firm, $\mathbf{Y}$ is a $M \times J$ matrix for outputs, $\mathbf{X}$ is a $N \times J$ matrix for inputs, θ_j is a shrinking factor, $\boldsymbol{\lambda}$ is a $J \times 1$ vector of weights for firms, and $\mathbf{j}$ is a vector of ones.

The Farrell efficiency estimate is the reciprocal of the input distance function with the input-oriented model. Also, if there is no restriction of $\mathbf{j}'\boldsymbol{\lambda}=1$, then the model is the case of CRS.

The cost minimization model with VRS can be specified as

$$\text{(14)} \quad \begin{aligned} &\min_{\boldsymbol{\lambda},\mathbf{x}_{\mathrm{j}}} \ \mathbf{r}_{\mathrm{j}}'\mathbf{x}_{\mathrm{j}}^* \\ &\text{s.t.} \ \ \mathbf{y}_{\mathrm{j}} \leq \mathbf{Y}\boldsymbol{\lambda}, \ \ \mathbf{X}\boldsymbol{\lambda} \leq \mathbf{x}_{\mathrm{j}}^*, \ \ \mathbf{j}'\boldsymbol{\lambda}=1, \ \ \boldsymbol{\lambda} \geq 0, \ \ j=1,\ldots,J, \end{aligned}$$

where $\mathbf{r}_{\mathrm{j}}$ is a $N \times 1$ vector of input prices for the j^{th} firm; $\mathbf{x}_{\mathrm{j}}^*$ is the cost-minimizing $N \times 1$ vector of input quantities for the j^{th} firm, which is calculated by the linear programming given a vector of output quantities for the j^{th} firm ($\mathbf{y}_j$) and a vector of input prices for the j^{th} firm ($\mathbf{r}_j$); and the other variables are the same as above.

Then, efficiency measurements for the j^{th} firm can be defined as

(15) $$CE = \frac{\text{minimized cost}}{\text{actual cost}} = \frac{\mathbf{r}_j' \mathbf{x}_j^*}{\mathbf{r}_j' \mathbf{x}_j}, \quad AE = \frac{CE}{TE}, \quad TE = \theta_j,$$

where CE is the cost efficiency, AE is the allocative efficiency, and TE is the technical efficiency derived from the linear programming problem in equation (13).

4. Data and procedures

A Monte Carlo study is used to examine the effects of heteroscedasticity due to data aggregation. Based on equation (2), our true model is assumed as

(16) $$C_{ij} = r_{ij} + u_j + w_{ij} + v_j,$$

where r_{ij} is the input price of the ith unit in the jth firm, while the other variables are as previously defined.

Aggregation over all units yields the following model:

(17) $$\sum_{1}^{n_j} C_{ij} = TC_j = n_j r_{\bullet j} + n_j (u_j + w_{\bullet j} + v_j).$$

Taking the natural log and a first-order Taylor series around the mean of random errors (u_j and $w_{\bullet j}$) and the frontier (zero) of inefficiency error (v_j) gives

(18) $$\ln TC_j \approx \ln(r_{\bullet j}) + \ln n_j + \frac{1}{r_{\bullet j}}(u_j + w_{\bullet j} + v_j).$$

So, our stochastic frontier cost function of equation (18) can be rewritten as

(19) $$\ln TC_j = \beta_1' \ln r_{\bullet j} + \beta_2' \ln n_j + (u_j' + w_{\bullet j}' + v_j'),$$

where heteroscedasticity is incorporated into the variances by assuming

$$\mathrm{var}\left(u_j' + w_{\bullet j}'\right) = \left(\sigma_u^2 + \frac{\sigma_w^2}{n_j}\right)\frac{1}{(r_{\bullet j})^2} \text{ and } \mathrm{var}\left(v_j'\right) = \left(\sigma_v^2(1-2/\pi)\right)\frac{1}{(r_{\bullet j})^2}$$

. Here, β'_1, β'_2, σ_u^2, σ_w^2, and σ_v^2 are unknown parameters to be estimated.

Input prices are generated as $r_{ij} \sim N(12,4)$. Also, numerous small firms and a few large firms are assumed by truncating a random number drawn from a distribution of $5*\exp(N(0,1))+1$; the mean units is 8.89 with variance around 112. To see the changes in relative variability of error terms, three scenarios of variances are considered: $[\sigma_u^2, \sigma_w^2, \sigma_v^2(1-2/\pi)] = [1, 4, 1.45]$, $[1, 4, 5.81]$, and $[1, 4, 13.08]$. The relative variability for these are, on average, $\lambda \approx 1$, $\lambda \approx 2$, and $\lambda \approx 3$, respectively. These scenarios show how much the inefficiency indexes change as the variability of inefficiency increases.

Using NLMIXED in SAS with 100 samples[2] of 100 observations, the stochastic frontier cost function with heteroscedasticity and without heteroscedasticity is estimated. Since one output and one input are assumed, cost inefficiency is the same as technical inefficiency from DEA. Inefficiency measurement of DEA using the data envelopment analysis program (DEAP) is also calculated and compared with those from the stochastic frontier cost function. Both constant return to scale (CRS) and variable return to scale (VRS) are used.

5. Results

Table 1 shows mean values of estimated parameters for the stochastic frontier cost function. In no case are the estimates significantly different from the true value. The variability of parameter estimates is slightly larger when homoscedasticity is incorrectly assumed. Certainly, the results

[2] The simulation takes considerable time and the differences between DEA and the stochastic efficiency measures are large enough that using one hundred samples is sufficient.

show that ignoring the effects of data aggregation does not create a serious problem for estimating a stochastic frontier cost function.

Table 1. Mean Parameter Estimates from Monte Carlo Trials

Parameters	Case 1			Case 2			Case 3		
	Expected Values	MLE w/ Hetero	MLE w/ Homo	Expected Values	MLE w/ Hetero	MLE w/ Homo	Expected Values	MLE w/ Hetero	MLE w/ Homo
β_1'	1	1.0207 (0.0220)	1.0235 (0.0222)	1	1.0330 (0.0301)	1.0332 (0.0312)	1	1.0415 (0.0366)	1.0418 (0.0419)
β_2'	1	1.0020 (0.0152)	1.0032 (0.0160)	1	1.0013 (0.0200)	1.0040 (0.0203)	1	1.0008 (0.0244)	1.0052 (0.0256)
σ_u^2	1	1.4232 (0.5697)		1	2.2525 (1.1257)		1	2.9857 (1.7572)	
σ_w^2	4	4.0161 (2.4111)		4	4.5953 (3.0724)		4	5.5293 (3.8383)	
$\sigma_v^2(1-2/\pi)$	1.45	1.3759 (1.3034)		5.81	5.2340 (3.1574)		13.08	10.7124 (5.2404)	
$\mathrm{Var}(u'+w')$	0.01	0.0160 (0.0043)	0.0166 (0.0048)	0.01	0.0210 (0.0085)	0.0215 (0.0092)	0.01	0.0255 (0.0131)	0.0268 (0.0146)
$\mathrm{Var}(v')$	0.01	0.0098 (0.0093)	0.0083 (0.0086)	0.04	0.0372 (0.0226)	0.0355 (0.0227)	0.09	0.0760 (0.0374)	0.0746 (0.0415)

Note: Simulated standard errors are reported in parentheses. In no case are the estimates significantly different from expected value.

1) Case 1 is the case of $[\sigma_u^2, \sigma_w^2, \sigma_v^2(1-2/\pi)] = [1, 4, 1.45]$.

2) Case 2 is the case of $[\sigma_u^2, \sigma_w^2, \sigma_v^2(1-2/\pi)] = [1, 4, 5.81]$.

3) Case 3 is the case of $[\sigma_u^2, \sigma_w^2, \sigma_v^2(1-2/\pi)] = [1, 4, 13.08]$.

Table 2 shows the mean of average inefficiency. Inefficiency indexes with heteroscedasticity are slightly bigger than those assuming homoscedasticity, which agrees with previous findings by Caudill, Ford, and Gropper (1995), but the differences between inefficiency indexes with and without heteroscedasticity are small. In no case are the estimates significantly different from true values, which agrees with Table 1. So, biases in terms of average inefficiency are also small.

Table 2. Mean of Average Inefficiency from Monte Carlo Trials

Methods	Case 1	Case 2	Case 3
True	0.1330	0.2656	0.3990
MLE w/ Hetero	0.1165 (0.0590)	0.2402 (0.0835)	0.3500 (0.0988)
MLE w/ Homo	0.1058 (0.0592)	0.2343 (0.0876)	0.3456 (0.1068)

Note: Simulated standard errors are in parentheses.

Table 3 shows correlations between true firm-specific inefficiency indexes based on the conditional mean in equation (11) and firm specific inefficiency indexes from each method. Since the units of firm specific inefficiency indexes resulting from parametric and non-parametric methods are different, it is better to look at their correlations to compare the two methods. Also, rank correlations are reported in parentheses because ranks are frequently used after estimating an efficiency index. The stochastic frontier inefficiency measures show high correlations (mostly greater than 0.9) with the true values. DEA, however, has much smaller correlations ranging from 0.4 to 0.6.

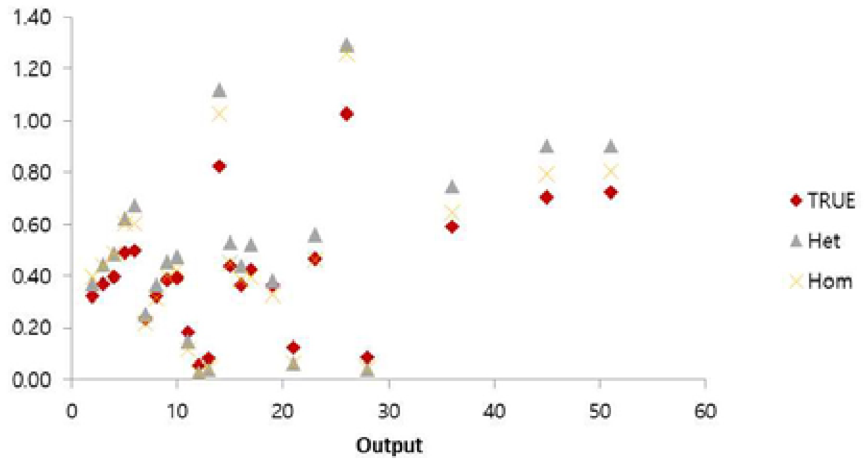
Table 3. Correlations from Monte Carlo Trials of True Inefficiency and Estimated Firm Specific Inefficiency

Methods	Case 1	Case 2	Case 3
MLE w/ Hetero	0.9155 (0.9784)	0.9259 (0.9876)	0.9331 (0.9891)
MLE w/ Homo	0.8959 (0.9717)	0.9217 (0.9880)	0.9265 (0.9914)
DEA-CRS	0.3767 (0.8518)	0.4839 (0.8371)	0.5614 (0.8300)
DEA-VRS	0.4044 (0.5720)	0.5202 (0.6537)	0.5899 (0.6985)

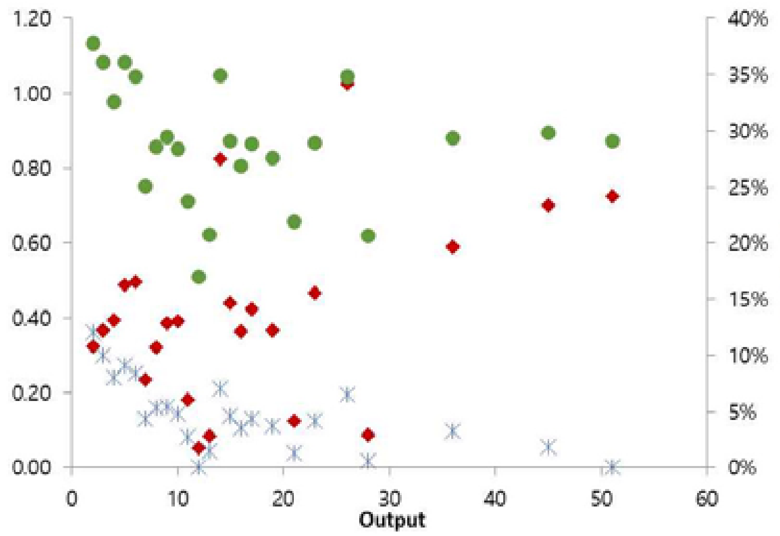
Note: Rank Correlations are reported in parentheses.

Figure 1 shows the relationship between firm-specific inefficiency indexes and output in the first sample in case 3 where variability of inefficiency error is high. The figure shows how data aggregation can affect estimates of inefficiency by size of firm. As shown in Figure 1(a), inefficiency indexes from stochastic frontier cost functions have a similar pattern regardless of whether heteroscedasticity is considered or not.

Figure 1 - Firm specific inefficiency index over averaged output in the 1st sample in case 3



(a) Inefficiency Index from Stochastic Frontier Cost Function



(b) Inefficiency Index from DEA of Constant Return to Scale and Variable Return to Scale

However as shown in Figure 1(b), inefficiency indexes from DEA with VRS have a much different pattern compared to true inefficiency indexes. DEA with CRS does not show greater inefficiency with small farms, but this result is due to imposing constant returns to scale. DEA with VRS, however, tends to have inefficient small firms relative to efficient large firms even though the true inefficiency indexes do not vary by size. Thus, as the example shows, DEA falsely leads to finding small firms having greater inefficiency, but this result is driven both by the heteroscedasticity and the larger number of small firms.

6. Conclusions

This article studies estimation of stochastic frontier (total) cost functions with heteroscedasticity from using aggregated data. Aggregation creates heteroscedasticity in the unexplained error. Each unit within a firm is assumed to have identical inefficiency. Future research may want to consider the effects of aggregation when the inefficiency varies by individual unit. The stochastic frontier functions hold up rather well in the presence of data aggregation, but DEA shows low correlations with actual inefficiency and also DEA with VRS incorrectly finds that small firms have more inefficiency.

ABSTRACT

Statistics on cassava production and productivity present large gaps across the developing world. The deficiencies are rooted in the inability of the existing survey methodologies in accommodating continuous harvests that cut across agricultural seasons, with timelines that vary significantly by variety. This paper explores the results of a randomized household survey experiment testing 4 survey treatments that differed in the approach to data collection on production, namely (1) daily diary-keeping at the household-level for 12-months with in-person supervision visits twice per week, (2) daily diary keeping at the household-level for 12-months with supervisory mobile phone calls twice per week, (3) recall-based data collection at the plot-level for a 6-month reference period, administered twice during the 12 months, (4) recall-based data at the plot-level for a 12-month reference period (the prevailing practice in household and farm surveys collecting information on cassava production). In all households, 1 cassava plot was randomly for crop cutting and all cassava plot areas were recorded based on farmer self-reporting and handheld GPS units. Multivariate analyses will be undertaken within a multi-level framework comparing household-level annual cassava production and productivity estimates obtained from the different treatment arms and the crop cutting exercise. The heterogeneity of survey treatment effects, at the household- and plot-levels, will be explored by observable attributes, for instance, by clusters of districts in unique production systems, and by objectively identified improved cassava variety cultivation status, based on DNA fingerprinting of leaf samples obtained from the crop cut subplot. Additionally, household-level estimates of consumption of own cassava production obtained from D2, R1, and R2 will be compared to those based on D1.

Keywords: Agriculture, Harvest Diaries, Household Surveys

PAPER

1. Introduction

Cassava is the second most important staple crop to maize in Malawi and is cultivated in most parts of the county. Approximately 10 percent of the population depends on cassava as their main staple crop (Schoning and Mkumbira 2007) and with unpredictable weather patterns it is now garnering even more attention from policymakers because it performs better under poor soils, is drought tolerant and does not require the use of fertilizers. Cassava is mainly grown in districts along Lake Malawi where it is considered the main food staple crop and in other areas that rely primarily on maize, cassava is grown for commercial purposes or as a security measure in case of unforeseen events.

Despite the importance of cassava as a staple crop in Malawi and Sub-Saharan Africa, serious weaknesses still exist in obtaining accurate measures of crop production, land area, and variety identification. In Malawi, there is high level of variability in farm yields reported. Schoning and Mkumbira (2007) estimated that the average cassava root yield is estimated to be 19 tonnes per hectare ranging from 8 to 39 tonnes per hectare. and this high variation can be associated with challenges in estimating cassava yields arising from irregular and partial or piecemeal harvesting of cassava (Haggblade and Zulu 2003). In addition, farmers grow both improved and traditional varieties with varying yield potential thereby increasing yield variability.

2. Experimental Design

To help address the observed gaps in agricultural data and to test the relative accuracy and cost-effectiveness of old and new methods in the context of gold-standard approaches for the estimation of cassava yields and variety identification, the World Bank Living Standards Measurement Study (LSMS) and the Malawi National Statistical Office (NSO) are collaborating on a randomized household survey experiment. The experiment, formally known as CVIP: Methodological Experiment on Measuring Cassava Production, Productivity, and Variety Identification, has been implemented between July 2015 and August

2016 to compare different production measurement methods, land area measurement techniques, and methods of cassava variety identification.

2.1 Sampling

The target universe for CVIP includes households cultivating cassava in five major cassava producing districts in Central and Southern Malawi. To select the districts, key members of the LSMS and NSO teams working on the experiment embarked on a number of missions to consult with experts on agriculture and cassava production in Malawi throughout 2014. Topics discussed included, but were not limited to, production figures for cassava at the national and district levels, planting and harvesting times for cassava, the many different varieties cultivated, and approaches to cassava production estimation and the challenges faced with each. After meetings with key policy makers including the Ministry of Agriculture and Food Security, the Department of Agricultural Research Services, Lilongwe University of Agriculture and Food Security and the International Institute of Tropical Agriculture (IITA), five of the top cassava-producing districts were identified and chosen so that the sample includes one district from each agro-ecological zone or Agricultural Development Division across Malawi excluding Karonga ADD. Districts selected for this study are Nkhatabay, Nkhotakota, Lilongwe, Zomba and Mulanje. Although the Northern region of Malawi (more specifically the Karonga ADD) is also known for cassava, due to the location of the NSO headquarters in Zomba, Malawi, the experiment focused on the Central and Southern region so that regular supervision trips by NSO management team members were feasible from a cost and time management perspective.

After selecting the districts, the LSMS and NSO teams then met with the district agricultural development officers and the assistant agricultural development officers along with crop specialists in each of the five districts selected to gather more information. These individuals helped to identify areas within each district cultivating cassava and provided the production figures for the Extension Planning Areas which the agricultural sector in Malawi uses as project implementation areas so that NSO could identify the census Enumeration Areas (EAs) producing cassava.

The sampling frame for CVIP is based on the 2008 Population and Housing Census (PHC) and a stratified sampling procedure was used. The primary sampling unit was at the EA-level and the second sampling unit was cassava-producing households that were randomly selected from the 45 target EAs. A total of 9 EAs were sampled per district and after a complete listing of all cassava farming households in the selected EAs, 28 households were sampled per EA.

2.2 Treatment Arms

In each EA, CVIP randomly allocated 7 cassava households to 4 survey treatments that differed in the approach to data collection on production, namely (i) a diary-based method (D1) spanning the entire agricultural season administered by resident enumerators who visited this group of households twice a week to assist the selected respondents in keeping record of all cassava harvest events. This is assumed to be the gold standard for data collection on production. (ii) a second group (D2) of households were also given a diary to record their cassava harvest, along with a mobile phone with a solar charger as an incentive and to insure participation in the project. The resident enumerators visited D2 households once a month but these respondents also received calls twice a week from a call center located at NSO Headquarters in Zomba to check on the record keeping and provide assistance, if needed. The respondents also had the option to call an enumerator/supervisor, whenever needed. (iii) a recall-based approach that is commonly utilized in multi-topic household surveys and that governed the same length of time in comparison to the diary. This group (R1) was visited twice in the course of a 12 month period to collect information on cassava production based on a 6-month recall period. (iv) a second recall-based approach (R2) will be interviewed once using a 12-month recall period.

In all 1,260 households, 1 cassava plot was selected at random for crop cutting (CC), and a 5x5m subplot was set up in line with international best practices. The land areas of all cassava plots were recorded based on farmer self-reporting and handheld GPS units, and D1 and D2 households were given scales to measure their harvests in standard units.

2.3 Variety Identification

An additional component of the experiment focused on cassava variety identification. A number of different methods were tested for this purpose and compared against the gold standard: DNA testing of samples from the plots. Along with self-reporting the variety of cassava cultivated on a particular plot, during the administration of the agriculture questionnaire respondents were presented with questions regarding phenotypic or morphological characteristics of cassava and were required to answer these questions both before and after the enumerator presented the respondents with pictures of the different attributes of the cassava to the farmer. On the randomly selected sub-plots for crop cutting, leaf samples were also collected for DNA analysis. The samples were sent to the National Tuber and Roots Laboratory of Malawi for DNA extraction. The responses from the farmers were then compared with the standard descriptors for each cassava variety.

2.4 Fieldwork

The fieldwork for CVIP ran approximately 12 months starting in July 2016. In the first month of the operation, the resident enumerators administered a questionnaire collecting general information about each household and its members along with detailed information on the gardens and plots owned or cultivated by the respondents. These components of the questionnaire were identical across survey treatment groups and built on the questionnaires from Malawi's Integrated Household Survey Program. This complementary information enables the research team to explore whether the gender and other characteristics of the plot manager(s) and other household socioeconomic characteristics have any bearing on the results.

Also within the first month of fieldwork, enumerators introduced diary households to the concept of the production diary and enumerators assisted in showing them how to weigh the cassava harvested each day on the scale provided and then fill the required information in the diary. The call center located in Zomba, Malawi at NSO headquarters began calling the D2 households within the first 1-2 weeks of fieldwork as soon as an adequate number of households had received their diaries, and the resident enumerators began bi-weekly visits to the D1 households at this time, as well.

Although production information for the R1 and R2 households was not collected until later in the year, at the start of the fieldwork resident enumerators also began approaching households from all 4 treatment arms to randomly select one of their cassava plots for crop cutting and to lay the crop-cutting sub-plot. Enumerators instructed respondents to inform them as soon as the crop cutting sub-plots were ready for harvest and the enumerators worked with their crop cutting assistants in each EA to monitor this. R1 households received their first visit to collect production information for the period from August 2015 – January 2016 in February 2016 and for a second time in July/August 2016. Enumerators also visited R2 households to collect information on production for the full 12-month period in July/August 2016.

For all questions regarding agriculture and cassava, the enumerators attempted to interview the plot manager(s) or household member(s) most knowledgeable about decision-making on the gardens and plots owned and cultivated by the household. Harvest diaries were also to be filled by the plot manager(s); however, if the plot manager for a particular household was illiterate, then the enumerator assisted the respondent in identifying another literate household member or trusted colleague to assist them in weighing the cassava and filling the diary.

2.5 Data Entry and Quality Control

To ensure data quality and timely availability of data, CVIP was implemented using the World Bank's Survey Solutions CAPI software.1 Given the complex set-up of the experiment, a number of different questionnaires were administered covering information on households and plots from all treatment arms. All versions of these questionnaires along with the data from the crop cutting exercise were directly entered into the tablets. Enumerators distributed paper production diaries to the D1 and D2 households leading up to the start of each calendar month and after collecting the diaries from the prior month the Supervisors for each district entered the data into CAPI. A second data entry of the diary data will take place in September 2016. The use of CAPI also assisted in the accurate collection of leaf samples. Enumerators labelled leaf samples from each randomly selected sub-plot with a barcode and directly scanned this into the Survey Solutions questionnaire to enable the linkage between the DNA results and the households.

3. Summary Statistics

3.1 Land Area

Land area for all cassava plots was collected in hectares for all cassava plots using GPS measurement. Respondents were also asked to self-report the land area. The majority of respondents reported in acres, with approximately 5 percent reporting in hectares or square meters. Table 1 shows that the average farmer-reported area in hectares is .37 while the average GPS-based area measurement is is .19 hectares. The difference between self-reported and GPS-based represent represents 94% of the GPS area mean and does not exhibit statistically significant variation by survey treatment which is another indication that randomization was successful across survey treatment arms. To delve further into understanding this large gap between the GPS and self-reported area, Figure 2 shows the mean difference across plot area decile. The difference is largest in the 2nd decile and and shows an overall trend of decreasing as the plot size increases.

3.2 Production

Given that the fieldwork is ongoing for the CVIP experiment, the analysis presented focuses on the first 6 months of cassava production computed in kilograms from the two diary treatment arms and the 6-month recall arm. Since all diary households were provided with a hanging scale, they were expected to record all entries in kilograms and production for these households is simply the total of the daily records from the first six months of fieldwork (August – January). The 6-month recall households were administered a module on cassava production in February. Although recall respondents were encouraged to report total production over the last 6 months in kilograms, the majority of households were unable to and instead reported in non-standard units. Recall respondents reported production for 19 percent of cassava plots in kilograms, 74 percent in 50 KG bags, 3 percent in 70 KG bags, and the few remaining plots in pails (small and large), and pieces (medium and large). To convert these non-standard units to kilograms, conversion factors were computed from the data on non-standard units collected in the diary records. For all diary entries, respondents weighed the cassava harvested in KGs, but also recorded the production in non-standard units. For the majority of harvest information the respondents reported production in 50 KG sacks as these are one of the most common units used by households and the NSO provided sacks as part of the experiment. Households that cultivated cassava for home consumption and harvested in small quantities reported in small, medium, and large pieces. Given the variation in the size of cassava across the 5 districts, EA-level averages were computed and used to calculate total production for recall households.

Table 2 shows the average 6 months of cassava production for households across the three treatment arms and by month for the two diary arms. The mean for total production is the highest for the D2 households at 829.3 KGs, and the lowest for R1 households at 529 KGs. D1 households, on average, reported 594.7 KGs harvested across the first 6 months.

4. Empirical Approach to Estimating Survey Treatment Effects

4.1 Production

This section provides a description of the empirical framework for estimating the relative survey treatment effects that CVIP was designed to isolate. Within-EA randomization of the systematically sampled households across treatment arms allows us to estimate the causal effects associated with each treatment arm. The core specification is:

$$y_i = \alpha + \beta_1 \mathrm{D2}_i + \beta_2 \mathrm{R1}_i + \gamma C + \varepsilon_i$$

where i represents household; y is the dependent variable; α and ε represent constant and error terms, respectively; D1, R1 and R2 are identifiers representing a household's assignment to diary-phone or 6-month recall, with diary-visit being the comparison category; and C is a vector of household attributes that is included with the intention of capturing any remaining unobserved heterogeneity that may be correlated with these controls and that may also jointly determine both the dependent variable and household survey treatment assignment.

The dependent variable of focus, as described in Section 3, is the total 6-month production in kilograms. The results from each regression are coupled with the full spectrum of tests of equality of for complete inter-arm comparisons. The standard errors are clustered at the EA-level.

4.2 Variety Identification

To determine the accuracy of the subjective methods (farmer elicitation and use of morphological attributes) of varietal identification, the DNA finger printing of the leaf samples serves as a gold standard. The DNA reference samples have been matched with the field samples and the subjective methods evaluated at three levels. The first level relates to assessing farmers' ability to predict or state the unique name of the variety. The second is the accuracy of the unique prediction or the number of matches of the stated or uniquely predicted varieties to the varieties in identified through DNA finger printing. The third is the accuracy in predicting or identifying improved or local varieties. After assessing the accuracy, we also extended the analysis to accuracy of adoption studies estimates of different methods. This analysis is done by first examining the adoption of individual varieties and secondly at the adoption of improved and local varieties. Statistical tests and discrete choice models are conducted to examine the determinants of misidentification of crop varieties by farmers.

5. Results

5.1 Production

If we assume that a respondent filling a harvest diary does not over report cassava production, then we can conclude that diary arm with the highest yield is provides the best estimate. As discussed in Section 4, the D2 households reported, on average, significantly higher production than D1 households. Relying on the assumption that respondents do not have an incentive to misreport daily entries as higher than the cassava they weighed, and that they do not record entries on days that they did not harvest any cassava, this implies that D2 households are closest to the true production value.

Table 5 shows the results of comparisons from the full sample of CVIP households. Taking our D1 households as the control group, we can see that total production reported by the D2 households is significantly higher than that of the D1 households as well as the R1 households. Total production as reported by the R1 households is not significantly different from that of the D1 households.

To investigate further, Table 4 shows results from comparisons by land area tercile. The first two terciles based on land holdings are consistent with the findings from the full sample in that D2 production is statistically significantly higher than both D1 and and R2. In the second tercile the D1 production is also significantly higher than R1. None of the results comparisons from Tercile 3 are significant.

Given the multiple production systems covered across the five CVIP districts, examining results from each district is imperative. Nkhatabay and Nkhotakota districts are both along the lakeshore and known for cultivating cassava as a staple crop. This is apparent in the percent of diary-based production allocated to consumption. 94 percent of the diary entries in Nkhatabay were intended for home consumption while 87 percent of diary entries in Nkhotakota were intended for the same. Lilongwe represents an area cultivating cassava almost exclusively for commercial purposes. In the case of Lilongwe, only 9 percent of the production diary entries were intended for consumption. The first three districts listed have similar production systems across their EAs, however, in the case of Zomba it varies more within the district. On the whole, 61 percent of diary entries from D1 and D2 households in Zomba were intended for consumption. Mulanje is the district furthest South in Malawi and geographically not far from the second largest city in Malawi, Blantyre, and in this area diary households reported 27 percent of their daily harvests as intended for consumption. Nkhatabay, Nkhotakota and Mulanje each represent the overall trend of highest production coming from D2 households, followed by D1 households, followed by R1 households. Lilongwe differs in that R1 production is higher than D1, though this difference is not significant. Zomba, where overall production is also the lowest, varies from the other districts the most in that R1 shows the highest production, then D1, then D2. None of the comparisons in Zomba are significant. D2 production is significantly higher than D1 production in Nkhatabay and Lilongwe. D2 production is significantly higher than R1 production in Nkhotakota, Lilongwe, and Mulanje. D1 is significantly higher than R1 in Nkhotakota and Mulanje.

5.2 Variety Identification

The results from the cassava DNA analysis reveal that only 31 percent of farmers correctly identified the variety in comparing the farmer-reported names with the DNA analysis. Beatrice and Manyokola, two of the most popular varieties, were more likely to be correctly identified by farmers as shown in Figure 3, whereas there was high misidentification for the less popular varieties. Incidence of correct varietal identification was only 5 percent based on the morphological protocol.

Furthermore, as shown in Table 6, according to DNA analysis only 10 percent of the varieties planted by farmers were improved varieties, however, the results from the farmer elicitation show that 79 percent of the households planted local varieties, 19 percent planted improved varieties and 2 percent did not know whether the variety was local or improved. About 99 percent of the varieties farmers stated as improved were found to be local and 12 percent of the varieties farmers stated as local were found to be improved varieties. This implies that only 1 percent of samples were correctly identified as improved and 88 percent correctly identified local varieties as local. The results also show that farmer elicitation over estimates adoption of improved cassava varieties and underestimates adoption of local varieties.

6. Key Preliminary Findings

In line with previous work on land area measurement, the results from self-reported and GPS-based measurement of cassava plots indicates the importance of relying on GPS-based land area measurement whenever possible to ensure accuracy.

The preliminary analysis of production data from the D1, D2, and R1 treatment arms indicates that, overall, the D2 approach to diary data collection through mobile phone monitoring attains potentially the best estimate of production. Given the variation of these results across land terciles and production systems, however, it is essential to explore these comparisons further and to do so using the complete data from the experiment set to conclude in September 2016. With only 31 percent of farmers correctly identifying the variety based on comparisons of farmer-reported names with DNA analysis, farmer-reported information is unreliable for accurate variety identification.

ABSTRACT

Adoption of new agricultural technology has different impacts. This study analyzed the different impacts of NERICA adoption on rice producers in Nigeria using the treatment effect estimation approach. It was a cross-sectional survey of 621 rice farmers through a multistage sampling procedure. Although a high percentage of rice farmers were aware of two main NERICA lines: NERICA I (82 percent) and NERICA II (76 percent), the actual adoption rate of these varieties is still very low (57%) in Nigeria. To control for endogeneity, the study used the local average treatment effect estimation methodology and the results showed that NERICA adoption significantly increased the area planted of rice by farmers,yield, and total farm income. The positive impact of NERICA adoption on rice yields and total farm income of farmers respectively is a clear indication that NERICA has the potential to increase rice productivity, reduce poverty and food insecurity. NERICA cultivation should still be further encouraged to rice farmers through the extension agents so as to raise rice yield, reduce rice importation and ensure a sustainable production.

Keywords: Counterfactual framework, sustainable production, productivity, farmers" welfare.

PAPER

1. Introduction

Rice is an extremely important food and cash crop in Nigeria. This strategic commodity is the fourth largest cereal crop grown in the country behind sorghum, millet and maize. Rice is widely cultivated under diverse ecosystems and a wide variety of climatic and soil conditions (rainfed lowland, irrigated lowland, mangrove swamp, upland)with a total annual production of about 2 million metric tons (MT). This annual production is far less than the total national rice consumption which exceeds 5 million MT per year, or more than 30 kg per capita per annum leading to an annual importation of about 2.5-3 million MT (USAID, 2009).Adoption of new technologies is an important issue developing countries have to put into consideration in order increase farm productivity. This study presents the empirical findings from Nigeria on the impact of NERICA adoption.

The study is necessary because it approaches the problem of estimation of adoption rates and their determinants from the perspective of modern evaluation theory (Imbens and Wooldridge, 2009; Imbens, 2004; Wooldridge, 2002; Heckman and Vytlacil 1999; Angrist et al., 1996).

2. Research Methodology

This study draws its methodology from previous surveys conducted in other West African countries. These include among others:Wiredu et al., 2014 in Ghana; Ojehomon et al., 2012, Awotide et al. 2012, Dontsopet al., 2011 in Nigeria; Diagne et al., 2009a,b, Diagne, 2006 in Cote D„lvoire; Spencer et al., 2006, Diagne et al., 2007 in Guinea.

This study was conducted in selected states in Nigeria, in 2012. The states were: Kaduna (located in the Northwestern Nigeria), Nasarawa (located in the Northcentral Nigeria), Ondo Osun, Ogun and Ekiti States (located in the Southwestern Nigeria). Data for the study were generated mainly from primary sources. The primary data were collected using a Focus Group Discussion across the rice growing communities to obtain prior information on their livelihoods and rice farming system. The semi-structured questionnaire was also administered to elicit information on the farmer"s socio-economic conditions, the farm"s characteristics, participation in the new rice variety selection, and experience with NERICA adoption, farm productivity, and income etc.

2.1 Sampling procedure

A multi-stage random sampling technique was used to select rice farmers from the six baseline states. The six states were selected purposively because no study as far as we know has evaluated the adoption rate of this variety in all the baseline states in Nigeria since the official release in 2005. In the second stage (due to the difficulty of getting the list of rice-producing farmers in the selected states as a result of lack of rice farmers" census), the lists of all the rice growing Local Government Areas (LGAs) where rice is grown and NERICA seeds have been disseminated were collected from the respective Agricultural Development Programme (ADPs) officers. This was followed by a random selection of the villages where NERICA dissemination activities have taken place, known as PVS villages. For every two NERICA villages selected, one adjacent village (that is within 15 to 20km radius) where NERICA is yet to be disseminated was also randomly selected as control. The selections were based on the fact that the more the number of control villages in the research sample, the more the number of non-adopters that is expected to be selected. The distance was chosen because the closer the non NERICA village is to the NERICA village, the greater the possibility of farmers" knowledge of the variety through other means apart from official means of dissemination. In each state, six villages were selected (two PVS villages and one non-PVS village per LGA). The chance of selecting a non-PVS village was based on the selection of a NERICA village within that vicinity. The selection of the PVS villages within each state was based on the ADP zones. However, non- rice producing ADP zones were not selected.

The third stage of the sampling involved the random selection of at least a hundred (100) rice farmers in each of the selected states. A total of 12 LGAs and 36 villages were selected for the study; and a total of 621 rice farmers were selected from the list of rice farmers in selected villages. The distribution of rice farmers interviewed per selected villages was based on the availability of rice farmers" guided by the NERICA field extension worker covering the selected villages. The sample size would have been based on the population size of rice farmers but this was not available.

2.2 Econometric procedures

This study used treatment effect estimation approach (counterfactual framework)to determine the impact of NERICA adoption on rice farmer"s income, yield, expenditure and per capita expenditure. The choice of this approach was based on the ability of the methods to produce consistent estimates (Imbens and Wooldridge, 2009). Also, we used the framework in order to overcome "non-exposure" bias and "selection" bias of the traditional procedures.This approach detects two important sources of bias in the estimation of treatment effects. These include the initial differences between on adopters and non-adopters in the absence of treatment, and the difference between the two groups. The parameters of interest are the average treatment effect (ATE) which is the expected effect of treatment on a randomly drawn person from the population, the average effect of the treatment on the treated (ATT) which represents the mean effect for those who actually participate in the treatment, and the average effect of treatment on the untreated (ATU) that measures the expected treatment effect for an individual drawn from the population of non-participants. By the counterfactual outcome framework a randomly selected rice producing household had two potential outcomes of adopting NERICA varieties .That is

$$Y = Y_1 \; if T = 1 \; and Y = Y_0 \; if T = 0 \text{ -- } 1$$

In equation 1, Y is the outcomes of interest such as total farm income. T is the adoption status. For the sample of randomly selected rice producing households the average effect of adoption, which is also known as ATE is generally given by:

$$ATE = E(Y_1 - Y_0) \text{ -- } 2$$

Differences in knowledge and access to information, physical accessibility as well as socioeconomic condition were expected to present unequal opportunities for adoption (Tambo and Abdoulaye, 2011). The impact parameter given adoption status, also known as the ATT is also given by:

$$ATT = E(Y_1 - Y_0) \,|T = 1) \text{ -- } 3$$

In this study access to the NERICA varieties was considered the most satisfactory condition for adoption. However, it was possible that some farmers had access to the seeds but did not plant the seeds. This implies that some farmers may have complied while others did not comply. In this case the impact on the farmers who received the seeds and subsequently planted, which is the local average treatment effect (LATE) is a more useful estimate of impact.

The non-parametric LATE framework was used to estimate the causal effect of the adoption of NERICA on total farm income, yield, expenditure, poverty status. The LATE parameter was expressed as;

$$LATE = E(Y_1 - Y_0)|P = 1, T = 1)\text{------}4$$

In addition to NERICA adoption, the incomes of the rice producers were assumed to be also affected by some exogenous factors, X, such that the potential outcomes of adoption in terms of X and the unaccounted factor, μ, was given by

$$Y = Y_1 = X\beta_1 + \mu_1 if T = 1\ and Y = Y_0 = X\beta_0 + \mu_0\ if T = 0\text{------}5$$

The LATE was re-expressed as:

$$LATE = X\beta_1 - X\beta_0 + E(\mu_1 - \mu_0|\ X, T = 1, P = 1)\text{------}6$$

Subsequently, the observed income, $= Y_1 + Y_0$, was expressed following Wiredu *et al.*, (2014) in terms of the LATE as:

$$Y = X\beta_0 + T * LATE + \varepsilon_{LATE}\text{------}7$$

The estimation of the LATE parameter in equation 7 followed a two stage instrumental variable regression procedure In the first stage a model of adoption was estimated with access to seeds of NERICA, P, as an instrument, W, as additional explanatory variables, and γ, as coefficient estimates. The model for adoption was specified as:

$$Prob(T = 1) = \emptyset(PW_\gamma)\text{------}8$$

The second stage involved the estimation of the LATE model with the predicted probability of adoption. The model was also specified as;

$$Y = X\beta_0 + \hat{T} * LATE\ (X) + \varepsilon_{LATE}\text{------}9$$

To analyze the various factors influencing the adoption of NERICA, we employed the ATE-Probit model.

$$T = E\ (y\,|\ x, w) = \alpha w + \delta w\ (x\text{-}X)\text{------}11$$

Where T = Status of adoption(1 = if adopted and 0 otherwise); y = outcome of exposure to treatment; w = a binary indicator variable for NERICA exposure (w =1 indicates exposure and w = 0 otherwise.); x = a vector of explanatory variablesX_1 = the gender of farmers (1 = male and 0 = female); X_2 = the age of farmers (years); X_3 = Education of farmers (1 = formal education and 0 Otherwise); X_4 = the Household size which is the number of people living under the same roof; X_5 = past participation in PVS trials (PVS participation = 1 and 0 otherwise); X_6 = contact with extension agent where (extension contact = 1 and 0 otherwise); X_7 = access to phone (where access to phone = 1 and 0 otherwise); X_8 = growing upland rice (growing upland=1, and 0 otherwise); X_9 = growing lowland rice (lowland rice = 1 and 0 otherwise); X_{10} = Distance to market (km); X_{11} = No of livestock; X_{12} = Kaduna State dummy (Kaduna state =1 and 0 otherwise); X_{13} = Ekiti State dummy(Ekiti State =1, otherwise 0); X_{14} = Nasarawa State dummy (Nasarawa = 1 and 0 otherwise); X_{15} = Ogun State dummy (Ogun =1 and 0 otherwise); X_{16} = Access to radio (access to radio =1 and 0 otherwise); X_{17} = access to television (access to television =1 and 0 otherwise); X_{18} = Ondo State dummy (Ondo=1 and 0 otherwise); X = vector of sample means of x; α and δ = are the parameters to be estimated

3. Results and Discussion

3.1 Adoption rates of NERICA varieties

The actual adoption rate of was 57 percent (Table 1). Across the individual states, the actual adoption rate was 77 percent, 67 percent, 62 percent, 62 percent, 47 percent and 8 percent in Ondo, Ekiti, Nasarawa, Ogun, Kadunaand Osun States respectively. The potential population adoption rate (ATE), which represent the true demand for NERICA varieties by the target population was estimated to be 80 percent for the study area, and 98 percent, 90 percent, 86 percent, 84 percent, 82 percent and 13 percent in Nasarawa, Ondo, Ekiti, Ogun, Kaduna, and Osun States respectively. This suggest that if the whole population was aware of, and have access to NERICA seed before the time of the survey, the NERICA adoption rate in the study area (Nigeria) could have been 80 percent instead of the actual 57 percent. Thus, for entire study area (six states), the estimate of the population adoption gap is accordingly 23 percent, and is statistically significant at 1 percent level. The corresponding estimates of the population adoption gap (i.e., the non-awareness bias) for Nasarawa, Kaduna, Ogun, Ekiti, Ondo, and Osun States are 36 percent, 35 percent, 22 percent, 19 percent, 14 percent, and 5 percent respectively, and all are statistically significant at 1 percent level. At the time of this study, the adoption rates among the NERICA exposed subpopulation (ATE1) in the study area was 81 percent while in Nasarawa, Ondo, Ekiti, Ogun, Kaduna, and Osun States, the adoption rate were estimated to be 98 percent, 90 percent, 86 percent, 85 percent, , 83 percent and 12 percent respectively.It is also instructive to compare adoption rates estimated in this study with estimates from other studies conducted in Nigeria and elsewhere in Africa. Although the adoption rate of 57 percent was considerably higher than the 4 percent reported by Diagne (2006) for Cote d‟Ivoire, greater than 18 percent reported by Adegbola et al., (2005) for Benin republic, 30 and 40 percent reported for Ekiti and Kaduna (Nigeria) States respectively by Spencer et al., (2006), and 20 percent reported by Dontsop et al.,(2011) for Osun State (Nigeria), the 23 percent adoption gap estimates imply that there is still a potential for significantly increasing NERICA adoption rates in Nigeria.

3.2 Comparative farm-level economic benefits from NERICA adoption

The difference statistical test shows a productivity difference in NERICA yields and also a difference in variable production costs between adopters and non-adopters (Table 2). NERICA adopters were about 14 per cent more productive compared to the non-adopters. Variable costs for adopters were 61.6 percent lower than non-adopters on average, suggesting greater benefits from this source. The simple comparisons between adopters and non-adopters demonstrate that the adopters are distinguishable in terms of considerably higher NERICA net income. This result agrees with the finding of Ojehomon et al., (2012) who reported that investment in NERICA rice production in Ekiti State, Nigeria is more profitable than the other non-NERICA varieties grown in the area. This suggests that NERICA can really be considered as a poverty alleviating crop (Table 3).

Table 2 - Comparative physical and economic benefits in NERICA Adopters production in Nigeria

3.3 Determinants of NERICA adoption in Nigeria

In Table 4, the results of the log-likelihood of -122.3, the Pseudo R2 of 0.353 and the LR (chi2) of 0.0000 (significant at 1 percent level), imply that the overall model fitted and the explanatory variables used in the model collectively explain the adoption of NERICA decision among the rice farming households in Nigeria. The analysis showed that only gender and farmers access to radio were statistically significant. Men were more aware of NERICA than the women probably due to the large difference between men and women in rice farming in Nigeria (84 percent to 16 percent as indicated). This is in line with Dontsop et al.,(2011) findings who observed that though women were more likely to be aware of NERICA existence in Osun, Niger and Kaduna States of Nigeria, their men counterpart were most likely to adopt NERICA. The findings of the study also revealed that farmers that did not have access to radio were more likely aware of NERICA than those that have radio. This result however differs from other countries in Africa such as Côte d'Ivoire where factors like the household size, growing upland rice, past participation in PVS trials, age of the farmers have significant effects on adoption of NERICA (Diagne 2006).

The marginal effect shows that a unit decrease in number of those that have access to radio leads to 0.13 decreased in the likelihood of being aware of the NERICA varieties (Table 4). The significance of the dummy variables (Ekiti, Nasarawa, Ogun, Kaduna and Ondo) at 1 percent level in positive direction in Table 4 is an indication that there are differences in the determinants of NERICA adoption across the states in the study area. This result corroborate with the information obtained from the Focus Group Discussions (FGDs) in Sabon-Girke (Pako) in Igbebi Local Government Area (one of the PVS villages) of Kaduna State that farmers preferred, and adopt NERICA due to its high productivity and market value Similarly, in Ondo State, the outcome of the FGD at Eleyowo village showed that farmers adopt and preferred NERICA to other rice varieties due to its early maturity and its high yield, short stature, stability, and inability of the paddy to get dislodged before harvest and even after maturity. In Nasarawa State, the FGD revealed that farmers adopt NERICA because of the low fertilizer requirements; high tolerant to most diseases, better tastes, better than other cultivars and early maturity given room to farmers to harvest two to three times a year

4. Conclusion and Recommendations

This study explored the impact of new agricultural technology (NERICA) on farm yield, total farm income/expenditure in Nigeria. The study uses the average treatment framework for its estimations. The key findings reveal that the Nigerian government is promoting the adoption of the new rice varieties to help boost rice production through her rice transformation agenda. Average farm size for NERICA farmers is 2.6ha. This shows that in spite of evident of the adoption of NERICA varieties; rice production in Nigeria is still at the small scale level. The adoption of NERICA varieties was observed as being relatively high in the study area compared to the reported values for other countries such as Côte d"Ivoire (9% by Diagne, 2006). Adoption of NERICA significantly increase (at 1percent level) the area of land cultivated, farm output, yield, household expenditure, per capita expenditure and total farm income. The positive impact of NERICA adoption on rice yields is a clear indication that NERICA has the potential to increase rice productivity significantly among NERICA farmers. The positive impact on income signifies that NERICA has potential to reduce poverty while the significant effects on food expenditure reveals that NERICA can help solve food insecurity. NERICA adoption has great potential for poverty reduction and improved livelihood of rice farmers in Nigeria. The estimates for the sub-population of exposed farmers (ATE1) and that of the non-exposed farmers (ATE0) suggest that there is still a potential for significantly increasing NERICA adoption rates in Nigeria. The federal, state and local governments in collaboration with agricultural research institutes and other NGOs should upgrade rice farmers" knowledge base, improve knowledge sharing, and close the gap between science, technology and innovation and development practice in order to make the best use of NERICA technology.

Spatial nonstationarity in the stochastic frontier model: an application to the Italian wine industry

ABSTRACT

This research estimates the efficiency of a representative sample of Italian wine producers from the Italian FADN survey following a recent spatial stochastic frontier framework that allows to isolate the spatial dependence among units and to evaluate the role of intangible local factors in influencing the economic performance of firms. The empirical exercise shows that the specific territorial patterns in the data cannot be merely explained using a standard set of contextual factors. This intangible component can be interpreted as the role of the local business climate: in most localities, the presence of an embedded community stimulates a process of local learning that generates the diffusion of tacit knowledge through continuous interaction among the local actors. This effect is found to be different across firm size, with a larger impact on small firms

Keywords: Spatial nonstationarity, Spatial Stochastic Frontier Model, Wine, Efficiency

PAPER

1. Introduction

The globalization of productive processes and liberalization of trade activities have generated a strong competition between regional economic systems: paradoxically, rather than drastically reducing the role of spatial proximity, this new open scenario has shed new light on the key relevance of local and agglomeration externalities in the generation of competitive advantage (Porter, 2000). The relevance of these aspects is particularly evident in certain sectors, such as wine production, where the rapid transformations occurred in the last few decades have fostered a rapid process of technological change in which firms are constantly required to be at the forefront of the productive process in order to survive in the competitive arena (Cusmano et al., 2010). In this context, the role of intangible factors associated with the 'business climate' is crucial in stimulating the process of knowledge accumulation and learning through continuous interaction with peers located in close proximity: in several circumstances, the presence of these mechanisms ensures the diffusion of new productive practices that prevents local firms from increasing their gap with the technological frontier.

The classical stream of the literature linking productive efficiency to the territorial determinants assumes that the dynamic process leading firms to concentrate in specific subregions is only associated to specific tangible aspects: this assumption leads to neglect the role of spatial non-stationarity, intended as "a condition in which a simple global model cannot explain the relationships between some sets of variables" (Brunsdon et al., 1996). This problem is particularly evident in the parametric frontier framework, where it is essential to specify a priori an explicit functional form of the boundary of the production set: however, in the early contributions the spatial dependence among productive units has often been ignored and associated to the stochastic error. A number of recent works have attempted to address this issue by specifically including a set of contextual factors in the model (see e.g. Hughes et al., 2011,Brehm, 2013): however, such a strategy is not always effective as it ignores the fact that the relationship between the dependent variable and the covariates (a) tends to vary in a continuous rather than a discrete manner among spatial units and (b) may not be necessarily related to measurable local factors. This problem is particularly evident in specific spatial contexts, such as industrial districts, characterized by the presence of global intangible factors that cannot be measured empirically (Vidoli and Canello, 2016).

Ignoring spatial autocorrelation among residuals limits the validity of the empirical investigation for several reasons. First, it causes serious consequences to statistical inference, reducing both the efficiency and consistency of the estimations and generating a negative impact on the validity of testing procedures and on the predicting capability of the model. This drawback generates significant distortions in the interpretation of the stochastic frontier model, as higher values of the inefficiency term may be associated with a territorial effect rather than the ability of a productive unit to generate more output with the same amount of inputs. In this respect, the inclusion of spatial autocorrelation into the stochastic frontier production framework has been the subject of a lively debate in the econometrics literature in the recent past, generating a multitude of approaches aimed to address this issue: in this context, the specification proposed by Fusco and Vidoli (2013) appears to be particularly suitable in that the spatial autoregressive specification is modelled in the error term, generating results that can be directly compared with those of the classic stochastic frontier approach.

In this paper, the above mentioned spatial stochastic frontier approach is implemented on a sample of Italian firms specialized in wine production, using data extracted from the 2013 FADN Survey. This archive is particularly suitable for the scope of the analysis, as it allows to account for a wide variety of structural and economic factors that are believed to influence the territorial effects: moreover, the presence of specific reference to a wide variety of inputs allows to build a solid production function with several benefits for the estimation process. The aim of the empirical exercise proposed in this paper is to evaluate the contribution of both tangible and intangible factors in influencing the performance of these firms, discussing how the space can play a different role for the different members of a local network. In this respect, the specification proposed is of particular use as it allows to isolate the local intangible factors, often statistically and economically difficult to capture through specific proxies, that nonetheless are determinant in influencing the firms productivity. The role of tangible factors is nonetheless evaluated through a second stage estimation.

The remainder of the paper is structured as follows: section 2 presents the main features of the Italian wine sector, highlighting how the recent technological and structural changes have increased the importance of local learning and continuous access to new knowledge. In section 3, a brief review of the parametric frontier models is introduced, stressing on the recent debate on spatial approaches and presenting the proposed method and the benefits deriving for its application in the present context. In section 4, the focus is moved to the empirical application: after the main features of the database used for the analysis are introduced and discussed, the results of the spatial stochastic frontier model are introduced, comparing them with those of the traditional approach and highlighting the effectiveness of the Spatial Stochastic Frontier (SSFA) specification (see section 3) in isolating the spatial dependence that are present in the data. Finally, the structural features of the spatial effect are inspected and evaluated through the analysis of territorial imbalances, showing that the mere use of contextual variables is not sufficient to explain the variability of local effect: this result provides evidence of the existence of an intangible local effect in the wine industry that influence firm performances in different ways. Section 5 summarizes the main finding of the paper and proposes some concluding remarks and possible directions for future research.

2. The recent trends in the Italian wine industry and the role of agglomeration effects

Italy has played, together with France, a key role in the wine industry for several decades, dominating the international scenario in terms of both exported volumes and values. This established pattern has radically changed since the 1990s, when the entrance of the New World producers (United States, Australia, Chile, Argentina, South Africa) in the global market has fostered a radical transformation of the existing competitive arena (Cusmano et al., 2010). The increased complexity of the new global environment has further been influenced by several exogenous risk factors, such as the increased climate variability and the radical changes in wine consumption habits, with a shift in preferences towards high quality wines (Bardaji and Iraizoz, 2015). In this context, the sector has experienced a process of rapid modernization and technological change, identified by Crowley, 2000 as a "wine revolution". This radical transformation process is pushing wine producers to adopt improvement strategies in the quality and production process and acquire new knowledge in order to effectively respond to the volatile needs of the global markets. The potential gains from selecting an effective strategy are especially important in the wine sector where, despite the existence of a moderate correlation between price and quality, several price setting possibilities are available for wine producers given the incomplete quality information held by consumers (Oczkowski and Doucouliagos, 2015).

The current scenario generates several challenges for the Italian wine sector, which has recently faced a significant downturn in domestic demand and is characterized by a higher degree of fragmentation relative to other countries, such as Australia or Chile (Cusmano et al., 2010). Italian wine producers are often small and medium businesses that lack the financial and managerial resources to handle the increased complexity of the surrounding environment. This limit is especially problematic in the new global context, characterized by the constant need to update productive knowledge and acquire new skills and competences. In fact, small businesses are not generally equipped to gather relevant information outside the locality in which they are embedded; moreover, they cannot rely on the same formal channels used by leader firms, such as formal collaborations with research institutions (Giuliani et al., 2010) and interaction with foreign competitors, often through the presence of foreign subsidiaries (Felzensztein and Deans, 2013) or simply through the creation of relational networks with producers that are at the forefront of the industry (Turner, 2010). Given these opportunities are not generally accessible to small producers, the main source of learning and developing new competencies is the community in which these entrepreneurs are embedded. The role of this factor is especially relevant in Italy, where contrary to other countries, such as Australia, the wine sector cannot count on institutional assets and top-down measures to stimulate the above mentioned upgrading process.

Although several contributions have stressed the increasing importance of codified knowledge in the wine industry (e.g. Giuliani, 2007), the sector is still dependent on context-specific and localized informal practices of learning, that are crucial to take advantage of the specificities of each terroir (Turner, 2010). The effect generated by the local business climate and the informal interaction among local actors can be explained through the concept of "industrial atmosphere", that has generally been used in the industrial districts literature (Marshall, 1920): other than generating tangible benefits such as reputation, greater international demand and access to skilled labour pool, spatial proximity among wine producers stimulates everyday interaction, facilitating the opportunities for face-to-face contacts that are crucial to generate tacit knowledge flows and incremental learning. In this respect, wine clusters can be seen as communitarian networks, characterized by resource sharing and continuous informal interaction (Turner, 2010). The presence of interpersonal networks can be beneficial in many respects: producers can be rapidly informed of the presence of new business opportunities, but also of new sellers or providers that can form new partnerships and generate further spillovers. Inter-firms market cooperation can also foster marketing collaboration strategies, facilitating development of joint sales in foreign markets and allowing to overcome the limited exporting capabilities of several small and medium firms (Felzensztein and Deans, 2013). More importantly, the presence of a collaborative environment can allow small producers to fill the technological gap with competitors, as collaboration can foster the shared use of new technology, exchange of technical advices and information on the effective use of machinery and inputs (Morrison and Rabellotti, 2009).

A certain number of agglomeration externalities generates spontaneously as a consequence of spatial proximity between wine producers. For example, the successful performance of neighbouring wineries stimulates the development of positive marketing-related externalities for the whole area (Giuliani and Bell, 2005): these positive spillovers in terms of reputation for the neighbouring producers have been classified by Beebe et al. (2013) as "halo" effect. However, spatial proximity itself is not sufficient to guarantee the diffusion of agglomeration externalities among all the members of a local community. Indeed, two elements are required to enhance this process, i.e. the willingness of givers to share their knowledge and the absorptive capacity of the receiver: these conditions are generally meet when the cognitive proximity among the members of a network is present (Boschmaa, 2005). The presence of diversified abilities/attitudes to access to local informal knowledge has been documented in different regional contexts in the wine industry (Giuliani and Bell, 2005; Morrison and Rabellotti, 2009): according to Giuliani and Bell (2005), the presence of barriers to knowledge exchange is testified by the presence of different production methods within the same wine cluster.

What is the profile of those firms which are more often engaged in networking activities? The core of these local networks is generally represented by small firms, which are generally more inclined to cooperate and share information in order to overcome their structural limits: the lack of competencies among small firms act as stimulus to share different experiences and spread knowledge among the community. On the other hand, large firms tend to be located at the periphery of the local network and provide a limited contribution to the local learning system: these actors generally have stronger connections with external sources of knowledge and often prefer to share the acquired competencies with a restricted number of partners that are directly involved in their production process (Morrison and Rabellotti, 2009). This trend is confirmed by the empirical investigation of Turner (2010), who has shown that small wine producers are more interested with marketing practices associated with the territory while large firms are more interested in developing their own brand.

The brief review presented in this section has shown that the tangible and intangible local effects play a key role in determining the performance of wine producers. Against this background, the aim of the following section is to propose an empirical framework that can be effectively used to account for both effects in the estimation of productive efficiency, allowing evaluate the role of the different spatial factors in a consistent manner.

3 Disentangling the role of spatial effects on firm efficiency: the spatial stochastic frontier models

Efficiency estimation has been subject to considerable research during the last decades, generating important contributions both in the econometrics (see e.g. Aigner et al., 1977; Meeusen and van den Broeck, 1977; Aigner and Chu, 1968) and operational research literature (see e.g. Farrell, 1957; Charnes et al., 1978; Deprins et al., 1984; Grosskopf, 1996; Daraio and Simar, 2007). In this context, one of the most widely used parametric models is the Stochastic Frontier Analysis (SFA), which was originally proposed in two different contexts by Aigner et al. (1977) and Meeusen and van den Broeck (1977): under specific assumptions, this specification allows to estimate the parameters of the frontier production function and to perform hypothesis testing procedures to validate the model (see. g. Kumbhakar and Lovell, 2000 for a detailed introduction to frontier analysis).

In a cross-sectional framework, the productive process of the i^{th} firm using N inputs $\mathbf{x} = (x_1, ..., x_N)$ to produce M outputs $\mathbf{y} = (y_1, ..., y_M)$ can be specified as follows:

$$log(\mathbf{y}) = log(f(\mathbf{x}; \beta)) + \mathbf{v} - \mathbf{u} \quad (1)$$

where:

- $\mathbf{v} \sim \; iid \; N(\mathbf{0}, \sigma_v^2 \mathbf{I})$ is the random term;
- $\mathbf{u} \sim \; iid \; N^+(\mathbf{0}, \sigma_u^2 \mathbf{I})$ is the inefficiency term;
- $\mathbf{v}$ and $\mathbf{u}$ are assumed to be independently and identically distributed.

The traditional SFA specification estimates firm-level efficiency from the residuals, assuming that all producers in the sample are independent: however, this assumption rules out the possibility to account for spatial effects in the theoretical model. The limitations of this approach were already known in early contributions, considering Farrell (1957) highlighted the importance of incorporating the correlation between technical efficiency and variables representing location, temperature and rainfall. In his analysis, focused on the efficiency patterns in US agricultural firms, he argued that "the apparent differences in efficiency [...] reflect factors like climate, location and fertility that have not been included in the analysis, as well as genuine differences in efficiency".

When spatial effects are significant, the traditional techniques used to estimate the SFA (MLE or its variants) generate biased results: indeed, if the disturbances are spatially correlated, the assumption of a spherical error covariance matrix is violated, leading to biased and inconsistent estimators (LeSage, 1997). In order to overcome these issues, a number of recent contributions in frontier analysis have proposed alternative specifications aiming to incorporate spatial effects in the baseline models. This literature stream follows the approach used by spatial econometrics, a specific branch of econometrics that deals with spatial interaction (spatial autocorrelation) and spatial structure (spatial heterogeneity) in both cross-sectional and panel data (Paelinck and Klaassen, 1979; Anselin, 1988).

Subsequently, given the need to consider for spatial dependence also in frontier analysis, some models have been developed; they can be divided in two major fields distinguishing those that explain inefficiency/efficiency in terms of exogenous determinants analysing the heterogeneity from those that consider the spatial dependence by including in the model a spatial autoregressive specification.

As far as the first stream is concerned, some authors have proposed to analyse heterogeneity by including contextual factors as regressors or to modelling the inefficiency term. In particular, Lavado and Barrios (2010) used contextual factors to modelling the inefficiency part of a stochastic frontier model embedding a sparse spatial autoregression (SAR) in the deterministic part and a general linear mixed model into the efficiency equation; Hughes et al. (2011) considered specific spatial effects in the stochastic production frontier by adding climate effects as dependent variables; Jeleskovic and Schwanebeck (2012) proposed a two step deterministic estimation model to differentiate heterogeneity and inefficiency in world healthcare systems: (i) in the first step different fixed effects panel spatial models have been estimated; (ii) in the second step the obtained inefficiency has been regressed (also with various fixed effects panel spatial models) as dependent variable onto country specific variables that identify the heterogeneity; finally, Brehm (2013) proposed a correction of the SFA error term for panel data by introducing spatially correlated factors variables that affect the production process.

In the second set of analysis, others proposals consider spatial dependence by including a spatial lag into the dependent variable or into the covariates. More specifically, Affuso (2010) included spatial lag on the dependent variable reformulating the stochastic frontier density function; Glass et al. (2013), Glass et al. (2014) and Glass et al. (2016) introduced the concept of efficiency spillover, extending the non-spatial Cornwell et al. (1990) model to the case of spatial autoregressive dependence; Adetutu et al. (2015) proposed a local spatial stochastic frontier model that accounts for spatial interaction by allowing spatial lags on the inputs and on the exogenous variables to shift the production frontier technology; Han et al. (2013) proposed a method for investigating spillovers effects in panel data by maintaining the Schmidt and Sickles (1984) hypothesis of time-invariant inefficiency, but allowing global spatial dependence through the introduction of a spatial lag on the dependent variable.

Finally, others papers proposed to consider spatial dependence by including a spatial lag on the inefficiency term. Druska and Horrace (2004) extended the Kelejian and Prucha (1999) specification for cross-sectional data based on a standard fixed effects model by assuming an autoregressive specification of the error term and estimating inefficiency with the Generalized Moments Method; Schmidt et al. (2009) used a Bayesian approach to include latent spatial effects, that explain geographical variation of firms' outputs and inefficiency, dependent on a parameter that captures the unobserved spatial characteristics; e.g. Areal et al. (2010) suggested, with the aim of measuring the overall effect of spatial factors that affect the production, to include a spatial lag directly into inefficiency allowing the splitting of the inefficiency into a spatial component and into a specific term for every firm through a Bayesian procedure. Instead, Pavlyuk (2010) proposed to include spatial lags on the overall standard SFA model (see also recent enhancements, Pavlyuk, 2012, 2013). Following the approach implemented by Areal et al. (2010), Fusco and Vidoli (2013) have proposed to measure the global effect of spatial factors by including a spatial lag only in the inefficiency term of a stochastic frontier (SFA), not using a Bayesian procedure but by reformulating the SFA density function with a spatial error autoregressive specification (SEM). The Spatial Stochastic Frontier model (SSFA) is defined as:

$$\begin{aligned} log(\mathbf{y}) &= log(f(\mathbf{x};\beta)) + \mathbf{v} - \mathbf{u} \\ &= log(f(\mathbf{x};\beta)) + \mathbf{v} - (\mathbf{I} - \rho\mathbf{W})^{-1}\tilde{\mathbf{u}} \end{aligned} \tag{2}$$

where:

- $\mathbf{v} \sim iid\ N(\mathbf{0}, \sigma_v^2\mathbf{I})$;
- $\mathbf{u} \sim N^+(\mathbf{0}, \left[(\mathbf{I}-\rho\mathbf{W})^{-1}(\mathbf{I}-\rho\mathbf{W}')^{-1}\right]\sigma_{\tilde{u}}^2)$;
- $\mathbf{v}$ and $\mathbf{u}$ are independent of each other and of the regressors;
- $\tilde{\mathbf{u}} \sim iid\ N(\mathbf{0}, \sigma_{\tilde{u}}^2\mathbf{I})$.

In this paper, an empirical application of the SSFA has been proposed in order to avoid the subjective choice of the exogenous determinants and to focus the analysis of the spatial dependence only on the inefficiency term; this approach reduces the complexity of the model and makes the estimation easier computationally[1] as well as to be immediately comparable with the classical SFA model when no spatial autocorrelation is assumed on the error term.

It is important to note, moreover, that the formulation of equation (2) hide an interesting property: the identification of the error part imputable to the spatial proximities different for each unit allows to change (positively or negatively) the intercept of the model; therefore, in the SSFA framework the intercept is to be understood only as the "medium level" cleansed by the individual spatial effect.

Figure 1 clarifies the issue: departing from high spatial correlated simulated data (one input vs one output), OLS, SFA and SSFA has been estimated; in particular it can be noted that the SSFA specification impact both on the specific estimation of each unit (red continue line) both on the average slope (orange dashed line).

4. Application

In this section, the spatial stochastic frontier specification introduced in section 3 is used to evaluate the role of local effects in the Italian wine industry: as highlighted in section 2, the recent technologica advances in the sector has increased the importance of both the tangible and intangible factors associated with the specific territorial effects that cannot always be captured by the inclusion of ontextual variables. In this respect, the spatial technique proposed in the previous section appears to be especially effective to account for these factors and evaluate their role in influencing firm-level ef ficiency. The empirical investigation is focused on year 2013 and is implemented on a detailed database that includes a wide variety of economic and structural variables: the main features of this database are presented in the following subsection.

4.1 Italian FADN survey: the data source used for the empirical analysis

The Farm Accountancy Data Network (FADN) is a yearly survey carried out by the Member States of the European Union and established in 1965 by the Council Regulation No 79/65/EEC: this measure was aimed to establish a network for the systematic collection of accountancy data on incomes and usiness operations of agricultural holdings in the European Economic Community. According to Regulation n. 1859/82, this database includes all the agricultural holdings having an economic size equal to or greater than a minimum threshold, i.e. that identified to be considered commercial: in Italy, this threshold is set on 4,000 eof standard output. The selection of the holdings that take part to the survey is carried out according to sampling plans defined at the national level, following the guidelines and recommendations provided by the European Commission. The sampling procedure must ensure the representativeness of the identified subset and defines the number of farms to be selected, specifying the approach followed to select the productive units. According to FADN methodology, stratification variables are territorial location, economic size and type of farming.

The Italian section of the survey is based on the Agricultural Census, updated on a two-year basis by the Farm Structure Survey (FSS) carried out by ISTAT: this main data source is complemented with further sources of agricultural statistics. The Italian FADN sample is selected using the stratified random sampling technique described above: in particular, the territorial location corresponds to the 21 administrative regions; the economic size is expressed in terms of Standard Output and defined through several classes, the lowest of which starts from 4.000 eand the highest refers to those with more than 3 million e; the type of farming corresponds to the particular level grouped according to the importance of the specific agricultural activity in the region. According to the procedure, some types of farming and some classes of Standard Output could be aggregated in order to have a sufficient number of observation in each strata. Following the above mentioned approach, the 2013 version of the Italian FADN survey, which is the one used in this paper, includes a total number of about 700.000 farms. The productive units of the survey are allocated in each stratum according to strategic variables such as Standard Output, Utilized Agricultural Area, Livestock Units and Working days. To get the desired level of precision for each strategic variable are fixed sampling errors, in terms of percentage of coefficients of variation[2], they represent the errors that is possible to make, with a fixed probability, estimating a variable compared to its real value, hence they determine the reliability of estimates. Sample size and its distribution among the strata are established by setting the precision required in terms of percentage of coefficients of variation for strategic variables, both at national and at regional level. The methodology used to allocate the sample among the strata is a combination of Neyman and Bethel methods (Bethel, 1989). The main benefits associated with the use of this database can be summarized by the following two aspects:

- harmonization: FADN is the only source of micro-economic data that is harmonised at European level, i.e. the book-keeping principles are the same in all countries, and it represents an important tool for the evaluation of the income of agricultural holdings and the impacts of the Common Agricultural Policy. In Italy the FADN survey is carried out by the Center for Policy and Bio-economy of the Council for Research in Agriculture and the Agricultural Economics Analysis - CREA[3], as liaison agency between EU and Member State.

- information assets: The FADN survey collects more than 1,000 variables that refer to physical and structural data, such as location, crop areas, livestock units, labour force. It also contain economic and financial data, such as the value of production of the different crops, stocks, sales and purchases, production costs, assets, liabilities, production quotas and subsidies, including those connected with the application of CAP measures and recently were added also information linked to environmental aspects. These variables are extremely convenient for the purpose of this paper, as they allow to create both a solid production function and include a wide variety of local effects that are associable with the performance of these firms.

[2] The coefficient of variation of a variable is the ratio between the standard deviation of the variable layer and the estimate of the total layer of variable.
[3] Previously National Institute of Agricultural Economics - INEA

In this paper a sub sample of 853 wineries has been extracted from the Italian FADN database, which includes a total number of 11.319 farms in year 2013. Using this data, the application presented in the following sections compares the results of the traditional specifications of the production function with those of the SSFA model, showing the benefits associated with the use of the latter approach. An important caveat relates to the variable used to evaluate output, i.e. the litres of wine produced by each unit: given the information at disposal does not allow to evaluate the qualitative aspects of production (which are nonetheless relevant in the sector), the concept of efficiency should be interpreted from a technical point of view, avoiding any considerations on the quality of output produced.

4.2 Production function

The production function of the Italian wine firms has been initially estimated using a simple OLS approach, choosing a Cobb-Douglas[4] log-log functional from and relating the produced quantity of output with labour, machinery, water-energy-fuel and land capital inputs. The results of the estimation[5] (Table 1) appear to confirm the validity of the specification, given the significance of all covariates and the high R2 = 0:593; it is also worth noting that the intercept is negative and statistically significant.

Table 1 - Wine production function - OLS estimators

	Dependent variable: production output (log)
Intercept	−2.068*** (0.309)
Labour input	0.641*** (0.055)
Machinery capital input	0.307*** (0.045)
Water, energy and fuel input	0.067*** (0.014)
Land capital input	0.245*** (0.037)
Observations	853
R^2	0.593
Adjusted R^2	0.591
Note:	*p<0.1; **p<0.05; ***p<0.01

Using OLS as baseline for the analysis, the stochastic frontier model has been estimated (Table 2) and the results of the two specifications compared: the analysis confirms the stability of the latter model, since the values of the coefficients are similar in the two cases, except for the intercept that decreases in absolute value. This trend is expected and can be explained by the fact that the production function has been shifted from the average values to efficient ones without affecting the relationship between output and inputs. The specific parameters of SFA (σ^2, γ and the average efficiency equal to 0:59) confirm the validity of the proposed model. In particular, $\gamma = \sigma^2 \upsilon/\sigma^2$ depends on two relevant parameters, σ^2 u and σ^2 ϖ , that are the variances of the noise and inefficiency effects. Note that g varies from 0 to 1: when the value is close to zero deviations from the frontier are attributed to noise, while in the opposite case the deviations are entirely explained by the technical inefficiency of the firm. As discussed in Section 3, the stochastic frontier model is based on the hypothesis of mutual independence among the productive units: therefore, this specification ignores the role of any spatial effects that may be present in the data. However, the evolutionary trends emerged from the brief overview of the Italian wine industry presented in this paper suggests that efficiency in this sector could be influenced by a multiplicity of tangible and intangible local factors.

Table 2 - Wine production function - SFA estimator

	Dependent variable: production output (log)			
	Estimate	Std. Error	*z* value	$Pr(>\|z\|)$
Intercept	-1.411159	0.322292	-4.3785	1.195e-05 ***

Note:				*p<0.1; **p<0.05; ***p<0.01

[4]This model has been also estimated using a Translog specification for the production function. However, given the lack of significance of composite terms, a simpler model has been chosen for this part of the analysis.

[5]The basic statistics of the variables used in the analysis and the relative units of measurement are given in Annex, Table 5.

To evaluate the role of these effects, a formal statistical test has been implemented to verify the presence of spatial correlation mong residuals: specifically, the global and local indicators proposed by Geary (1954) have been used, previously specifying a distance matrix to map the neighbourhood of each production unit. The correct definition of the matrix is crucial to ensure the consistency of the spatial analysis: in this respect, the identification of a correct unit of distance must be driven by economic considerations associated with the peculiarities of the sector under investigation. In this specific case, characterized by the presence of productive units often concentrated in narrow geographical areas, a particularly close neighbourhood (nearest neighbour, n = 10) has been chosen in order to account for the specificities of the wine industry: the contiguity matrix resulting from the application of this criterion is graphically represented in Figure 2.

Figure 2 - Contiguity matrix, nearest neighbour (n = 10)

Using this distance matrix, the presence of spatial autocorrelation among residuals for the SFA model has been formally tested using the Geary C statistic[6]: the estimated value of this variable (0:733) leads to reject the null hypothesis of mutual independence among firms, confirming the presence of a positive neighbourhood effect among the Italian wineries that cannot be isolated and estimated through the traditional stochastic frontier model. This scenario motivates the need to use a spatial stochastic frontier approach with the data at disposal: in this respect, the SSFA model proposed in equation (2) seems a particularly effective tool to isolate and evaluate the territorial component separately from the individual performance of the productive units. The results of the estimation are reported in Table 3: in all cases, the value of the coefficients for the inputs are consistent with those obtained from the SFA specification, with the expectation of the intercept that becomes not significant; however, this result is expected as the spatial specification generates a further shift in the production curve with respect to the SFA as a consequence of the isolation of the spatial effect, transforming the average value of $\beta 0$ into a multiplicity of individual effects. This pattern as already been shown in section 3 (Figure 1). Interestingly, the value of the γ parameter (0:433) is lower than the one estimated with the SFA model: this evidence supports the hypothesis that part of the technical inefficiency was mistakenly attributed to the production process rather than to neighbourhood effects.

Table 3 - Wine production function - SFA estimator

	Dependent variable: production output (log)			
	Estimate	Std. Error	z value	Pr(> |z|)
Intercept	-0.0707772	0.7387170	-0.09581	0.923671
Labour input	0.6081372	0.0525574	11.57091	< 2e-16 ***
Machinery capital input	0.3328368	0.0436632	7.62282	< 2e-16 ***
Water, energy and fuel input	0.0500784	0.0132213	3.78770	0.000152 ***
Land capital input	0.3250007	0.0401612	8.09240	< 2e-16 ***
σ^2_{dmu}	0.3253159	0.1250316	2.60187	0.009272 **
σ^2_v	0.3591916	0.0456068	7.87584	< 2e-16 ***
Note:				*p<0.1; **p<0.05; ***p<0.01

[6] The value of Geary C lies between 0 and 2. Values lower than 1 demonstrate increasing positive spatial autocorrelation, whereas values higher than 1 indicate increasing negative spatial autocorrelation. C=1 is consistent with no spatial autocorrelation in the data.

The benefits of the proposed framework are also evident in terms of global and local spatial autocorrelation: indeed, the global Geary C statistic equal to 1.048 suggests that global autocorrelation has been effectively removed from the residuals, while local ci (for each unit i) associated with the SSFA estimates is significantly lower with respect to the unconditional SFA scenario (Figure 3).

4.2.1 Explaining the spatial effect through the analysis of territorial imbalances

The analysis presented in the previous section has confirmed the presence of a spatial effect in the data that has been successfully isolated using the SSFA specification proposed in section 3. In this part of the empirical investigation, the focus is moved to the spatial effect itself, in an attempt to explain its structural characteristics and interpret its nature in light of the considerations emerged in the brief review of the wine sector presented in section 2. In order to do so, the analysis is focused on the territorial imbalances, defined as the difference between the efficiency term estimated in the SFA specification and that identified with the SSFA approach[7]: in general, higher values of territorial imbalance suggest the presence of a stronger territorial component.

A geographical representation of the territorial imbalances is presented in (Figure 4): the map shows the presence of a heterogeneous distribution of the spatial effect, with areas characterized by a strong territorial factors while in other case the role of the locality appears to be negligible in determining the performance of the productive units.

Figure 3 - Local ci kernel density of the SFA and SSFA efficiency

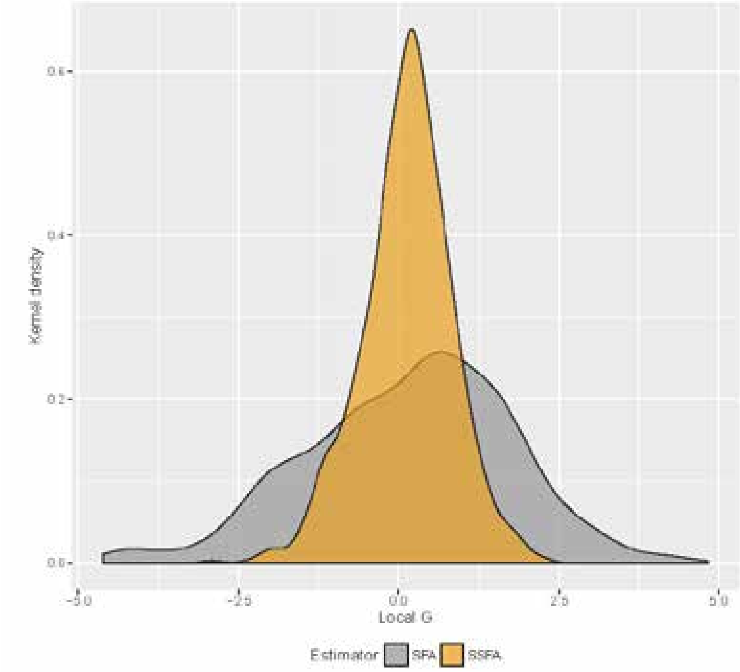

Figure 4 - Differences between SFA and SSFA efficiencies per quantile, q = 4

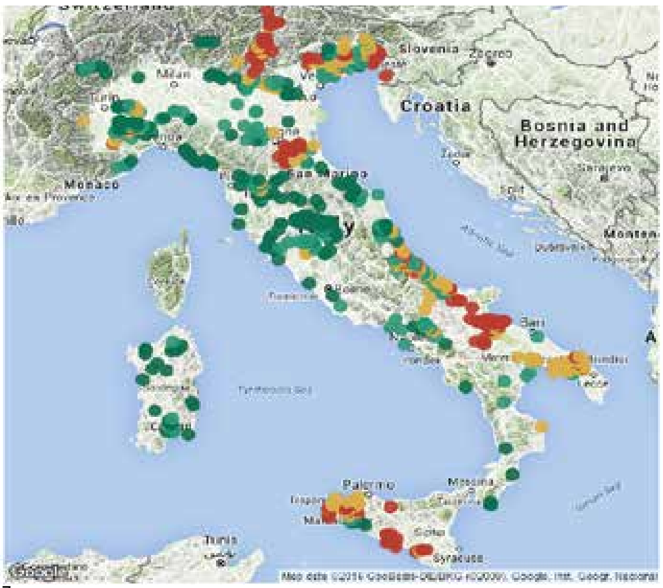

[7] this term is generally positive, given in the SFA the spatial effect is mistakenly incorporated into the error term, generating higher values relative to those estimated with the SSFA

Having established the presence of a relevant and heterogeneous spatial effect in the Italian wine industry, the immediate question is whether this effect can be satisfactorily explained by a plurality of tangible local factors. To address this issue, a second stage analysis has been implemented regressing the territorial imbalances on a plurality of contextual variables, following previous findings in earlier studies (see e.g. Hani et al., 2003, Reig-Martinez et al., 2011 and Bardaji and Iraizoz, 2015) and incorporating other determinants that are believed to have an impact on firm-level productivity in agriculture. In this respect, the wide variety of variables available in the FADN database can be effectively used to incorporate a number of relevant factors that are believed to explain the spatial effect in the wine industry8: specifically, the set of covariates include (i) endogenous factors linked to the productive process or to the corporate characteristics, (ii) exogenous physical factors and (iii) exogenous economical indicators related to the local supply factors.

The results of the estimation are reported in Table 4: in most cases, the coefficients are significant and the sign is that expected. As far as the endogenous factors are concerned, the first interesting result is determined by the key role played by quality and reputation: in fact, firms producing a better wine quality (OTE = 3510, wineries specialized in the production of quality wine) appear to benefit from a larger territorial effect. Moreover, being located in an area characterized by a higher reputation of the production process (i.e. DOCG production area) is also associable with an increase in territorial imbalances, irrespective of the quality of wine produced by the firm. The data also reveals the importance of the territorial effect for family-owned firms (Family owned) and those productive units characterized by an higher degree of product differentiation. Regarding the exogenous physical factors[9] it is worth noting that the coefficients of both Physical disadvantage (climate) and the Biophysical disadvantage are negative and statistically significant: this result is not surprising considering the beneficial effects associated with a temperate climate, an advantageous slope inclination and slope exposure on wine production. Finally, a set of exogenous economical factors[10] have been included in the model, in order to account for the role of elements external to firms and internal to the region that generate a competitive advantage among economic agents. The results are consistent with the expectations, showing that a higher level of the surrounding economic and network infrastructure has an indirect beneficial effects for the productive units specialized in wine production; on the other hand, the presence of a lower level of human capital in the region (higher Scholastic drop-out indicator) has a negative impact on the territorial imbalances. Despite the results of the estimation confirm the important role played by the above mentioned variables, it is worth noting that the presence of these tangible factors is not sufficient itself to explain the variance of the territorial imbalances (R2 =0:214). This evidence indirectly confirms the presence of intangible factors associated with context specific and informal practices of learning that cannot be evaluated through the mere inclusion of specific contextual variables in the model: in this respect, the implementation of a SSFA approach can effectively address this issue, allowing to isolate the intangible effects associated with tacit knowledge flows and incremental learning that are peculiar of the wine industry and cannot be merely proxied through the inclusion of specific contextual variables.

4.2.2 Do spatial effects vary with size? The different role played by the local network in small and large firms' efficiency

The analysis implemented in the previous section has highlighted that a combination of tangible and intangible factors explain the presence of a spatial effect in the Italian wine industry. In this scenario, the role of intangible effects appears to be particularly significant and possibly associable with the local business climate and informal interaction among local actors that has been discussed in Section 2: in this respect, the results support the empirical evidence emerged in previous contributions focused on case studies in specific wine regions, suggesting the presence of communitarian networks, characterized by resource sharing and informal interaction.

[8] Note that the physical/contextual data used in the estimation do not exhaust the multiplicity of issues that characterize the production within a territory.

[9] This data are available at an extremely detailed territorial level, i.e. the municipality (CREA, 2013).

[10] These composite indicators are present in the Istituto Tagliacarne (2013) database and defined at a narrow territorial level, i.e the municipality.

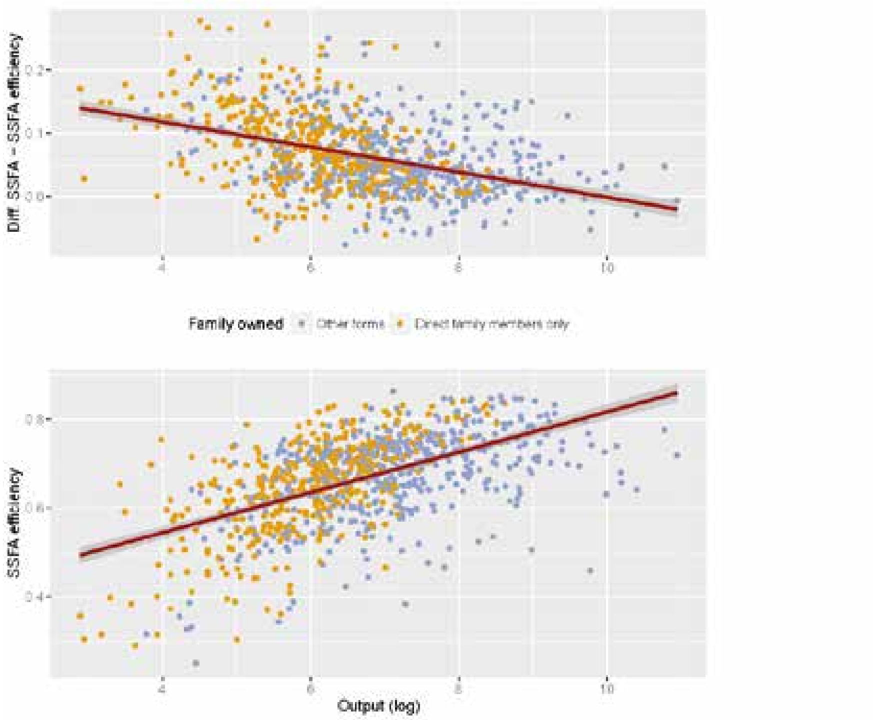
However, as several recent contributions have shown, access to these networks appears not to be uniform among local actors: not infrequently, small firms tend to be more inclined to engage in informal interaction practices with local peers, given the higher expected benefits, while large firms tend to acquire new knowledge from external sources, using the wide variety of formal channels at their disposal.

The possible presence of this differential has been evaluated by plotting the difference between the SFA and the SSFA efficiencies against the size of the firm. Figure 5 confirms that an inverse relationship exists between the two variables, with a higher territorial effect for small firms that tends to decrease when firm size become larger: however, the presence of a negligible spatial effect among large wine producers seems not to be associated with lower levels of technical efficiency: in fact, Figure 5 shows that these firms are more efficient than small producers.

This apparently contrasting trend can be easily interpreted in light of the patterns already identified in Section 2: the presence of a negligible spatial effect among large firms should not be motivated by their difficulty to access to local networks, but rather by a voluntary choice aimed at focusing on alternative sources of knowledge, such as internal learning, interaction with producers located outside the neighbourhoods and formal collaborations with institutional actors. The choice of these alternative forms of learning enables these firms to stay at the forefront of technical development, focusing on the most efficient technologies and maintaining high levels of technical efficiency. On the other hand, small producers who cannot access to external knowledge are required to rely on the informal learning practices associated with continuous interaction with the local community, generating the spatial effect identified for this subset of the firm population in the model. Although these intangible factors allow to reduce the gap with the leaders, small firms still display a lower level of efficiency relative to the larger ones.

The main finding introduced in this section confirms that spatial proximity does not necessarily generate knowledge spillovers. The main reasons explaining this pattern are probably two: on the one hand, large producers generally do not need to link to local networks to access informal sources of learning; on the other hand, leader firms may not be willing to share the knowledge acquired through access to external of formal sources, generating positive externalities for small firms located in the close neighbourhood. In this respect, the behaviour of large firms could be interpreted as a rational strategy aimed at retaining a competitive advantage in the production process, ensuring higher levels of technical efficiency.

Figure 5 - SSFA efficiency and difference with SFA per produced output (log) and ownership.



5. Final remarks

The empirical exercise, implemented on a sample of wine producers extracted from the Italian FADN survey, shows that the spatial specification proposed by Fusco and Vidoli (2013) is extremely effective in disentangling the spatial effect that is present in the data, isolating a specific component that is erroneously attributed to the error term in the standard SFA approach.

The main features of the spatial effect are evaluated through a second stage analysis, in which the territorial imbalances (i.e. the difference between the inefficiency term calculated with the SFA specification and that identified with the SSFA approach) are regressed against a set of contextual variables that are generally associated with the presence of a stronger effect: although the role of these factors is confirmed by the results of the estimation, a relevant share of the variance in the model remains unexplained, suggesting that a key role is played by intangible factors that cannot be formally included in the model. Following the recent findings in the literature, it is reasonable to assume that this intangible component is the consequence of a network effect associable with the local business climate: in most localities, the presence of an embedded community stimulates a process of local learning that generates the diffusion of tacit knowledge through continuous interaction among the local actors. Although the investigation does not allow to evaluate whether this flow relates more to business information of technical knowledge, the identification of such aspect is by itself a key finding of the contribution.

The analysis of the degree to which the spatial effect varies with firm size provides evidence of a clear tendency of this effect to be significantly lower among large firms. This finding is in line with previous research, confirming that firms interacting in economic networks are not an homogeneous entity, but play different roles in the local scenario: although it is not a direct consequence of the results of the paper, it can be speculated that the different size of the territorial effect found in small and large wine producers is associated with different abilities and willingness to interact and share knowledge with neighbours located in close vicinity: such a scenario would confirm the trend already identified in case studies on wine sector (Giuliani, 2007; Morrison and Rabellotti, 2009), showing that large firms have a strong tendency to access to external and formal sources of knowledge, sharing the information acquired from outside with a small number of firms with which they collaborate on a regular basis. The regular interaction with external sources of knowledge enable these firms to stay at the forefront of the technological frontier, enabling them to face the challenges required by the rapid technological change: such a trend would be consistent with the higher levels of technical efficiency found among large firms in the empirical analysis.

The results of this investigation open some interesting avenues for further research. The SSFA specification can be extended to accommodate the use of panel data: the implementation of such an approach would be particularly convenient to control for seasonal or other unobserved factors that can influence harvesting in a particular year, such as the presence of parasites or other transient factors.

FINDING THE NEEDLE IN THE HAYSTACK: ESTIMATING COMMODITIES THAT ARE DIFFICULT TO CAPTURE IN OFFICIAL AGRICULTURALSTATISTICS (ILLICIT COMMODITIES AND NOMADIC LIVESTOCK)

Session Organizer
C. Bussink | United Nations Office on Drugs and Crime | Statistics and Surveys Section, Trends Monitoring and Analysis Programme | Vienna | Austria

ABSTRACT

Statistics on illicit crops, illegal fishing, illegal hunting and wildlife trade, illegal logging and nomadic livestock have their specific challenges due to the illicit, transient and hidden nature. Thes e populations are often scarce, the units can be small in size (for example fields with illicit crops), present in low densities and/or in clusters, transitory nature and isolation with poor access to surveyors. These challenges require a different approach in terms of survey design and data collection methods from those used for official agricultural statistics. In this session, solutions are presented for overcoming these challenges. Possible topics for papers include: how to deal with data scarcity and uncertainties; zero-inflated data; survey design (e.g. line transect sampling, adaptive sampling); spatial risk maps; the use of remote sensing and overflights; ground-truth data collection and accuracy assessments.

ABSTRACT

Since 2002, the United Nations Office on Drugs and Crime (UNODC) has continuously supported annual surveys of coca cultivation in Bolivia. The mapping of coca fields is based on the visual interpretation of very high and high resolution satellite imagery. A full area mapping approach is applied, i.e. all fields where illicit crops are grown in a certain geographic region are visually interpreted and delineated on screen. The process bears the risk of several types of biases in the interpretation results and is time consuming. As an alternative a dot grid sampling approach was tested in order to diminish biases and to optimize the cost-accuracy-ratio of the visual interpretation in comparison to full area mapping. The paper summarizes the experiences and discusses the pros and cons of the approach for illicit crop monitoring under given conditions.

Keywords: remote sensing, illicit crop monitoring, dot grid sampling, coca cultivation, area estimates

PAPER

1. Introduction

The United Nations Office on Drugs and Crime (UNODC) supports monitoring systems of illicit crop production in the main drug-growing countries of the world. Jointly with the respective governments, UNODC produces annual illicit crop surveys for specific countries. The results are used for monitoring measures to reduce coca cultivation and global analysis of the drug situation, e.g. in the World Drug Report (UNODC, 2015).A key component to estimate plant-based drug production is the assessment of the area under cultivation. This is based on the visual interpretation of remotely sensed images. A full area mapping approach is followed. In such a case, all fields where illicit crops are grown are identified in the whole country or in pre-defined geographic regions. Polygons are visually interpreted and delineated on screen by qualified and trained staff who use classification keys to guarantee consistency between interpreters. Nevertheless, this process is time consuming and bears the risk of several types of bias in the interpretation results. Apart from thematic errors, systematic errors may occur when drawing the boundaries of the polygons, leading to inaccurate results.

Various internal tests have been carried out by UNODC and the University of Natural Resources and Life Sciences,Vienna (BOKU) to automatize the interpretation process using image processing techniques. These tests have shown that it is difficult to replace visual interpretation due to various reasons. On the one hand the characteristics of the plant (perennial, up to 4 harvests per year, with fields at different stages of development at any observation time, no unique spectral signature) make it difficult to detect plantations automatically.On the other hand the interpretation of fields strongly relies on the experience of the interpreter (knowledge of the geographic region, inclusion of context information) which makes it difficult to derive rules for an automated approach.

This study attempts to overcome the specific problem of one type of bias, with regard to the digitizing of the field boundaries (geometric errors), by using a sampling approach widely known as (squared) dot grid sampling.

Sampling methods are often applied successfully in the fields of forest inventory and agricultural statistics. The dot grid method originally was used in aerial photo interpretation as a simple and inexpensive tool for measuring land cover areas of irregularly shaped features (Lillesand et al., 2007). Forest areas are obtained in many national forest inventory schemes with aerial photo dot grid methods (Tomppo et al., 2010). An example for a method with points as sampling units in agricultural statistics is the EU-project LUCAS (Land Use/Cover Area frame statistical Survey; Bettio et al., 2002).

The assumption is that the dot grid estimate can bemore accurate than full area mapping due to the gain of time for the decision to classify the crop and due to the avoidance of delineation inaccuracies. No time has to be spent for delineating the boundaries. In case of illicit crop monitoring, dot grid sampling therefore could optimize the cost-accuracy-ratio of the visual interpretation in comparison to full area mapping.

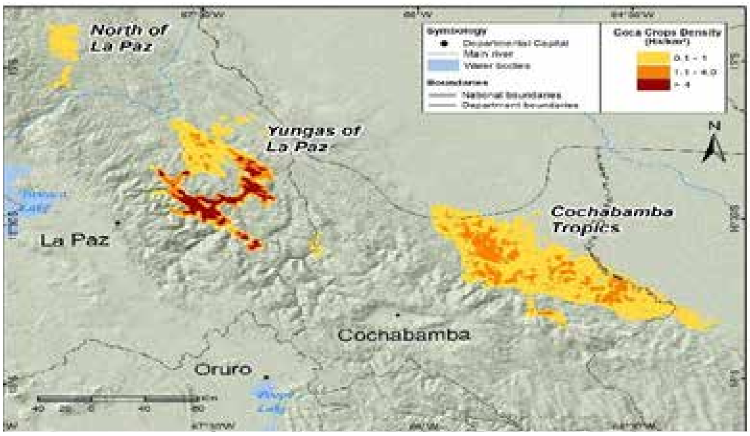
For testing the methodology two test sites were selected. One objective was to test the effect of different image types with different spatial resolutions on the interpretation process and accuracy. Secondly, the grid method was tested for different densities of coca fields, whichwill require different densities of dots to achieve the same accuracy and thuseffect the time to spend on conducting the interpretations.

It should be noted that interpretation errors (mistakes in the identification of coca crops) which may occur in the same way in the interpretation of full parcels and in the interpretation of (the surroundings of) single points (dots) are not considered in this report. The term "error" in this article refers to "sampling errors".

2. Coca growing in Bolivia

In Bolivia a monitoring system was established in 2001, resulting in first estimates in 2002. Coca is mainly grown in three geographic regions: Yungas ofLa Paz, Cochabamba Tropics and Norte of La Paz. In 2011 an area of 13.760 km² was covered with different types of very high spatial resolution satellite images (UNODC, 2012). The programme has used satellite images such asIkonos-GeoEye, Pleiades, Spot, RapidEye and WorldView and occasionally aerial photos. The satellite images are visually interpreted on screen supported by extensive field work. In 2012, 27.200 hectares of the area monitored were under coca bush cultivation. The density and sizes of the fields vary from region to region. Whereas in the Yungas ofLa Paz large fields or clusters of coca fields can be found (ranging from0.25 hectaresupto coca groupsof surfaces with 5 ha), fields in Cochabamba Tropics are relatively small (usually coca crops of 0.16 hectares) and are found dispersed in the landscape. Figure 1 shows a map of the main coca growing areas in Bolivia and the density given in hectares per km² calculated on the basis of a visual interpretation (UNODC,2012).

Figure 1 - Coca growing areas in Bolivia



3. Dot grid sampling

In the dotgrid method, the sample units to be interpreted are drawn in the form of a regular grid of points (dots). The population is assumed to be infinite, consisting of infinitesimal areal units (points) covering the area of interest. This infinite population is not really related to the pixels of the image: in visual interpretation of a digital image, the interpreter usually locates parcel boundaries with subpixel accuracy, taking into account a neighbourhood of pixels. Therefore, the interpreter does not assign pixels as a whole to a certain land cover class. Rather, a dot is assigned to a land cover class depending on its exact position within a pixel in a certain surrounding pixel pattern.Systematic sampling in a regular grid can be treated like simple random sampling if the units of the population can be assumed to be randomly distributed (Thompson, 1992). For actual land cover distribution patterns one cannot assume a truly random distribution of the units. The consequences of this will be mentioned below. The number of dots falling on the land cover class (crop type) to be monitored, divided by the total number of dots, gives an estimate of the proportion of the area covered by the specific land cover class. Applying this proportion to the surveyed area leads to the total crop area in the study area. We assume a square grid of dots superimposed to a total area of arbitrary shape.

$$p = \frac{A}{F}, \quad \hat{p} = \frac{\hat{n}_c}{n}, \quad \hat{A} = \hat{p} \cdot F$$

F…total area, A…crop area, p…fraction of crop area in total area (coca density), n…total number of dots (i.e. number of dots falling upon total area), n_c …number of dots falling upon coca fields. The hat symbol denotes a random variable.

The probability distribution of n_c is the binomial distribution. Its variance is calculated with:

$$\sigma_{\hat{n}_c}^2 = \mathrm{var}(\hat{n}_c) = n \cdot p \cdot (1-p), \quad \sigma_{\hat{p}}^2 = \mathrm{var}(\hat{p}) = \frac{p(1-p)}{n}, \quad \sigma_{\hat{A}} = \sigma_{\hat{p}} \cdot F$$

$\sigma_{\hat{n}_c}^2$ …variance of the number of dots falling upon coca

$\sigma_{\hat{A}}$… standard deviation of the crop area A due to sampling error

The required size of the sample (number of dots) to obtain a certain precision of area estimates with a certain confidence is the critical decision during the set up. The selection of an appropriate spacing between the dots depends on the coca density of the total area of investigation and on the error of the result that is acceptable.

In order to obtain a result (an estimate) for the coca area A with a standard deviation σ_A, i.e. a relative error (σ_A/A) of the coca area estimate, one has to use a grid with n dots in total:

$$n = \frac{p(1-p)}{\sigma_p^2} = \frac{p(1-p)}{\sigma_A^2 p^2} A^2 = \frac{1-p}{p}\left(\frac{A}{\sigma_A}\right)^2$$

The space between dots (dot grid spacing, s) thus has to be chosen according to

$$n \cdot s^2 = F = \frac{A}{p}, \quad s = \sqrt{\frac{A}{p \cdot n}} = \sigma_A \sqrt{\frac{1}{(1-p) \cdot A}} = \left(\frac{\sigma_A}{A}\right)\sqrt{\frac{p \cdot F}{(1-p)}}$$

The precision of the estimate will be higher for narrower dot grid spacing, with a larger sample.

Of course, at the start of a project, the fraction of crop area in total area, p, which is required to calculate a proper value of s, is not known. A likely, expected value for p has to be assumed here, e.g. the coca density determined in previous years.

This equation can also be used to calculate the relative sampling error (A/A) for a given dot grid spacing and a given fraction of crop area in total area, p (if this has finally been determined).It should be noted that there is a certain spatial correlation in land cover distribution patterns. Nearby units tend to have similar attributes. The assumption of random distribution of the units in the sample as mentioned above therefore is not quite justified. As a consequence, the dot grid method will tend to overestimate the variance of the area estimates. We are "on the safe side", underestimating the precision of the result rather than overestimating it. The area estimate itself is unbiased. There are various methods to obtain a better estimate of its variance in the case of spatial correlations (see e.g. Wolter, 1984).

If different coca cultivation densities prevail in different parts of the total area, a stratification approach might be followed.

4. Case studies

4.1 Test of different satellite imagery

The first test site is located in the Yungas ofla La Paz area which, is characterized by large fields, often clustered into larger areas.

A small area was selected where cloud free images of WorldView-2 (Acquisition date: 03-10-2011; spatial resolution: 0.5 meters) and RapidEye (Acquisition date: 31-05-2011; spatial resolution: 5 meters) were available; the images were orthorectified before doing the interpretations. As the area under crop is stable, the two different acquisition dates are comparable. The total area of interest comprises 1,259 ha of which 210 ha were used for coca plantations according to the results of the survey 2011 which was based on the visual interpretation of the WorldView-2 imagery. This serves as a reference data set. The two different types of images are shown in figure 2. Interpretations applying dot grid sampling were carried out by one interpreter familiar with the geographic region.

Two different settings for dot grid sampling were defined to demonstrate the effect of different dot spacings using different imagery. The parameters were selected to keep the amount of time necessary for the interpretation within an acceptable range. Two different distances between the dots were independently tested: 200 meters and 100 meters. The features of the grids and the results are shown in table 1.

Figure 2 - Dot grid sampling on WorldView-2 and RapidEye of the same coca growing area (yellow polygons: coca fields resulting from a visual interpretation of WV-2 data)

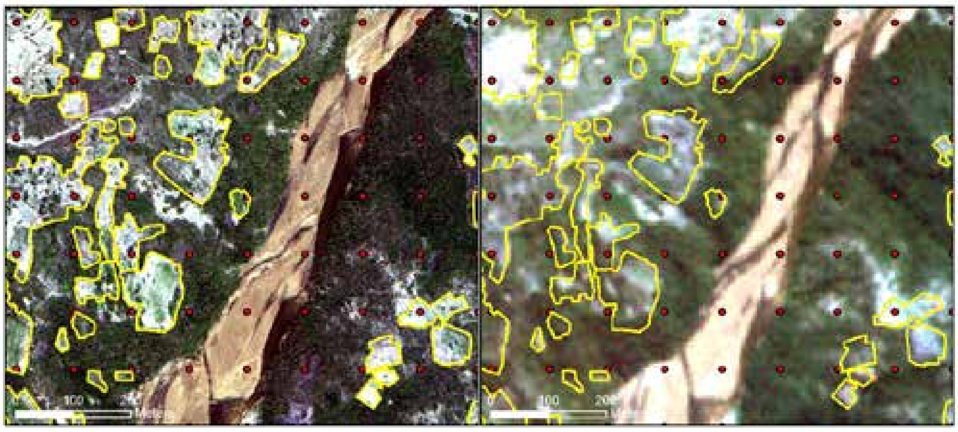


Table 1 - Interpretation results; case study 1, comparing images with different spatial resolution and two different grid spacings

Reference	Visual interpretation of WorldView-2 image (polygons)
Total area (ha)	547
Crop area from polygon interpret. (ha)	130.7
Number of polygons	187
Time needed for polygon interpretation	80 min

Results:

Sensor	WorldView-2		RapidEye	
Dot spacing (m)	100	200	100	200
Total number of dots	547	137	547	137
Number of dots falling upon coca fields	117	29	105	27
Estimated fraction of crop area in total area	0.2139	0.2117	0.1919	0.1971
Estimated crop area (ha)	117.00	115.79	105.00	107.80
Standard dev. of crop area	9.59	19.09	9.21	18.59
Relative sampling error (%)	8.20	16.49	8.77	17.24
Difference to polygon interpretation (%)	-10.48	-11.41	-19.66	-17.52
Time needed for dot interpretation	20min.	6 min.	15 min.	7 min.

4.2 Test in areas with different densities of coca fields

The objective of the second exercise was to test the dot grid approach in geographic regions with different coca field densities. The test areas are located in the Cochabamba Tropics which is characterized by small fields. An IKONOS image with a spatial resolution of 1 meterwas used. Each area comprises 10,000 ha. A 250 meter dot spacing was chosen as an example for dot grid interpretation with extreme time saving under the assumption that a relative sampling error of approximately 20% still might be acceptable for a first estimate.

Table 2 - Interpretation results; case study 2, with an Ikonos image and three areas with different coca density levels

Sensor	Low density	Medium density	High density
Total area (ha)	10000	10000	10000
Crop area from polygon interpret. (ha)	85.18	149.82	240.55
Number of polygons	718	1103	1766
Time needed for polygon interpretation	264 min	198 min	168 min
Dot spacing (m)	250	250	250
Total number of dots	1600	1600	1600
Results:			
Number of dots falling upon crop	15	23	29
Estimated fraction of crop area in total area	0.009	0.014	0.018
Estimated crop area (ha)	93.75	143.75	181.25
Standard dev. of crop area	24.09	29.76	33.35
Relative sampling error (%)	25.70	20.70	18.40
Difference to polygon interpretation (%)	+ 10.06	- 4,05	- 24.65
Time needed for dot interpretation	44.5 min	55.5 min	41.5 min

5. Discussion

The results show that the dot grid method severely reduces the time required for interpretation. In the examples given here, between approximately 10% (Table 1, 200meter spacing) and around 25% (Table 2) of the time required for full area (polygon) interpretation are sufficient for dot interpretation. The time saving obviously is higher for coarser dot grids (where fewer dots have to be interpreted) and for higher coca field densities (where more polygons have to be delineated). The time needed for the interpretation of 1 dot is approximately 2 seconds in all cases. The time needed to interpret and delineate 1 polygon is between 10 seconds (for smaller polygons) and 20 seconds (for larger polygons). The time saving is obtained at the expense of a certain sampling error. Basically, three types of errors have to be distinguished: interpretation errors, delineation errors, and sampling errors. We can assume that interpretation errors are of a similar magnitude in full area interpretation and in dot grid interpretation, if performed by the same interpreters. However, no information on this is at hand here, as exact data on the true coca areas are not available. In all cases with exception of the 100meter dot grid interpretation of RapidEye, the differences between polygon interpretation and dot grid interpretation can be assumed to be sampling errors:as can be seen from the tables, these differences between polygon interpretation and dot grid interpretation are usually smaller than 2 times the standard deviation of the crop area due to the sampling error.Taking the normal distribution as approximation to the binomial distribution, 95% of the results of dot grid interpretation should lie within this interval around the true value (here assumed to be the polygon result). The larger difference for the 100meter dot grid interpretation of RapidEye obviously is due to the systematic interpretation differences between WorldView-2 and on RapidEye. Most likely, the WorldView-2 results are more reliable, which is also supported by the assertions of the interpreters that it is more difficult to interpret coca on images of lower spatial resolution.

Fig. 3 - Comparison spacing/time for dot grid interpretation and time needed for interpretation and delineation of polygons in "Tropico de Cochabamba"

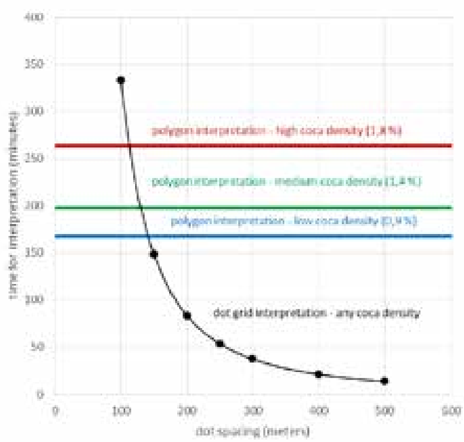

Fig. 4 - Comparison betweenrelative errors of different dot grid spacings for different coca density areas.

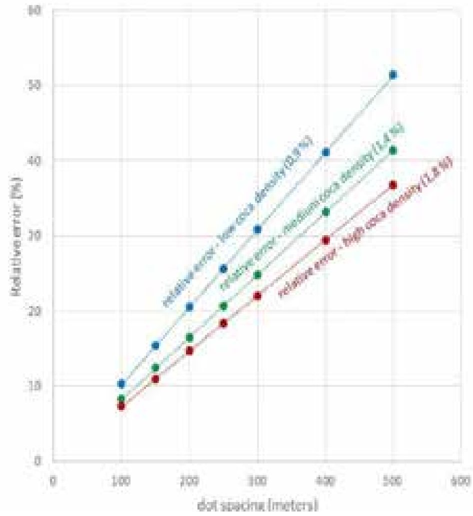

Figure 3 compares the time necessary to interpret dots compared to the time needed to interpret polygons for different coca field densities in the second test area. It can be seen that the dot grid interpretation becomes faster than polygon interpretation when the spacing between dots is larger than about 125 to 160 meters, depending on the coca field density. Of course, at the same time the relative sampling erroralso increases. It changes for low coca field densities from 10% (100 meter spacing) to 50% (500 meter spacing), for medium coca field densities from 8% (100 meter spacing) to 40% (500 meter spacing) and for high coca densities from 7% (100 meter spacing) to 37% (500 meter spacing). It follows from experiences in many fields of land cover mapping that it is hardly possible to reach thematic accuracies above the range of 80% to 90% (see e.g. Büttner and Maucha, 2006). Therefore, additional sampling errors up to 10% usually should be tolerable. Nevertheless, the additional sampling errors (figure 4) should be evaluated against the expected improvements for the interpretation accuracy, which can be considerably high but have not been quantified in this study.

6. Conclusion

Illicit crop area is usually determined by digitizing polygons on remotely sensed images, and by calculating the areas of the polygons. A map showing the crop areas is produced by this method. The method is time consuming and potentially inaccurate, as there may be systematic errors in delimiting the fields (drawing the boundaries of the polygons). If a detailed parcelmap is not needed, or if a sort of "soft map" (map of the density of coca plantations, without showing the exact locationsand boundaries of individual fields) is sufficient, a sampling approach (dot grid method) may give results of a higher accuracy than polygon delineation. Even if polygons are still required, dot-grid sampling can be an efficient method to test and train interpreters or to carry outa quick quality control.

The case studies have shown the pros and cons of the dot grid approach.The dot grid method is particularly favourable when interpreting areas with a high density of fields: in this case, a larger spacing ofthe dots can be chosen, and the substantial effort and time necessary for the polygon delineationisavoided. The tests in theYungas of La Paz area show that thedot grid interpretation can be more than 10 times faster than the full area interpretation with delineation of single fields. Interestingly there are hardly any time differences using the dot grid method for coca areas with different densities.

With the given crop densities for this case study, the maximum additional relative error of 10%, the following distances would be beneficial from a time-gaining point of view: 115 to 270 m for high density, 125 to 240 m for medium density, 140 to 190 m for low density.

An option to further speed up the dot grid interpretation is a pre-selection of points. Based on an automated land cover classification, a mask can be generated which includes for example dense forested areas, water bodies, built-up areas, rocks, etc.. Points falling upon such land cover units donot have to be interpreted.

Further research is necessary (a) on the variance that exist in polygon delineation, which has to be compared with the sampling error inthe dot grid method, and (b) on the potentials to quantify systematic biases by different interpreters and on methods to correct for that.

Using law enforcement data to estimate illicit activity in an internationally traded illegal commodity

F. M Underwood | Independent Statistical Consultant/Researcher | Taunton | UK
DOI: 10.1481/icasVII.2016.b09b

ABSTRACT

Estimating illicit activity of an internationally traded illegal commodity is challenging because of the hidden nature of the trade. This makes it difficult to observe and to collect data. One source of data is that collected by law enforcement agencies, from seizures of illicit goods. But this data does not represent a random sample of illicit activities. Instead it represents those activities that have come to the attention of law enforcement agencies either due to intelligence or via routine activities. To be able to use law enforcement data to understand patterns in illicit activity, for example estimate trends through time or compare activity in different countries, it is therefore necessary to account for the mechanisms by which the data is obtained and reported.

In this paper I describe a strategy for dealing with the biases in seizures data using the example of the illegal ivory trade. Countries are mandated to report seizures of illicit ivory to the Elephant Trade Information System (ETIS) which holds over 20,000 records of illegal ivory seizures from 1989 onwards. Countries differ in their ability to make and report seizures and in the quality of the information they provide to ETIS. A suite of proxy variables was identified that could potentially explain differences in reporting and seizure rates between countries and over time. By fitting Bayesian hierarchical latent variable models to the data, the proxy variables that best explained the variability in the data were selected. The model was used to produce relative indicators of the number of transactions and the total weight of ivory over time for individual countries for different sizes and types (raw or worked ivory) of ivory shipments.

In addition to outlining the methodology I also discuss the more general implications of this strategy on data collection and analysis to learn about international trade in an illicit commodity.

Keywords: Illegal ivory seizures data, Bayesian hierarchical latent variable models, bias adjustment

PAPER

1. Introduction

Records of seizures of illicit products are sometimes used to learn about trade in illicit activities. For example, the UNODC's World Drugs Report (UNODC, 2015) reports on numbers and sizes of seizures and changes in numbers of seizures of different drugs by region and transportation methods. Similarly, the World Customs Organisation reports on seizures of many different items including drugs, endangered species, counterfeit goods, highly taxed goods such as tobacco, and weapons (WCO, 2015). A major difficulty with seizures data is understanding what these figures say about the relative importance of different countries in the trade and trends in the trade over time.

This paper describes ivory seizures data collected by the Elephant Trade Information System (ETIS), the biases in these data and strategies for accounting for these biases. An overviewof a methodology described in detail in Underwood et al (2013) to estimate trends in the illicit trade using seizures data is given. This paper then reflects on key features of the methodology and data that need consideration when applying to other commodities.

Ivory seizures data

Demand for ivory is mainly for high status decorative and artistic purposes. Elephants are the main source of ivory and are killed to remove the tusks. Raw ivory, tusks or pieces of tusks, are taken to processing plants where the ivory is carved into finished objects, now defined as worked ivory, and then reshipped and sold wholesale or retail to consumers. A single piece of worked ivory may have been involved in multiple transactions and passed through several countries in shipments of varying sizes. Typically, ivory is sourced from Africa and "consumed" in Asia.

In 1997, the Convention for International Trade in Endangered Species of Wild Fauna and Flora (CITES) set up the Elephant Trade Information System (ETIS) database to monitor status and trends in the illegal ivory trade. The data were to be used to report to CITES meetings to inform decision making on elephants and trade in elephant products. These decisions may require specific countries to strengthen control of their ivory trade and commit to legislative and enforcement actions. As such analyses are needed to identify trends in the trade and key players in the trade and how these change over time.

ETIS includes data on seizures that have been made all along the trade chain. Seizures might be made (1) at various locations such as national parks with elephant populations, warehouses, or ports with ivory waiting to be consolidated into shipments, ivory processing plants or ivory markets or (2) when the ivory is in transit between countries either by air, sea or road in containers, luggage or the mail. Law enforcement organisations that make seizures include national park rangers, customs officers, and local police.

A country's CITES Management Authority (CMA), rather than the organisations that make the seizures, have the responsibility of reporting seizures to the CITES Secretariat or ETIS directly. CMAs are mandated to report ivory seizures within 90 days but in practice this does not happen. Some CMAs send information regularly, for example quarterly or annually, others send records when prompted by CITES notifications which are sent to all CITES Parties and others only in response to direct questions from ETIS, for example about specific seizures that have been noted in the press. Some countries do not report any seizures to ETIS even though it is suspected that seizures might be made in that country. ETIS also receives reports from World Customs Organisation and NGOs. In the past ETIS staff, in collaboration with government officials have carried out focused data collection exercises to ensure that a country's backlog of ivory seizure records is entered into ETIS.

There is a standard pro-forma for seizure records but not all of this information is provided for each seizure. Data for all records used in the main analyses include the country that made the seizure, the year in which the seizure was made, whether the seizure was of raw or worked ivory and an estimate of the quantity – either weight or number of pieces. The information on quantity is of mixed quality. Only about half the seizures record the weight and these can range from a few grammes to several tonnes (the maximum recorded being 6.4 tonnes). In many cases the weights, in particular of large seizures, are only approximately recorded – for example four tonnes. For seizures that only reported the number of pieces of ivory the ivory class was predicted based on statistical models fitted to seizures data where both the number of pieces and weight of the seizure were recorded. Conversion of raw ivory into worked pieces leads to some wastage of ivory. To account for this the weight of worked pieces of ivory is converted to an equivalent raw weight, the Raw Ivory Equivalent (RIE). Additional information that is requested includes other countries in the trade chain, that is the other countries through which the shipment has passed, originates from or is on route to, the methods of concealment and detection and the nationality of suspects. Most of this additional information is reported in less than a quarter of the reported seizures.

The ETIS database currently holds over 20,000 records from over 90 CITES Parties (countries or territories that have signed up to CITES). Approximately half of the CITES Parties have not reported any seizures themselves. The aim of the trends analyses is to describe the main trends and countries involved in the trade. As such it is necessary to consider both countries that have made seizures themselves and countries that have been implicated in seizures. To make the analysis tractable countries that play a minor role should not be included. Thus a threshold for inclusion in analysis is defined based on the total number of seizures and estimated weights of seizures that a country has made or has been implicated in over the time period of the analysis. For example, for early analyses this threshold was at least 30 seizures or seizures with a combined weight of 300 kg.

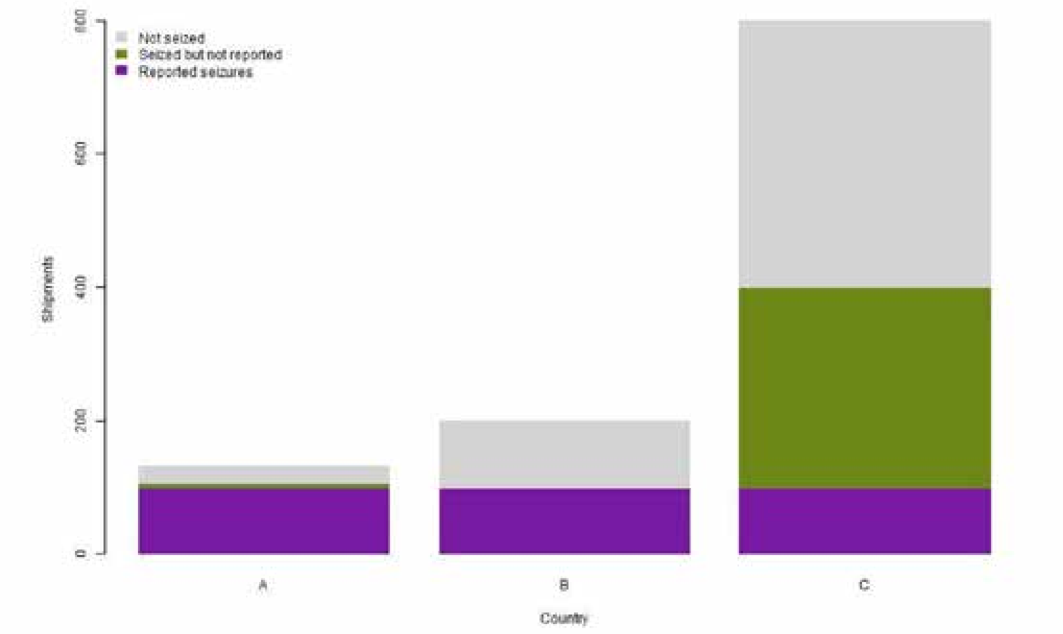
Over the period 1996 – 2011,68 countries met the threshold described above with a total of nearly 12,000 seizures. The USA and China both reported around 2,000 seizures, although the USA's were relatively evenly spread over the whole time period, but over 1,500 of China's reported seizures were from 2009 and onwards. Over the same time period Germany, France, Kenya and Switzerland each reported around 500 seizures in total and at least twenty countries reported between one and ten seizures. Other countries such as Angola, Laos and Togo did not report any seizures but met the threshold for inclusion because of the seizures they had been implicated in.

Biases in seizures data

The difficulty with seizures data is that simplesummaries of the total number, or weight, of seizures do not provide an accurate description of the trends and patterns in the illicit trade. Seizures do not represent a random sample of illicit transaction. Instead they represent the dysfunctional part of the trade and are themselves an intervention in the trafficking process. The mechanisms by which data are obtained, in particular the differences in how seizures are made and reported both between countries and over time, needs to be accounted for.

In particular, we cannot assume that changes in the number of seizures over time or differences in the number of seizures reported by two countries represent actual differences in the trade. For example, consider three countries which all report 100 seizures in one year as shown in Figure 1. For now, let's ignore the size of these shipments.

Figure 1 - Total number of shipments disaggregated by number of reported seizures, unreported seizures and unseized shipments under different scenarios. Although the number of reported seizures is the same in each case the total number of shipments, varies greatly between the three countries.

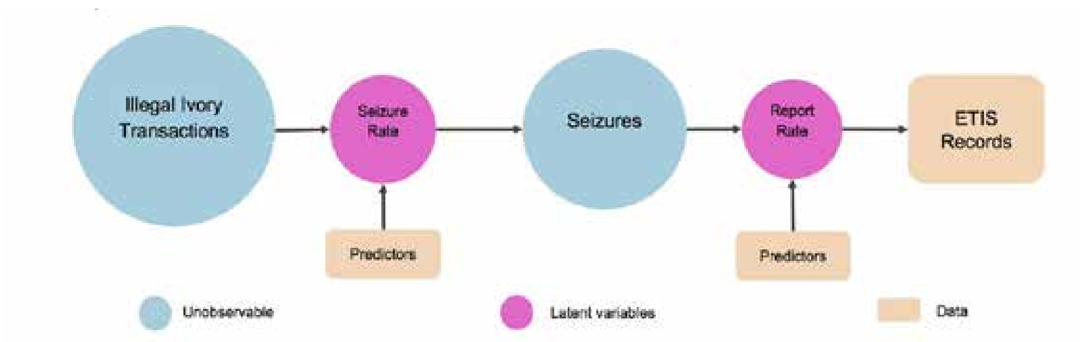


If all countries were equally good at making seizures (we call the proportion that are seized the seizure rate), and reporting these seizures (we call the proportion of seizures that are reported the reporting rate), then we could assume that the illegal trade in each of the three countries is the same. But Country A seized 80% of the shipments that passes through their country and reported 95% of these to ETIS. Countries B and C only seized half of the ivory shipments that passed through their countries. Of these Country B reported all of these seizures and Country C reported one quarter of the seizures. Although A, B and C all report the same number of seizures they represent 76%, 50% and 12.5% of the transactions within each country. The total number of shipments, or transactions, are then 132, 200 and 800 respectively for the three countries. That is, the observed number of seizures is a product of the number of transactions, seizure and reporting rate for each country.

Accounting for biases in seizure and reporting rates

In practice, it is not possible to know the actual seizures and reporting rates for any country, or how the rates vary over time.An alternative approach is to obtain estimates of relative seizure and reporting rates, by identifying the reasons why these rates might vary over time or differ between countries and finding predictor variables that describe aspects of the reasons. Using these relative rates and knowledge of the number of reported seizures it is then possible to estimate the relative number of transactions, as shown in Figure 2.In the Figure 1 example relative rates would indicate that Country C has four times as much trade as Country B and Country B has 50% more activity than Country A. The estimates of the relative number of transactions can be used to describe trends in the trade over time and the relative importance or roles of different countries in the trade.

Figure 2 - Conceptual model of seizures data. From Underwood et al. (2013)



It can be challenging to find data on variables that potentially describe the reasons why countries differ in their ability to make and report seizures.In particular,to find variables on comparable scales across multiple countries. For example, countries may differ in their ability to make seizures because of the effort expended on law enforcement, such as the resources to make seizures, and the effectiveness of this effort. Direct measures of law enforcement, for example the number of staff and the availability of equipment, are not readily available for all countries that report or are implicated in ivory seizures.

Instead, proxy variables are sought. These proxies are not perfect descriptors of a country's ability to make or report a seizure but potentially capture some aspect of their abilities. For example, the effectiveness of a country's ability to make seizures may depend on the socio-economic environment within which law enforcement agencies operate. In countries with poor governance and little relevant legislation one might expect fewer seizures to be made. World Governance Indicators, UNDP's Human Development Index, and the IMF's per capita GDP were used as background measures of effectiveness and a score from the CITES National Legislation Project used as a measure of the strength of wildlife trade legislation.

For law enforcement effort, data on the number of staff and the availability of equipment is not available for all countries. Instead an internally generated variable – lagged law enforcement ratio – was used as a proxy. This variable is the number of seizures that a country has made divided by the number of seizures that have passed through that country – i.e.both those the country has made and those made by other countries but passed through the country of interest before seizure. A low score, close to zero suggests that a country has low law enforcement effort whereas a high score, close to one suggests much more effort.

Differences in the reporting rate may depend on both the ability of a country to submit records to ETIS and actions made by ETIS to acquire information. The mechanism by which each seizure entered the database was captured to create the data collection score. This was summarised to represent the proportion of records in any year that were either actively sought by ETIS or obtained via automated and regular reporting systems. A high score might suggest that most seizures are reported.A low score, obtained when most records are obtained in ad-hoc methods, possibly from sources other than the CMA such as the media or other organisations,might suggest thatmany seizures are not being reported by that country. A second measure, the CITES reporting score, was derived as the proportion of years that a country fulfilled their reporting obligations to CITES (including ETIS) divided by the number of years that the country had been a CITES Party. A high score, close to one, might indicate that a country takes their reporting requirements to CITES seriously and so could suggest that the seizures reported to ETIS represent most of the seizures that have been made by that country. The socio-economic variables used as proxies for the seizure rate were also considered as possible proxies for reporting rate.

Statistical modelling

The number of transactions that a country is involved in is modelled using the general framework described above with a Bayesian hierarchical latent variable model. We do not expect trading patterns to be the same for raw and worked ivory or for shipments of very different sizes. For example, we might expect different countries to be involved in shipments of raw and worked ivory and trends over time to differ between small and large shipments. Because of the uncertainty with the weights data we categorize the seizures into six ivory classes representing three weight categories, small (less than 10kg), medium (10kg to less than 100kg) and large (at least 100kg) and the two ivory types.

We want to be able to compare the relative number of transactions between the different ivory classes so we jointly model all six ivory classes together. Let y_{ijt} represent the number of seizures made by country i of ivory class j in year t. Then the number of seizures is modelled as a negative binomial distribution with mean μ_{ijt}.

$$y_{ijt} \sim NegBinom(\mu_{ijt})$$

The mean of this distribution is the product of three latent variables. The key variable of interest, λ_{ijt}, the number of ivory class j transactions for country i in year t, the relative seizure rate, θ_{it}, and reporting rate, ϕ_{it}.

$$\mu_{ijt} = \lambda_{ijt}\,\theta_{it}\,\phi_{it}$$

The seizure and reporting rates are common across ivory classes for each country because of identifiability issues and because not all countries report seizures in each ivory class. The seizure and reporting rates are functions of relevant covariates. Because of identifiability issues the relative seizure and reporting rates have no intercepts and by standardising variables the average country has a reporting and seizure rate of 0.5.

$$logit(\theta_{it}) = \sum_{l} b_l x_{lit}\; logit(\phi_{it}) = \sum_{m} c_m z_{mit}$$

The number of transactions for each country in each ivory class is modelled as a smooth function over time. The intercept and linear trend were allowed to vary between countries but remained correlated across ivory classes within each country. Higher order terms are shared across all countries in each ivory class to reduce the number of model parameters and because of the lack of data in many cases.

$$log(\lambda_{ijt}) = a_{0ij} + a_{1ij} f_1(t) + \sum_{k} a_{kj}\, f_k(t)$$

$$\underline{a}_{0i} \sim MVN(\underline{\alpha}_{0i}, \Sigma_0)\underline{a}_{1i} \sim MVN(\underline{\alpha}_{1i}, \Sigma_1)$$

Model selection was carried out using the Deviance Information Criterion and inspection of credible intervals. The order of fitting was to first identify which covariates best described the seizure and reporting rate, when $log(\lambda_{ijt}) = a_{0ij}$. Given these variables the number of polynomial terms for the trend was identified.

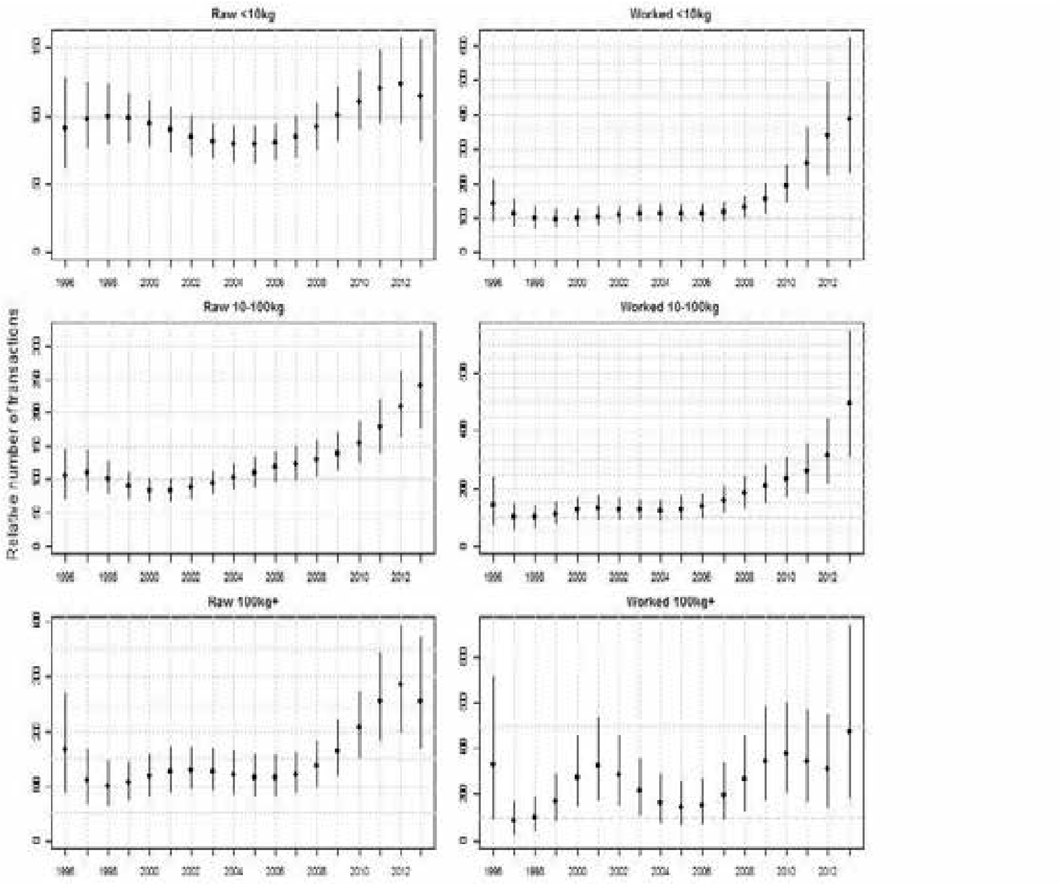
In addition to modelling the number of transactions a relative weights index is calculated. First the rounded values of the λ_{ijt} s are interpreted as the number of illegal ivory transactions in each ivory class for each country and year. By fitting statistical distributions to the weights of shipments for raw and worked ivory separately we simulated weights of each of the λ_{ijt} s.

Further details of the modelling, and the creation of proxy variables, are provided in Underwood et al (2013) and Burn and Underwood (2013) and results in Milliken et al (2o13).

Modelling outputs

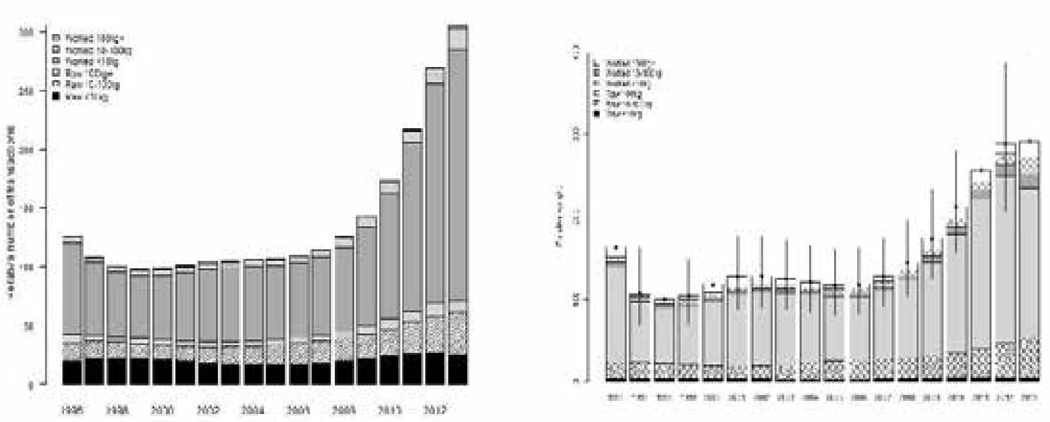
The λ_{ijt} sare the relative number of illegal ivory transactions for each country in each year in each ivory class. These indices represent the number of seizures that we might expect from each country in each year if they were all equally good at making and reporting seizures.

Figure 3 - Transactions Index for each ivory class. From SC66 (2015). Some but not all ivory classes show an increase in trade over time.



For reporting purposes, the relative number of transactions is summarised across countries to show (1) trends in the number of transactions in each ivory class (Figure 3) (2) the relative contribution of each ivory class to the total number of transactions (Figure 4a) and (3) a global Transactions Index. There are different trends in these six ivory classes and the global Transactions Index is dominated by the small worked ivory class whereas most of the weight of ivory in circulation is dominated by the large raw ivory class (Figure 4b).

Figure 4 - Relative contribution of each ivory class to (a) Transactions Index (b) Weights Index. From SC66 (2015). Note how the small worked ivory class contributes most to the Transactions Index and the large raw ivory class most to the Weights Index.



We also obtain estimates of the relative seizure and reporting rates for each country over time. The important variables for seizure rate were the lagged LE ratio and, except in the most recent analysis, rule of law. For reporting rate,the main variable was the data collection score and the CITES reporting score. Examination of the relative rates show considerable variation between countries and over time. The relative importance of different countries and different years using the Transactions index can be considerably different to an interpretation based only on the unadjusted seizures data. This can encourage countries to report their seizures because reportingmore seizures does not necessarily make them more likely to be implicated as major players in the illicit trafficking of ivory.

Requirements for modelling trends in seizures data

The strategy has been developed to describerelative trends in the illegal ivory trade. Here I reflect on some of the data characteristics needed to transfer the approach to other commodities.

The analysis needs a large number of seizures to be able to model trends over time, especially if trade dynamics are thought to vary across different commodities or shipment size. Modelling the trend in each category as a combination of a random intercept and slope for each country and polynomials shared across countries for higher order terms overcomes the problems of very small numbers that are reported by some countries in anycategory. Not all countries can report only small numbers of seizures for this approach to work

The key challenge is dealing with the biases in the seizures data. In the ETIS analyses it is the data collection score which describes how seizures enter the database, that contributes most to bias adjustment. For ETIS, it was possible to identify the different mechanisms by which records enter the database partly because countries are mandated to report ivory seizures to ETIS. If there is no mandate for reporting it can be difficult to identify proxies to represent the reporting process. For example, there are a number of databases where individuals or organisations have tried to capture information about seizures of particular species without any mandate, procedure or requirement for countries to report their seizures. In these cases, seizures data have been obtained by scouring the internet for official and unofficial reports of seizures and by building up networks of people within law enforcement agencies to supply information. The challenge then is to identify proxy variables for the reporting rate that capture the different ways in which searches and networks are used.

To make global statements about the illicit ivory trade, national level seizures data is required. Conversely, it is not possible to make statements about trade at the level of individual countries without the global analysis. This is because the law enforcement ratio, one of the variables that adjusts for biases in seizure rate, uses information about seizures that implicate a country. This would not work without a significant number of seizures recordinginformation about the trade route.

The lack of good quality weights information for all seizures meant that categorizing seizures into only three broad weight categories was an obvious choice. If the weights data had been more accurate and complete, a strategy that directly modelled weights and numbers of seizures together might have been considered. This is a more challenging exercise than has been described here.

Conclusion

Biases in seizures data mean that changes in the number of seizures are not necessarily a good indication of changes in the illegal trade. By identifying the reasons why countries differ in their ability to make and report seizures and seeking out, or creating, predictor variables it is possible to extract useful information out of the data, to be able to make comparisons over time and between countries.

Opium yield estimates in Afghanistan using remote sensing

D. M. Simms | Cranfield University | Cranfield, Bedfordshire | UK

DOI: 10.1481/icasVII.2016.b09c

ABSTRACT

Accurate estimates of opium production are essential for informing counter-narcotics policy in Afghanistan. The cultivated area of opium poppy is estimated remotely by interpretation or digital classification of very high resolution (VHR) satellite imagery at sample locations. Obtaining an accurate estimate of average yield is more challenging as poor security prevents access to a sufficient number of field locations to collect a representative sample. Previous work carried out in the UK developed a regression estimator methodology using the empirical relationship between the remotely sensed normalised difference vegetation index (NDVI) and the yield indicator mature capsule volume. The application of the remote sensing approach was investigated in the context of the existing annual opium survey conducted by the United Nations Office on Drugs and Crime and Afghanistan's Ministry of Counter Narcotics (UNODC/MCN) and indicated the potential for bias correction of yield estimates from a small targeted field sample. In this study we test the approach in Afghanistan using yield data and VHR satellite imagery collected by the UNODC/MCN surveys in 2013 and 2014.

Field averaged measurements of capsule volume were compared to field averaged NDVI extracted using visual interpretation of poppy fields. The study compares the empirical relationships from the UK field trials with the Afghanistan data and discusses the challenges of developing an operational methodology for accurate opium yield estimation from the limited sample possible in Afghanistan.

Keywords: Opium poppy, remote sensing, yield bias correction

PAPER

1. Introduction

The United Nations Office on Drugs and Crime and Afghanistan's Ministry of Counter Narcotics (UNODC/MCN) produce annual opium production estimates based on survey data collected across Afghanistan. The opium yield estimate is based on the empirical relationship of dry opium gum to mature capsule volume per unit area, measured at sample locations. The indirect yield measurement of mature capsule volume is used as it is quicker than removing and drying capsules for weighing.

Sample sites are chosen randomly from a sample frame of the villages located in the poppy producing provinces. At each selected village three fields are subjectively chosen by a field surveyor representing a poor, average and good quality poppy crop. In each field, measurements of capsule volume (capsule height and diameter) and the number of yielding capsules are made within three 1 m^2 quadrats arranged randomly along a transect. The average dry opium gum yield (Y) in kg ha^{-1} is calculated for each quadrat using the model (UNDCP, 2001)

where Vc is the mature capsule volume ($cm^3\ m^{-2}$). The average yield per unit area weighted by province area is then calculated and multiplied by the cultivated area of poppy to estimate the total production.

$$Y = \frac{(V_c + 1495) - ((V_c + 1495)^2 - 395.259 \cdot V_c)^{0.5}}{1.795} \quad (1)$$

There are difficulties with implementing the yield survey because security limits access to poppy fields within the major opium producing areas. Surveyors are unable to access many of the field locations from the sample frame which results in a low number of surveyed fields and a non-random distribution of samples (UNODC, 2012). The statistically un-representative sampling will bias the average dry opium yield and hence the yearly estimate of opium production.

A methodology for bias correction of opium yield estimates was proposed by Waine et al.(2014) using the existing very high resolution (VHR) imagery and the non-random field observations from the opium yield survey. The approach makes use of VHR imagery collected at random sample locations for visual interpretation of poppy crops as part of the cultivation component of the UN-ODC's annual opium survey. For each image, a bias-corrected estimate is made by substituting the field average Normalised Difference Vegetation Index (NDVI) of all poppy fields (population) into the linear regression of NDVI and mature capsule volume determined using a small number of high-quality field observations. As each image is randomly selected an unbiased estimate of opium yield can then be made.

Remote sensing of yield exploits the relationship between linear combinations of red and near-infrared reflectance, known as vegetation indices (VI), and crop biophysical parameters. VIs such as the NDVI are correlated to leaf area index and above-ground biomass which are in turn correlated to final yield in crops such as wheat, millet, soybean, cotton, barley, and maize (Domenikiotis et al., 2004; Liu and Kogan, 2002; Prasad et al., 2006; Rasmussen, 1997; Tucker et al., 1980; Weissteiner and Kühbauch, 2005).

Wood et al. (2003) demonstrated how image derived NDVI could be used for mapping within-field variability in crops of wheat (Triticum aestivum) and barley (Hordeum vulgare L.) using a small number of ground samples to construct a regression based model. They found as few as eight sample observations could be used to correlate yield indicators to NDVI for groups of fields, with a single observation per field. Based on this approach, the relationship between opium yield indicators and NDVI was inves-tigated by Taylor et al. (2010) as part of wider research into improving opium production estimates using remote sensing. Field trials conducted in the UK showed a high correlation between NDVI and measurements of mature capsule volume (R^2 = 0.70) across multiple fields and three growing seasons (Waine et al., 2014).

Investigations using 2011 yield and VHR image data from the UNODC's annual survey in-dicated the potential for operational use but there were too few ground observations per image to validate the methodology. The following conditions were recommended by Waine et al. (2014) for field measurements in support of the bias-correction approach: (1) accurately geo-referenced ground data; (2) samples should be distributed across the range of crop variation with respect to NDVI; (3) ground measurements of poppy crop parameters must be accurately co-registered with ortho-rectified imagery; and (4) imagery used to derive NDVI should be targeted for collection around the flowering growth stage to maximise the correlation between yield indicators and NDVI. This conference paper presents investigations into a bias-correction methodology using ground observations and image data from the UNODC's 2013 and 2014 annual opium surveys.

2. Data and methodology

2.1. Yield datasets

Field observations from the annual opium survey in 2013 and 2014 were supplied by the UN-ODC for sample sites with coincident VHR satellite images collected for poppy interpretation. This data included quadrat level measurements of the number of capsules/flowers and mature capsule vol-ume together with ground photography and GPS data. The UNODC also supplied interpretations of poppy fields as digital boundary files for each image. Quadrat level data was used to calculate the mean volume of mature capsules per unit area (cm^3 m^{-2}) for each sampled field. Confidence inter-vals (95%) for the mature capsule volume (field average) for each image were calculated using the formula:

$$\mathrm{CI} = \bar{y} \pm \left(\frac{s}{\sqrt{n}} \cdot 1.96\right) \quad (2)$$

where $\bar{y}$ is the mean mature capsule volume for the image,

$$s = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(y_i - \bar{y})^2}, \quad (3)$$

y_i is a sample observation (field average) and n is the number of sample observations.

2.2. Image data

Multispectral QuickBird (QB) and WordView2 (WV2) satellite image scenes were supplied by the UNDOC. The image data had a spatial resolution of 3.6 m (QB) and 2 m (WV2), spectral resolutions of 630–690 nm (QB and WV2) in the red and 760–900 nm (QB) and 772–890 nm (WV2) in the near-infrared. The timing of each VHR image in relation to crop growth-stage was assessed using high-frequency satellite imagery from the Moderate Resolution Imaging Spectroradiometer (MODIS) (Simms et al., 2014). Timing of growth-stage was found to be similar within individual scenes. Table 1 shows a summary of the yield datasets for 2013 and 2014. Hilmand 2013 (held8) was not considered for further analysis as the satellite imagery was collected too late in the growing cycle. The Uruzgan images in 2014 (uruz-erad1 & uruz4) were collected on the same orbital pass and treated as a single image scene. Each image was corrected to top-of-atmosphere reflectance to minimise spectral differences between the WorldView 2 and QuickBird sensors (Pacifici et al., 2014). The images were then or-thorectified to reduce geometric distortion and

NDVI calculated as (ρNIR −ρR)/(ρNIR +ρR), where ρNIR is near-infrared and ρR is the ref reflectance.

2.3. Mature capsule volume and NDVI

Within each selected image the location of the sampled fields was identified using a combination of GPS coordinates, geo-tagged ground photography and visual interpretation of pan-sharpened VHR imagery. The field-average NDVI was then extracted for each sample field as the mean of the image pixels intersecting the field polygon. For each image the empirical relationship between mature capsule volume and NDVI was de-termined using linear regression of the form y = a(NDVI) + b, where y is the mature capsule volume

Table 1: *Summary of 2013 and 2014 yield datasets provided by UNODC/MCN for this study and multispectral satellites QuickBird (QB), WorldView2 (WV2) at 3.6 and 2 m pixel size respectively. Image held8 excluded as poppy crop was cleared*

Year	Image	Reference	Province	Acquisition	Sensor	Poppy growth stage (image)	Fields analysed	Poppy parcel interpretation
2013	*held8*		Hilmand	22/04/2013	QB	cleared	0/2	yes
	held	HLD	Hilmand	27/04/2013	WV2	sceneced	5/10	no
	kand-cnc p3-4	KDR	Kandahar	14/04/2013	WV2	capsule	6/6	yes
	uruz-target1	URZ	Uruzgan	27/04/2013	QB	capsule	3/9	yes
	farah-erad1	FRH	Farah	13/04/2013	WV2	capsule	12/12	yes
2014	held	HLD	Hilmand	24/04/2014	WV2	sceneced	6/8	yes - part
	uruz-erad1 & uruz4	URZ	Uruzgan	27/04/2014	WV2	capsule	9/9	no
	fara	FRH	Farah	15/04/2014	QB	flowering	12/12	yes
	bada-erad3-p1-2	BKN2	Badakhshan	26/06/2014	WV2	capsule	15/15	yes
	bada-erad1	BKN1	Badakhshan	26/06/2014	WV2	capsule	9/9	yes
	kand	KDR	Kandahar	10/04/2014	WV2	capsule	3/9	no

per unit area, a is the slope and b is the offset. The 95% confidence intervals of the mean expected value of y for a given NDVI (x^*) were constructed using:

$$\hat{y} \pm t_{0.025,n-2} \cdot s_y \cdot \sqrt{\frac{1}{n} + \frac{(x^* - \bar{x})^2}{(n-1) \cdot s_x^2}} \quad (4)$$

where s_y is the standard deviation of the residuals, $t_{0.025,n-2}$ is the student t-value for 95% CI (two tailed), s_x^2 is the variance and $\bar{x}$ is the mean NDVI.

The field delineations of poppy crops supplied by UNODC from their cultivation survey were used to extract the average NDVI for each poppy field in the image. Geometric differences between the field polygons and the orthorectified images were corrected by manually shifting individual polygons to align them with the imagery. A 2 m internal buffer was applied to the field parcels to reduce the edge effects.

The bias-corrected mature capsule volume was calculated by substituting the mean field average NDVI for all poppy fields in an image (population mean, $\bar{x}_{pop}$) into the empirical relationship between mature capsule volume and NDVI from the sampled fields.

3. Results

The linear regression of mature capsule volume and field average NDVI for 2013 and 2014 images are shown in figures 1 and 2 respectively. Image 2014 BKN1 was excluded from the analysis as there was no relationship between the mature capsule volume and NDVI from the image. Bias correction using the linear regression models above is summarised in table 2 for six of the nine images from the 2013 and 2014 data. There were no poppy field interpretations for HLD 2013, URZ 2014 and KDR 2014 as either the image was too late, the R^2 was low or there were too few field observations to warrant image interpretation. The correlation between mature capsule volume and NDVI is highly variable between images, with R^2 ranging from 0.08 to 0.42 for images with more than three fields. Images FRH 2014 and BKN2 2014 have an R^2 value greater than 0.4 and yield figure corrections of -17% and 17% respectively, with improved or similar confidence intervals compared to the sample data alone. KDR 2013 and HLD 2014 have low R^2 values indicating high variance in the relationship between mature capsule volume and NDVI. This is shown in the increased CI of the bias corrected mature capsule volume. The bias-corrected yield for FRH 2013 is within 1% of the sample yield despite a very low R^2 of 0.14.

Figure 1 - Field average NDVI plotted against mature capsule volume per unit area for individual image sites in 2013. Dashed lines show 95% confidence interval for the regression line

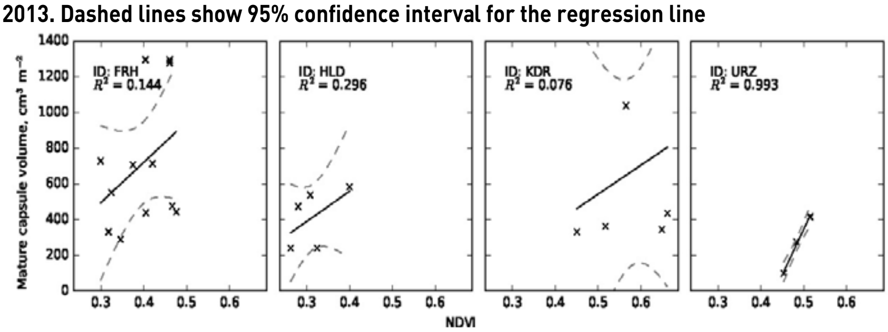

Figure 2 - Field average NDVI plotted against mature capsule volume per unit area for individual image sites in 2014. Dashed lines show 95% confidence interval for the regression line. BKN1 shows no relationship.

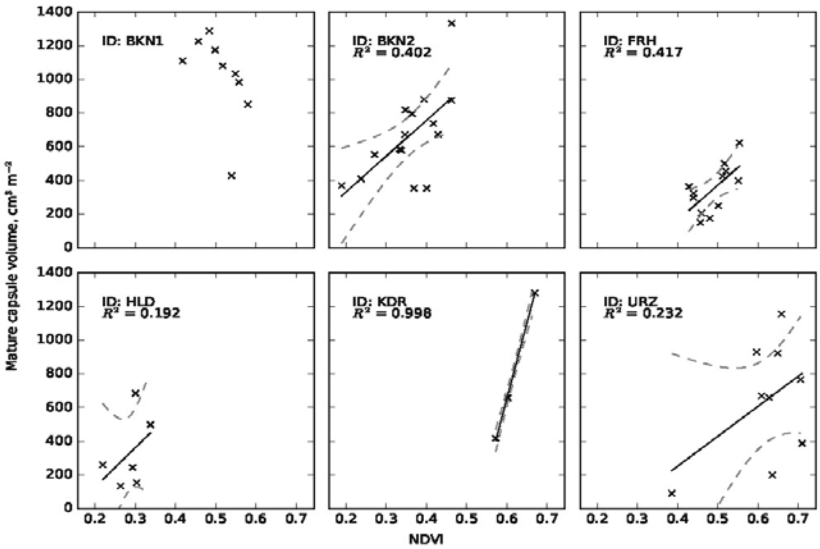


4. Discussion and recommendations

The empirical relationships between field average NDVI and mature capsule volume for the Afghanistan data (figures 1 and 2) are poor compared with the data from the UK (R^2 >0.7 at flower-ing). The potential reasons for the discrepancy are the differences in agricultural practices and poppy varieties, the differences in the methodology between the UK field trials and the Afghanistan data collection, and the quality of the yield observations.

The manual cultivation methods used in Afghanistan are likely to result in greater variation in the quality of crops than the standardised mechanised practices used in the UK. In the UK field trials, sample locations were co-located with pixel level accuracy (<1 m) across the range of NDVI variability. In Afghanistan accurate co-location of the quadrat locations (<1 m) is not possible using the current GPS units so the field-averaged yield and NDVI are used instead. Detailed examination of the Afghanistan field data and ground photography suggests that the average of the quadrat level data may not be representative of individual fields. Many of the quardats are located along field boundaries, which may introduce sample bias if these areas are consistently higher or lower yielding than the rest of the field.

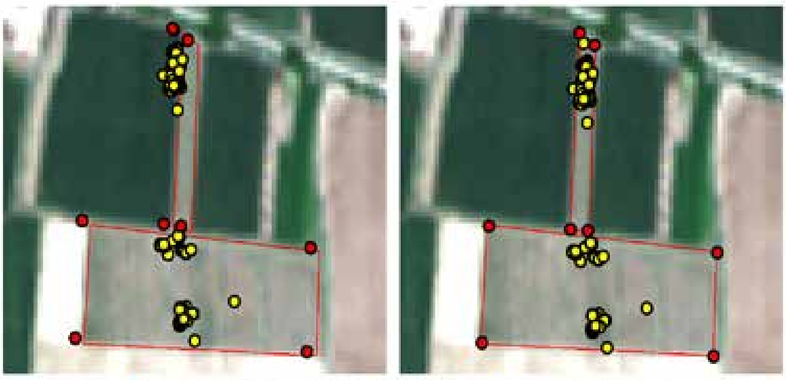
Table 2 - Results of bias correction methodology applied to 2013 and 2014 image data. NDVId is the difference between the mean NDVI of the sample fields and the mean NDVI of all poppy fields in the image. CIsamp is the 95% confidence interval of the sample yield estimate and the CIcorr is the 95%confidence interval of the regression model yield estimate.

Year	ID	No. fields	Yield sample mean (cm^3 m^{-2})	$\pm CI_{samp}$ (%)	Yield bias corrected (cm^3 m^{-2})	$\pm CI_{corr}$ (%)	R^2	NDVI range all fields	NDVI range sam-pled	Yield differ-ence (%)	$NDVI_d$
2013	URZ	3	262	69	395	13	0.99	0.439	0.062	51	0.026
2013	FRH	12	712	30	721	32	0.14	0.401	0.177	1	0.004
2013	KDR	6	669	59	577	114	0.08	0.659	0.211	-14	-0.057
2014	FRH	12	347	23	288	30	0.42	0.215	0.125	-17	-0.028
2014	HLD	6	329	53	428	77	0.19	0.192	0.119	30	0.042
2014	BKN2	15	666	20	778	18	0.40	0.496	0.273	17	0.053

There is also the potential for increased NDVI values relating to the presence of weeds where the density of opium cropping is low. Visual inspection of the quadrat photographs for KDR 2013 showed inconsistencies between capsule counts and the recoded data. There was also ambiguity in the labelling of sampled fields and data points. There is potential for error in matching the NDVI values with the correct field data as the plot photo-locations are used for linking the fields in the database with the image interpreted field parcels.

A better correlation of NDVI with mature capsule volume could be obtained by accurately co-locating individual quadrat measurements with the image pixels. The GPS coordinates and image ortho-rectification are not sufficiently accurate to ensure pixel level geo-location. However, by col-lecting the corner positions of the sampled fields the sample data can be shifted to better align with the image data (see figure 3).

Figure 3 - Suggested additional GPS point locations at field corners allow improved placement of yield points with imagery. GPS points shifted to image (right) using field corners.



The range of NDVI values from all poppy fields in the image is much greater than the range of NDVI for the sampled fields (table 2). This suggests the current approach of sampling the range of yield by subjective assessment of crop quality is not capturing the true variability.

Some of the errors in field data collection and the placement of sample quadrats are related to the security conditions faced by the field survey teams. Taking field measurements and photographs exposes surveyors to personal risk, which is reduced by taking measurement at the corner of fields or behind compound walls. An advantage of using an imagery based approach is that NDVI data can be used to preselect fields to sample. A range of field sites representing the range of NDVI could be pre-sented to the survey teams provided that images are collected around the crop flowering period. Once in the area of the image, a sub-selection could then be made based on an in-field risk assessment. This would also improve the field selection process compared to the current subjective assessment of a low, medium or high yielding crop. Implementing this approach would require improved communication with the field survey teams. Images would need to be processed and visually interpreted for opium poppy fields in the 2-3 weeks between image collection and capsule maturity when yield observations are made in the field.

Imagery that coincides with the 3–4 week period around poppy flowering has the the highest R^2 and greatest stability of the relationship between NDVI and capsule volume in UK data (Waine et al., 2014). The timing of the UNODC imagery from both years is towards the end of the growth cycle and close to crop senescence, where the relationship between potential yield and NDVI breaks down.

The remote sensing approach aims to relax the requirement for a random distribution of sample points and to reduce the number of samples required to make a yield estimate. It does not correct for error in the yield observations, which was found to vary between the images locations. Data recording errors and mislabelling that result in outliers in the regression of mature capsule volume and NDVI will have a significant effect on the results. The suitability of the imagery also varies according to its timing in relation to the crop growth stage. Imagery collected late in the growing season will have a shorter range in NDVI and less stable relationship with potential yield resulting from a reduction in photosynthesis as the crop senesces. As such the approach could not be used for all of the 2013 and 2014 images. However, the potential of the approach can be seen in the improved yield estimates for FRH 2014 and BKN2 2014. These image sites had more than 6 field locations, imagery at flowering or capsule stage and $R^2 > 0.4$.

A small targeted yield sample remains the best approach to improve the accuracy of yield ob-servations of mature capsule volume. However, field data quality is likely to remain highly variable given the unpredictable security conditions in which surveyors work. It is recommended to apply the following criteria for each image before applying a bias-correction: (1) suitable image timing (ide-ally 2–4 week period around poppy flowering); (2) ground locations of measured fields accurately determined in imagery; (3) minimum of six ground data points, positive correlation and $R^2 > 0.4$; and (4) image mean NDVI of poppy fields within the bounds of the model. The value of R^2 suggested is supported by findings in Taylor et al. (1997), where an $R^2 > 0.3$ was recommended for application of a regression estimator in cultivation surveys.

5. Conclusions

A bias-correction methodology using VHR satellite imagery was applied to the yield data of the UNODCs annual opium survey from 2013 and 2014. The aim of the approach is to reduce bias caused by the non-random distribution of the sample and reduce the number of samples required to make an estimate. Of the 12 VHR images, 6 were bias corrected with 2 resulting in an improved yield estimate. The remaining images had a low R^2 for the empirical relationship between mature capsule volume and NDVI, which was attributed to the quality of the yield observations and the accuracy of field-averaged yield data calculated from three quadrat locations in heterogeneous fields. Improvements to the survey methodology were recommended to improve the empirical rela-tionships between NDVI and capsule volumes. These were to optimise the timing of VHR imagery collection to coincide with poppy flowering, improve the relative alignment of quadrat GPS locations using field corners, and using the stratified NDVI image to target field locations to sample. Criteria for applying the bias correction methodology for operational use were also suggested. The authors acknowledge that the recommendations and quality criteria cannot currently be met in all cases given the complex logistical and security situation in Afghanistan. The UNODC seeks continuing improvement in the quality of ground data collection through improved surveyor training and concentrating its effort on a small and targeted yield sample. In this context the approach should be tested further for operational use in bias correction of yield estimates going forward.

6. Acknowledgements

The authors wish to thank the UNODC and Afghanistan's Ministry for Counter Narcotics for funding the research and permission to publish their data.

Survey methods for the Enumeration of Nomadic and Semi-Nomadic (Transhumant) Livestock

N. Keita | Food and Agriculture Organisation (FAO), ESS division | Rome | Italy

ABSTRACT

Despite the growing importance and contribution of the livestock sector to the economy of many countries, statistical data on the sector remains weak and surrounded with large uncertainties. Even the total number of pastoralists in the world is not known within any degree of confidence. Data on nomadic and semi nomadic livestock is even less reliable given the specific challenges related to collecting data on this type of livestock since standard survey methods cannot be easily applied. Nomadic and transhumant pastoralists move their animals according to the availability of fodder resources and tend to inhabit relatively remote and inaccessible areas, which are major constraints on the conduct of conventional field surveys. Special attention is therefore required to devise appropriate methods for enumerating nomadic and transhumant livestock.

FAO's previous guidelines on collecting livestock data (FAO, 1992) included a review of methods for enumeration of nomadic livestock, but this was published over twenty years ago. Since then, new methods of assessing livestock resources and production parameters have been developed and new tools have become available for geo-referencing, recording and analyzing data as well as computer software programmes for data capture, checking, analysis and display have also greatly improved.

In light of the importance of nomadic livestock for many countries, the lack of a document synthesizing the existing approaches and in order to reflect new methods and tools, the FAO Global Strategy to Improve Agricultural and Rural Statistics has developed new guidelines on collecting statistics on nomadic and transhumant livestock. The guidelines address the methodological and operational challenges to enumerating nomadic and semi-nomadic livestock (GSARS, 2016). This paper draws on findings and guidance provided in these guidelines.

Keywords: Nomadic and transhumant livestock, ground and aerial survey, agricultural census

PAPER

1. Introduction

In many developing countries, livestock production is one of the fastest growing components of agriculture and, as economic development progresses, is expected to become the largest contributor to the sector. Information on livestock producers and their animals is thus essential to the design, implementation, monitoring and evaluation of socially desirable interventions in the sector, including selective breeding, animal health, improved feeding, processing and marketing policies and investments.

The total number of pastoralists in the world is not known within any degree of confidence, because of inconsistencies in definitions and uncertain figures, but has been variously estimated at 20 million pastoral households (de Haan et al., 1997; referred to in Blench, 2001); 180.7 million individuals - pastoralists (Thornton et. al., 2002); and 200 million individuals - pastoralists (Rota and Sperandini, 2009). Estimating the number of nomads has been even less certain, with a commonly quoted figure about 30-40 million individuals. This figure seems to come from an estimate made at the latest in 1995 and numbers are likely to have fallen since then. ("Nomads: the facts". New Internationalist. Oxford, UK. 5 April 1995. Available at: http://newint.org/features/1995/04/05/facts/).

1. Issues to be addressed for enumerating nomadic and semi-nomadic livestock

Where agricultural households are settled and farm specific areas of land, the locations of towns, villages and farms are known and mapped. In these areas, the implementation of agricultural censuses or surveys – including on livestock – is a relatively straightforward process of organisation of statistical survey. Where livestock producers are transient pastoralists, standard survey methods of agricultural enumeration cannot be easily applied. Nomadic and transhumant pastoralists move their animals according to the availability of fodder resources and tend to inhabit relatively remote and inaccessible areas, which are major constraints on the conduct of conventional field surveys. Special attention is therefore required to devise appropriate methods for enumerating nomadic and transhumant livestock,.

FAO's previous guidelines on collecting livestock data (FAO, 1992) which included a review of methods for enumeration of nomadic livestock, were published over twenty years ago. Since then, new methods of assessing livestock resources and production parameters have been developed; and new tools have become available for geo-referencing, recording and analysing data. Computer software programmes for entering, checking, analysing and displaying data have also greatly improved. A review of existing literature shows that the enumeration of nomadic and semi-nomadic population or livestock is discussed in several documents and research papers. However, there is no single document holistically synthesising the existing approaches. In light of its importance for countries, and in order to reflect new methods and tools, the FAO Global Strategy to Improve Agricultural and Rural Statistics has included the development of new guidelines on collecting statistics on nomadic and transhumant livestock as a priority topic in its research programme, addressing the methodological and operational challenges to enumerating nomadic and semi-nomadic livestock (GSARS, 2016).This paper draws on findings and guidance provided in these guidelines.

2. Types of surveys[1]

In general, two types of surveys (or combination of the two types) can be used to enumerate nomadic and transhumance livestock: (i) ground surveys and (ii) aerial/satellite surveys. Each method has prerequisites, advantages and disadvantages that are summarised in Table 1.

Ground surveys methods are mainly derived from techniques of enumerating nomadic people as used in population censuses. In fact, collecting data on nomadic and transhumant livestock needs a good knowledge of the population who raise that category of livestock. Ground surveys are implemented through two main ways:

- First, animals can be counted on **enumeration points** which are sites where animals congregate. There are several types of enumeration points commonly used, such as watering points, vaccination points, dip tanks and spray races, temporary seasonal camps, stock routes and livestock markets. It is also possible in some situations to create specific enumeration points for the purpose of the survey. Often different type of enumeration points are used for the enumeration of pure nomadic livestock and of transhumant livestock. In the case of livestock census of Niger 2004/5, the watering points were used as enumeration points for nomadic (?) and internal transhumant livestock, and stock routes (transhumance corridors) were observed for the external transhumant livestock.

- Secondly, as in some countries nomadism and transhumance are practiced by some specific **ethnics groups or clans**, livestock enumeration can be done with the support of ethnic group/clan leaders and family networks to locate livestock by identifying and locating temporary seasonal camps of group members. The enumeration is then organised by visiting these camps. The basic conditions for using this approach are given in Table 1.

Aerial surveys are more suitable and effective for large survey areas and in areas that are difficult to access, including desert environments. Most of the aerial survey methods used for enumeration of nomadic livestock are derived from the techniques used by wildlife biologists to estimate population size of wild animals. A large number of publications can be found in the literature on the use of these methods. ILCA (1981) discusses these methods and their application to livestock, wildlife and land-use surveys.

Aerial surveys can be implemented in various ways:

- Low level aerial surveys, which are usually done from aircraft flown at between 300-1,000 feet (100-300 meters) above the ground, are ideally suited for coverage of extensive, remote areas, which are inaccessible by other means.

- Drones, which are relatively cheap and lightweight, are starting to be used for data collection in relatively remote areas. They can be fitted with video or still cameras for livestock enumeration purposes. The major limiting factor at present is flight duration which is very short now.

- An additional method of survey is reliance upon satellite imagery. Today, this is widely available and, in the absence of reliable maps, can be an effective substitute in planning and implementing field data collection for livestock enumeration. Satellite imagery provides a broad overview of the landscape and land cover, and can be useful in locating tracks, settlements and water sources, as well as updating existing maps. For the time being, such imagery is limited in terms of enabling animals to be counted.

[1] An indicative decision tree is provided in annex

Combining aerial and ground surveys

Generally, when implementing aerial surveys, it is necessary to conduct complementary ground surveys to address some of the disadvantages of aerial survey methods such as impossible distinction between sheeps and goats, which can only be recorded as small ruminants; as well as between donkeys, mules and horses, all recorded as equines. Cattle can only be distinguished by colour type. A ground survey is necessary to assess breeds, and herd age and sex structure (Ethiopia, nomadic livestock survey in Somali Region, 2004).

3. Census or sample survey?

In case of ground surveys, the first step is to establish a complete listing of all enumeration points for the selected type and/or ethnic groups or clan to build a reliable national sampling frame for data collection. The second step is to decide between implementing a complete enumeration census or a sample survey. Where possible the complete enumeration for nomadic and especially for cross-border transhumant livestock is preferred.

In case sampling is necessary, e.g. because of operational, financial or timing constraints, a stratification would be useful, depending on the availability of additional information. The stratification would reduce statistical variation and improve the precision of estimates. The strata may be the different categories of enumeration points in the selected type or administrative areas. Some strata may be completely surveyed and a sample of enumeration points may be selected for others.

4. Sampling design

4.1 Ground surveys

Sampling enumeration points for transhumant and nomadic livestock is quite challenging because of the mobility of animals. The calculation of the probabilities of selection (used for weight estimation) may be complex and the information needed for the calculus may be difficult to collect in the field. In most countries, a stratified simple random sampling may be suitable when it is necessary to sample enumeration points. Depending on the number of enumeration points and their geographical dispersion, a multi- stage sampling may be used to reduce the cost of the survey. Here the estimation of the probability of selection of each animal is complex. More details sampling and estimation issues are available in (GSARS, 2016).

4.2 Aerial surveys

There are two main methods of assessing livestock populations from the air: total aerial counts and sample counts. A total aerial count of animals in an area can be obtained by flying a series of closely spaced, parallel flight lines with overlapping observation strips, or by a circular "cork-screw" flight path of decreasing radius over the area of interest (see Figure 1). This flight pattern should cover the whole area with no gaps between the flown patterns.

Four main methods of sampling livestock populations from the air are used Systematic Reconnaissance Flights (SRF), Stratified Random Aerial Transects (SRAT), Aerial Quadrat Sampling (AQS) and Aerial Block Sampling (ABS);. For more information on these methods, refer to (GSARS, 2016). The total number of animals is calculated by estimating the density of animals in the sampled area and then the total number of animals is calculated by multiplying this density with the total area of the survey.

The most common aerial sampling method applied for enumerating nomadic livestock is the Systematic Reconnaissance Flight (SRF). The Central Statistical Agency of Ethiopia used the SRF in 2003 to conduct a livestock aerial survey (Central Statistical Agency, 2004). In SRF surveys, a series of parallel flight lines are flown at equal distance from each other across the designated area (Norton-Griffiths, 1978; ILCA, 1981; Clarke, 1986). Each flight line is divided in sectors equal in ength to the flight line spacing to create a grid over the entire area (see Figure 1). Within each strip flown, only a part of the area is counted.

Figure 1 - Total Aerial Count Patterns; SRF Sample Coverage

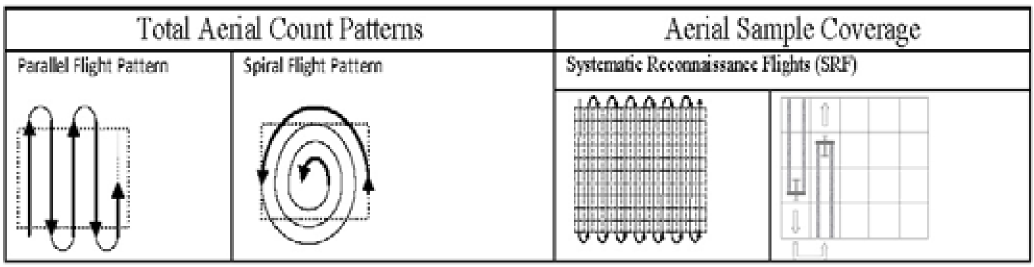

Table 1 - Prerequisites, Advantages and Disadvantages of Survey Methods

Prerequisites	Advantages	Disadvantages
Ground Survey - Water Points, Vaccination Points, Dipping/spraying points		**Example: Mali Survey 2001**
Requires complete list and map of all water or vaccination or dipping/spraying points in enumeration area.	• Animals can be easily seen and counted when coming to water or vaccination or dipping/spraying points where enumerators can be located; • Logistically simple and easy to organise.	• Frequencies vary with species and location; • Animals brought not necessarily nomadic/ transhumant; • In some situations can be difficult to avoid double counting; • Young stock may be excluded; • Additional information/surveys required to determine watering frequencies/ to assess proportions vaccinated / determine proportion dipped/sprayed and proportion of nomadic/ transhumant animals to estimate population size.
Ground Survey - Ethnic Groups/Clans		**Example: Ethiopian Afar Region Survey 2004**
Prior agreement and full cooperation of all group members; and list and map of all camp locations in enumeration area.	Involvement of Group/clan leaders in survey planning; in identifying and locating all members facilitates information collection.	• Assumes that clan leadership hierarchy know camp site locations of all members; • Areas may be very large, exact locations may not be known; • Some pastoral areas are shared by more than one group/clan, so more than one set of leaders may need to be involved.
Ground Survey - Stock Routes		**Example: Niger transhumant corridors Survey 2004/5**
Complete list and map of all stock routes in enumeration area; and cooperation of herder to channel animals through check points.	• Can be good indicator of numbers moving from one area to another; • Animals pass along stock route where enumerators can be located.	• May be many routes; • Routes not always well defined; • Often multiple tracks; • May change from year to year; • Not all animals use same route; • Difficult to count large herds of moving animals.
Aerial Survey - Systematic Reconnaissance Flight;		**Ethiopian Somali Region Survey 2004**
Preferably has clearly defined boundaries visible from the air: coastlines; mountain ranges; rivers; roads.	• Good for large, inaccessible areas, with no reliable ground counting frames; • No prior assumption with regard to livestock distribution;	• Cannot distinguish between sheep and goats - recorded as small ruminants ; • Cannot distinguish between donkeys, mules and horses; • Can only distinguish cattle colour types . • Requires ground survey to determine ratio/ herd age and sex structure
Aerial Survey – Stratified Random Aerial Transects		
Has clearly defined boundaries visible from the air.	• Good for large, inaccessible areas, with no reliable ground counting frames	• In addition to the above, it assumes that identified strata are relatively homogeneous with regard to livestock distribution is concerned
Aerial Survey-Aerial Quadrat Sampling and Aerial Block Sampling		
Has clearly defined boundaries visible from the air.	• In block and quadrat sampling, the aircraft makes as many passes as are required which can facilitate counting of animals.	• Suffer from boundary effects, (difficult to decide whether an animal is within or outside of the sample unit) particularly for quadrat sampling • Blocks and quadrats tend to accentuate sampling error .

5. What is the most appropriate way of counting animals?

In case of ground surveys, animals can be enumerated by physical inspection in herds and flocks (direct observations), or from the numbers reported by informants (interviews). The first option is the best in order to avoid declaration biases. Enumerators must count animals themselves by using various tools: hand tally or counter (single or multiple counters), photographs, etc. In order to avoid double counting, the counted livestock may be marked and an enumeration certificate may be provided to herders after counting. The second option of enumeration consists in using questionnaires to collect the number of livestock through the herders declaration. Some issues have to be taken into consideration: recall period should be different from large ruminants (12 months) and small ruminants (6 months), the herder is not always the owner, and herders are sometimes reluctant to provide accurate information. These issues may be sources of important declaration biases. It is thus important to select a sample of herds for a supplementary direct counting of livestock in order to correct these biases. In case of aerial survey, animals are counted and recorded during flight. In addition, photographs are taken of larger herds, for subsequent verification and correction of observer bias. Instead of having teams of people in a low flying aircraft, cameras can be installed that take photographs at regular intervals. Aerial photographs may be used to check the visual counts and correct for observer bias.

The information collected during a livestock enumeration depends very much on national and local circumstances and on the purposes of the survey. Potential tools for livestock enumeration, field data collection, analysis and presentation of results have greatly improved in recent years, with the advent of hand-held navigation devices, more powerful computers and general advances in Information Communication Technology (ICT). For example, there is an increasing use of Computer-Assisted Personal Interviewing (CAPI) tools in data collection on livestock that replace the Paper-and-Pen Interview (PAPI). Recording the location can be done manually using either dedicated GPS devices or using an add-on GPS app for smartphone or tablet (when CAPI data collection method is used).

An analysis of field data collection costs considering different methods implemented in tropical and sub-tropical countries shows variations between countries (table 2). The costs have been adjusted for inflation and converted to Purchasing Power Parity (PPP) values. The highest cost per animal counted was in Jordan at USD 0.74, which may be due to the building of specific facilities at which the animals were counted. The next highest was the aerial survey in Ethiopia at USD 0.47 and this is undoubtedly because of the use of aircrafts which require specialised equipment and highly trained staff. The remaining enumerations for which costs are available display a cost per animal counted that is much lower than registered in Jordan or for the aerial survey, in the order of 10 per cent per animal. The cost per animal counted ranges from US$ 0.06 to US$ 0.02. However, these figures, can only be considered as indicative.

Table 2 - Comparison of the costs of enumeration of nomadic/transhumance livestock

Country	Year	Method	Total cost (USD)	Total nomadic / transhumance animals counted	Estimated total nomadic / transhumance population	Cost per animal counted (USD)	Cost per animal in the estimated population (USD)
Afghanistan	2002	Census: village visits	No cost given	Unclear as many may be sedentary			
Ethiopia-Afar	2004	Stratified sample: household visits	312,416	Not clear	9,014,365	Cannot calculate	0.03
Ethiopia-Somali	2004	Aerial: 3.5% Systematic sample	223,453	477,684	13,648,408	0.47	0.02
Jordan	1991	Census: Constructed locations	2,476,616	3,346,000	3,346,000	0.74	0.74
Mali	2001	Census: water points	241,535	4,193,848	4,193,848	0.06	0.06
Mongolia	2012	Ground: 33% stratified sample	277,976	13,640,000	40,920,000	0.02	0.01
Niger	2004-5	Stratified sample: water points and transhumance routes	No cost given	Not given	10,644,899		
Nigeria	1992	Aerial: 5% systematic sample	No cost given				

6. Conclusions

The challenges to obtaining reliable information about nomadic livestock can be addressed using various approaches according to local circumstances and requirements. Also the advent of hand-held navigation devices, more powerful computers and general advances in Information Communication Technology (ICT) in recent years have greatly improved tools for livestock enumeration, field data collection, analysis and presentation of results. Different country experiences show that a careful analysis of country s conditions can allow the selection of the most suitable method for generating data on nomadic and semi nomadic livestock. Ground surveys have been used in Mali and Niger (ground surveys using water points and transhumance routes), Mongolia (stratified sample survey), Jordan (complete enumeration of designated concentration areas) and Bolivia (stock routes). Aerial surveys have been used in Ethiopia and Nigeria (aerial survey complemented by ground survey).

The main conclusion is that there is no universally applicable method of enumeration of nomadic and transhumant livestock in all country conditions. The available methods should be carefully analysed in the light of the country peculiarities, resource and time constraints in order to choose the optimal approach.

ABSTRACT

Food and nutritional security re-emerged as a major challenge facing developing countries since the global food, fuel and financial crises in 2008. A wide variety of approaches are used to gauge the status of food insecurity at global, national, household and individual levels. However different indicators often provide a diverseset of estimates and a contrasting picture owing to the nebulous concept of what constitutes food insecurity and the differences in measurement approaches adopted. In this paper, we briefly review the most commonly-adopted approaches used by researchers for assessing food and nutritional insecurity. These include FAO's prevalence of undernutrition indicator, household-based consumer expenditure surveys (CESs), and anthropometric measures used in evidence-based and policy-oriented research.

We also assess the prevalence of nutritional deficiency in India in terms of the macronutrients at the national levelusing the latest CES data (2011-12). We complement our analysis with anthropometric measures to assess the link between food intakes and nutritional outcomes. Finally,we conduct the multivariate analysis using a multilevel modelling framework to examine the relative importance of particular covariates and geographical contextual factors in determining the different measures of food and nutritional security. We highlight that applying uniform norms for a geographically and ethnically diverse country like India is inappropriate. We conclude there are serious limitations to measuring undernutrition solely through calorie intake; and argue that a multi-dimensional approach incorporating anthropometric measures and a multilevel modelling framework is required to better measure and understand the underlying causes of undernutrition.

Keywords: Undernutrition, Food security, Multilevel modelling

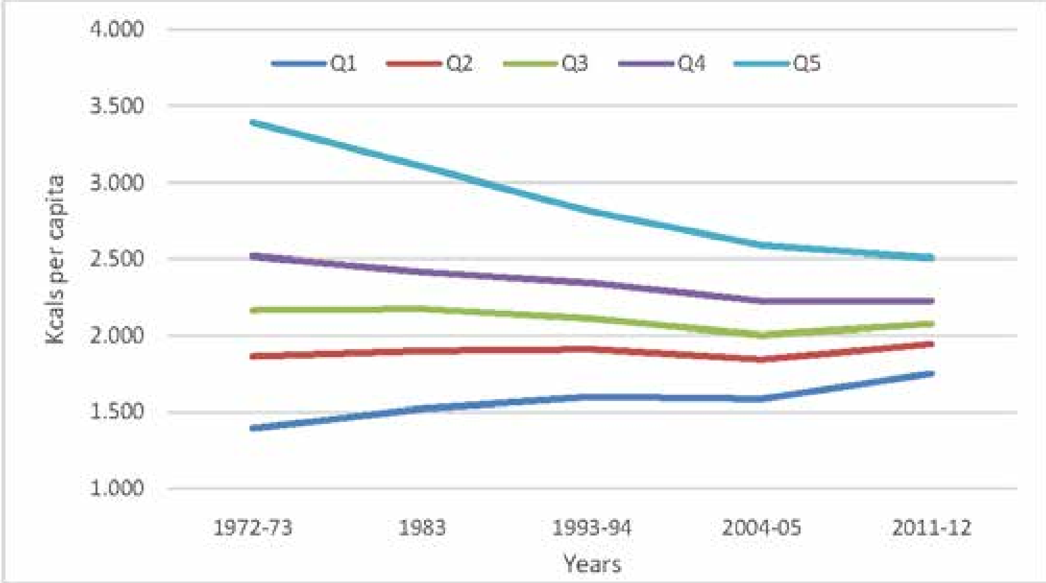
PAPER

1. Introduction

India is home to nearly 25% of the undernourished population in the developing world, and consequently, global undernutritionis highly sensitive to the prevalent situation in that country. Interestingly, total per capita calorie consumption in India has declined over the past three decades despite rising incomes over the same period. However, within income classes, our analysis (using various rounds of the National Sample Survey (NSS) data shown in Figure 1 belowreveals that overtime caloric intakes of poor Indians (two lowest quintile economic groups) has grown, albeit slowly,and for the rich (higher quintile groups) it has declined progressively since1972-73.

In this paper, we analyse alternative measures of undernutrition in India and undertake our own modelling of caloric intakes using multilevel analysis. The paper is organized as follows. The next section critically reviews the most commonly-adopted approaches used for assessing food and nutritional insecurity. Section 3 provides a comparison between calorie intakes and anthropometric outcomes in India using the most recently available survey data. Section 4 presents the multilevel modelling analysis of caloric intakes, wherein weexamine the relative importance of particular covariates and regional contextual factors. The last section summarizes the key findings of the study highlightingthe key policy implications.

Figure 1 - Trends in per capita calorie consumption across economic classes (quintiles) in rural India



Source:Authors' own estimation using NSS data.

2. Review of the existing approaches

A number of coexisting indicators are being used to infer on the state of food security and undernutrition at global, national, household and individual levels. Unfortunately, these different indicators tend to be used independently of each other and usually are seen as alternatives by the end-user. We briefly discuss below the main attributes of these indicators.

FAO's prevalence of undernutrition (PoU) indicator is the most widely-acknowledged indicator used in food security debates. It is based on three critical parameters: mean quantity of calories available in a country for human consumption, inequality in access to those calorie intakes and mean minimum age-sex specific calorie requirements of that population. FAO has been publishing this indicator annually as a 3-year average in its State of Food Insecurity in the World (SOFI) publications.The method has been widely criticised in policy circles as it measures food availability rather than food consumed. Notwithstanding recent improvements, FAO'sestimation method still suffers from some key non-remediable problems in the accurate assessment of food security. These include itsconsideration of being based on minimum activity levels whichistoo simplistic an assumption for developing countries where majority of the workforce is involvedin heavy manual labour. It is incapable of capturing the impact of short-term price and economic shocks whose frequencies have been increasing in the recent past. Also, as an aggregate measure,it is still unable to assess the nutritional status of households/ individuals and identify them.

Another commonly used approach is that of nationally representative household-level CES which contain a detailed component on food quantities consumed at the household level. The quantities consumed are converted to obtain estimates of nutrient consumption which can then be compared with the age-sex-activity specific requirement cut-offs to identify the households with undernourished individuals. The use of a non-parametric household survey approach is considered to be an improvement over FAO's aggregate measure as it helps to undertake multilevel targeting and monitoring within countries as it captures the demographic structure of the household population itself; and also has the ability to evaluate the dietary diversity and macronutrient status*. However, a problematic issue is that it does not capture the intra-household allocation of commodities. Also, data surveys are not undertaken on a regular basis and are computationally intensive and expensive both in terms of financial and technical resources. In addition, food eaten away from home, wastage, losses and non-food use within the households are not adequately captured across these surveys. Further, survey measures suffer from non-sampling errors due to misreporting, incomplete questionnaire forms and issues of telescoping and recall bias.

While the previous two indicators focus on macro level, another widely-acknowledged approach to measure food insecurity is the use of anthropometric indicators such as wasting (low weight for height), stunting (low height for age) and underweight (low weight for age; Body Mass Index (BMI) less than 18.5 for adults). This approach measures nutritional outcomes at the individual level. A key positive feature of anthropometric indicators is that they are simple, accurate and relatively cheaper to compute. They evaluate the nutritional outcomes at the individual level and thus can be used to determine intra-household allocation, for targeting interventions and monitoring them across age and gender traits in a population. These indicators directly connect to the development status of a population (Pelletier 1994; Deaton and Dreze 2009). However, the methods for measurement of nutritional outcomes in the adult population can be problematical due to the lack of consensus on the global reference standard for such population. Anthropometric failures might occur due to reasons such as manifestation of diseases, prolonged illness etc. that are completely uncorrelated with food insecurity. Also, such an approach does not identify the nutrients causing poor anthropometric status.

Given the merits and demerits of each of the approaches, one can conclude that there is no picture-perfect yardstick to measure undernourishmentas each method contributesas different pieces of the broader food insecurity puzzle. Accordingly,we argue it is time to link the household survey approach with the anthropometric surveys such that the outcomes of both approachescan be used in a mutually-reinforcing and complementary manner to provide a multi-dimensional insight into undernutrition issues. For instance, if the overall vital health indicators are weakening while that of anthropometric status are improving then it is suggestive of the fact that the available resources should be directed towards primary health care, disease prevention and other social support facilities rather than boosting up food supplies. Here, adopting a multi-dimensional approach becomes critically important for policymakers in assessing country-level food security and hunger and poverty-related issues. Attention in the following sections turns to these issues.

3. Calculation and comparison between prevalence of undernutrition and prevalence of underweight in India

In this section we compare and contrast PoU measures of undernutrition with anthropometric measures of underweight using the most recently available datasets in order to highlight differences between these two approaches and its implications for policy. We estimate prevalence of undernutrition (PoU) using the unit-level NSS data from 61st Round (NSS-61) for the period 2004-05 covering 1,24,680 households and the 68th round (NSS-68) for the period 2011-12covering 1,01,662 households. The nutrient intake of an individual is calculated using the quantity of each food item consumed by each household which is converted into its nutrient equivalent content of calories. We calculate PoU on the basis of the recommended dietary allowances (RDAs) as given by the Indian Council of Medical Research-National Institute of Nutrition (ICMR-NIN). A household was considered to be calorie deficient if its actual total calorie consumption was less than the calorie required for that household given the age, sex, activity status of household members as per RDAs (Chand and Jumrani, 2013).This computation uses the RDA levels for moderate activity in rural areas and assumes sedentary lifestyles in urban areas. PoU is estimated as proportion of people living in households that are not consuming threshold energy intakes. We present PoUfor major states in Table 1 below. We also present the prevalence of underweight by utilising the National Family Health Survey 2004-05(NFHS-3); a household survey which provides information on health-related matters. The survey covers 1,24,384 females (aged 15-49 years) and 74,369 males (aged 15-54 years) across 29 states. NFHS-3 collected information on height and weight of women and men which is then used to calculate BMI - calculated as weight in kilograms divided by height in meters squared (kg/m2). The WHO classification of underweight for adults is defined as the cut-off point where BMI ↓ 18.5; and used to define thinness or acute undernutrition. We also present preliminary results for a limited number of statesreleased thus far from the most recent NFHS-4 survey (2015-16). The prevalence of underweight among major statesis also presented in Table 1.

Although NFHS and NSS surveys are not strictly comparable owing to the different time periods,Table 1 servesto demonstrate the considerable differences that exist between PoU and BMI measuresof malnourishment when data is disaggregated at the regional level.These most striking differences are in the rural settingwhere states such as Kerala and Tamil Nadu have a PoU of 78% and 84%, respectivelyin 2004-05and are well above the all-India average; compared with a prevalence of underweight (using BMI measure)of 21% and 32% (for 2005-06) respectively, which sits below the all-India average. By the same token, states such as Bihar and Uttar Pradesh have PoU in the rural areas well below the all-India average for 2004-05, whilst in terms of BMI measures, those two states have prevalence rates of underweight (for 2005-06) well above the all-India average. Of particular concern here is insignificant correlation between the rank ordering of states ranked by BMI and those ranked by PoU. Moreover, whilst underweight prevalencehas fallen considerably between 2004-05 to 2015-16, based on preliminary NFHS-4 survey results, this has not been reflected in any significant reduction in PoU over the periods 2004-05 and 2011-12indicating that the differences between the two measures are widening overtime.

To have a state such as Kerala with human development index approaching that of a developed country status having one of the highest PoU in India questions the validity in the uniform application of calorific thresholds in India. India is a subcontinent withconsiderable ethno-physiological differences in its population across regions; differences in public health infrastructure and other social determinants impacting on health (inequalities) such that in some regions people can survive more effectively on lower calories; and differences in climatic and topographical conditions requiring differing calorie expenditure. In light of the above, there is an important role for multilevel analysis of caloric intake to play in setting the minimum calorie norms for different regions or states of India. We now explore this issue.

*In this study, we have analysed all the macronutrients but only the results for calories have been presented due to the word limit.

Table1: *Prevalence of underweight (BMI) and prevalence of undernutrition (PoU) in India by major states for rural and urban areas*

	Proportion of BMI<18.5 (NFHS-3; 2005-06) (15-49 years)		Proportion of BMI<18.5 (NFHS-4; 2015-16 (Recent preliminary data)						PoU (NSS-61) 2004-05		PoU (NSS-68) 2011-12

4. Multi-level modelling of calorie consumption

4.1 Data and methods

We now turn our attention to investigating the differing characteristics governing calorie consumption itself and use multi-level modelling to explore regional differences. We utilise the most recent NSS-68 (2011-12) CES to establish our mode1 (see earlier). We use the natural logarithm of total caloric intake as the dependent variable and incorporate a number of individual-level variables into the modelling framework. These include: monthly per capita expenditure (MPCE) as a proxy measure of economic status; MPCE2; household size; household employment activity (self-employed as reference); ration card (no card as reference); maximum education of household head (illiterate as reference); interaction effect between education*MPCE; socio-religious (Hindu-general as reference); quintiles (hectares) of land possession (first quintile as reference); sex of household head (male as reference). A multi-level regression model was used to estimate the impact of various factors affecting nutrient (i.e. calories) intakes. The model is written as follows:

$$Y_{ijk} = \alpha + \sum_m \beta^m X_{ijk}^m + u_k + v_{jk} + e_{ijk} \quad (1)$$

- Y_{ijk} – log per capita calorie intake of household i nested in j^{th} neighbourhood/first stage unit(FSU) and k^{th}state
- X_{ijk}^m –fixed component – where superscript m represents number of covariates
- u_k – intercept effect of k^{th}state
- v_{jk} – intercept effect of j^{th} neighbourhood (FSU) nested in k^{th}state

... e_{ijk} – residual error of householdi nested in j^{th} FSU nested in k^{th} state

The model shown in equation 1 contains a fixed component which has a separate intercept (x) and a slope parameter (b^m) estimating the effects of a one unit change in the covariates on y_{ijk}. The remaining terms in right hand side (random components) in equation 1 capture the independent effect of geographical space as an independent explanatory factor - in terms of the impact of the state, and the neighbourhood nested within the state. The advantage of multi-level modelling approach is that it allows the intercepts to vary with respect to states and FSUs to account for the macro-level unobserved contextual factors at the stateand neighbourhood level, beyond household-level attributes. Thus the intercept for a given state and neighbourhood can be expressed as x + u_k and x + u_k + v_{jk} respectively. We generate two regression models – both for rural and urban areas. All econometric analyses were conducted using Stata 13.

4.2. Results

Table 2 below presents the results of regression model for both rural and urban settings. As expected, we observe there is a highly significant and positive relationship between calorie intake and MPCE in both rural and urban settings; and this positive relationshipappears to be non-linear and diminishing in nature as evidenced by the negative coefficients for $MPCE^2$.

Consistent with the empirical literature, our model results reveal a negative relationship between household size and calorie intake reflecting possible scale economies in food preparation.Education on its own has a positive effect on caloric intake in both the settings. Interestingly,the interaction effect Education*log MPCE shows that its impact gets smaller with improvements in the economic status of Indian households. Of significance, at very high levels of MPCE, education actually starts showing a negative effect on caloric intake; a phenomenon that is particularly pronounced in urban areas.

As expected, people who possess any kind of ration card were likely to have a higher caloric intakecompared to the non-cardholder reference category; and those with a greater subsidy entitlement were more likely to have higher consumption of calories. Landholding size is positively associated with caloriewith this variable not being applicable in urban areas. With regards to socio-cultural characteristics, with only a few exceptions, there was little statistical variation across groups in calorie intake. Our estimation results also show that in comparison to the male-headed households, female-headed households are likely to have higher intakes of calorie in both rural and urban settings. With regardsto occupational categories in the rural areas, most households'occupational activitieshave a lower propensity to consume calories compared to the reference category of households who wereself-employed in agriculture, reflecting differences in physical activity across occupations. In the urban setting, casual labourers had higher propensity to consume calories relative to self-employed.

Of particular interest is the random component of our multilevel modelling for examining independent effect of region on calorie intakes. We find that in rural settings, about 33% of the total unexplained variation in log of per capita calorie intakes is explained by our random components - 15% by states and 18% by neighbourhoods (measured by the intra-class correlation, ICC). In case of urban settings, states explain around 11% of the total residual variance and neighbourhood around 20%. In Figures 2 and 3 below, states are ranked in terms of the impact of state-level unobserved factors influencing calorie consumption. We confine our discussion to the 20 major states of India which are modelled as intercept shifts in the propensity of calorie intakes along with their confidence intervals (95%) and are shown in the figures below as caterpillar plots. In rural areas, after allowing for individual household covariates, households belonging to states such as Kerala, Tamil Nadu, Karnataka, Andhra Pradesh, and Gujarat lie below the Indian average in calorie consumption. In contrast states such as Bihar, Jharkhand, Uttar Pradesh, and Orissa as well as mountainous states such as Uttaranchal, Himachal Pradesh and Jammu and Kashmir all laywell above the Indian average in calorie consumption. A similar pattern of regional differences also exists in the urban settings (Figure 3). The important issue here is that,besides household-level characteristics, unobserved contextual factors at the regional level play a significant role in determining calorie intakes across India. In this context, it becomes important to disentangle these regional-level effects in order to more appropriately inform policy matters relating to undernutritional issues.

Figure 2 - State level random effects in calorie intakes: rural areas

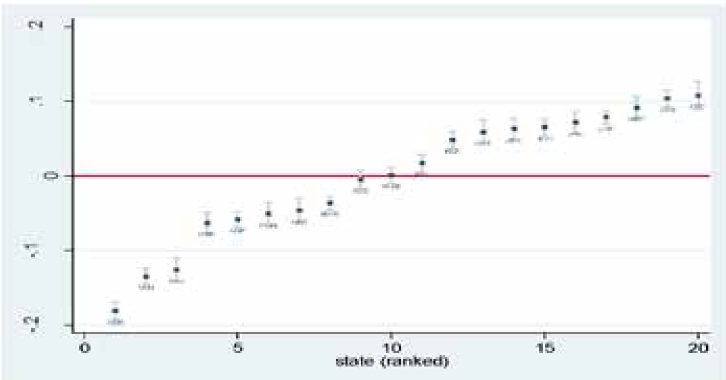

Figure 3 - State level random effects in calorie intakes: urban areas

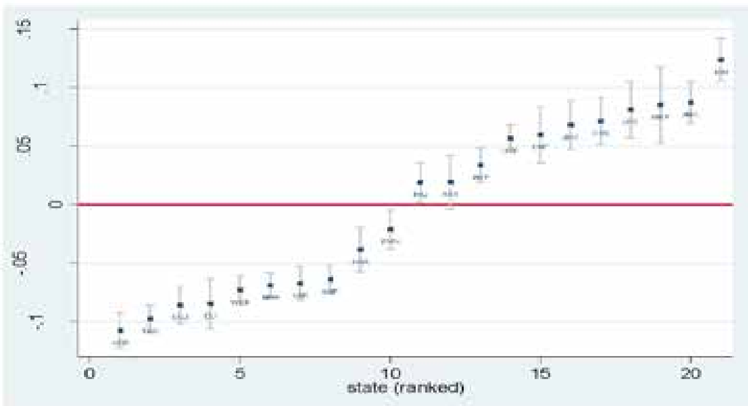

5. Conclusion

Using the most recently available surveys on calorie consumption and BMI, this paper shows there is considerable divergence between PoU and anthropometric methodsand consequently there is the need to adopt a multi-dimensional approach tomeasuring food and nutritional insecurity in order to inform policy in India. In recognition of this, we undertook multilevel analysis to model caloric intakes. Our results show that in addition to household level characteristics, unobserved contextual factors at the regional level play a significant role in determining calorie intakes across India. The extent to which these regional differences are due to factors such as, physiological differences reflecting different ethnicities across regions, differences in climatic/topographical conditions and consequent differing physical activities and calorie requirements, or differences in public health infrastructure and other social support and consequent differing calorie requirements to maintain minimal health, is unclear. What is clear, is that imposing a uniform calorie threshold across all of India, irrespective of region, in order to measure prevalence of undernutrition is inappropriate and leads to misinformed policy. As an imperative, more research is required into understanding contextual factors contributing to spatial differences in minimum calorie requirements necessary for maintaining good health. This paper makes an initial contribution to understanding these issues.

ABSTRACT

Food security has been a phenomenon of interest worldwide because population groups in several parts of practically all continents are said to experience some form of food insecurity, hunger or related phenomena. Ability to measure the extent or magnitude and severity of food insecurity makes it possible to come up with more realistic, adequate and robust ways of solving the problem. This study applied the Rasch model to measure food insecurity in Uganda. The dataset used was generated using the 18 USDA food security assessment questions. Model Testing was done using the Infit and the outfit test statistics with the range 0.7 to 1.3 considered acceptable.

An algorithm for the Rasch model was developed and run using the R-programming software which also generated the Infit/Outfit statistics, Beta coefficients and probabilities. The households were then classified into three categories; food insecure (0.0 to 0.49, moderately food insecure (0.5 to 0.79) and food secure (0.8 to 1.0). Most households (46.6%) were found to be moderately food insecure and one third (33.5%) were found to be food insecure.Children 5 to 17 years have a significant influence on the food insecurity status of a household.

Keywords: Household Food Insecurity, Infit/outfit, Household Classification, Rasch Model

PAPER

1. Introduction

Food security has been a phenomenon of interest worldwide because population groups in various continents are said to experience some form of food insecurity. The challenge has been how to measure it. Ability to measure the extent or magnitude and severity of food insecurity makes it possible to come up with more realistic, adequate and robust ways of solving the problem. Correct measurement of food insecurity is hinged on a clear understanding of its multi-faceted nature. Years of research and discussion led scientists to generally agree that food insecurity is constituted by four major components namely food availability, food access, food utilization and food stability. It has also been shown that macro level analysis results in outcomes that may reflect a large community as food secure when pockets of communities or individual community members are food insecure. One of the best ways of analyzing food insecurity is therefore the household as it is representative of community characteristics at micro level.

The household is the best unit to measure food insecurity due to the following reasons: Food security dynamics are at play at all levels from global community to individuals. Measurement at higher levels has led to wrong conclusions as many communities said to be food secure would still have many individuals or households in dire need of food. Whereas the ideal would be analysis at individual level, it is very cumbersome and expensive. The household has a good mix of individuals including infants, children, adults, males and females, young and old. It therefore provides a good representation of social economic and cultural characteristics of community. Household food security status can be aggregated to obtain food security status of bigger entities like villages, districts, nations, regions up to global level. According to Jones, Ngure and Young (2013), the food acquisition behaviors of households are important for translating physical and economic access to food into food security. All food security components namely food availability, access, utilization and stability as well as coping strategies are best assessed at household level. *It can be considered the best micro-level reflection of the global community.*

When the Rasch Model was introduced as an approach for measuring food insecurity by the United States Department of Agriculture (USDA), it attracted a lot of interest and has since been used in a number of countries to measure food insecurity. The 18 USDA food security questions include the 10 questions for adults and 8 questions for households with children. In West Africa, Obayelu (2012) disaggregated the 18items into 10 adult-referenced items and 8 child-referenced items (children were those less than 15 years) and found that household food security status with respect to adults and children showed a differential pattern. For instance, in Kogi rural, a lower proportion of adults (25.8%) were food secure compared to the children (40.6%). The pattern is similar for the urban with 24.4 per cent of the adults food secure compared to 29.9 percent of children. This is contrary to the findings of Esturk and Oren (2014) who in their study in Adana region in Turkey found that food insecurity was higher for households with children (69%) compared to households without children (39.6%). Lori Reid (1997) in the USA found that Prevalence of food insecurity among children zero to 12 years of age was not significantly different from that of households in general. The three studies resulted in differing outcomes. Could it be the consideration of which ages the children are that affected level of food security arrived at (One considered 15 years and below,This study considered adults and children below 18 years as they constitute a big proportion of Uganda's population. The 2012 Uganda's population report showed that over half of Uganda's population, (56.1%) are children (↓18 years). Unemployment rate for Uganda's youth aged 15–24 is very high, reported by World Bank (2008) to be 83%. This makes them vulnerable to food insecurity given that income is a decisive variable for household food security (Esturk and Oren, 2014). Other youth challenges are lack skills and market access for income generation to maintain food security.

The analysis involved determination of food security status using the 18 items and the 8 children-referenced items (Table 1). The dataset is from two Ugandan districts involved in fishing, livestock and crop farming for their livelihoods. The study also analysed the relationship between food security and three age categories – children below five years, five to below 18 years and adults (18 yearsand above).

Table 1 - Food Coping Questions: Variable Description

E1	Worried whether food would run out before getting money to buy more.
E2	Food harvested or bought just didn't last, and we didn't have money to get more.
E3	Couldn't afford to eat balanced meals.
E4	*Relied on only a few kinds of low-cost food to feed our child/children because we were running out of food and money to buy food.*
E5.	*Couldn't feed our children a balanced meal, because we couldn't afford.*
E6.	*Our children were not eating enough because we just couldn't afford enough food.*
E7	Did you/or other adults in your household ever cut the size of your meals or skipmeals because there wasn't enough food or money for food?
E8.	If Yes to E7, how often did this happen?
E9.	Ever eaten less than you felt you should because there wasn't enough money to buy food?
E10.	Were you ever hungry but didn't eat because you couldn't afford enough food?
E11.	Did you lose weight because you didn't have enough money for food?
E12	Did you(or other adults in your household) ever not eat for a whole day because there wasn't enough food or money for food?
E13.	If Yes to E12, how often?
E14	*Ever cut the size of (any of your children's) meals because there wasn't enough food or money for food?*
E15	*Did any of the children ever skip meals because there wasn't enough food or money for food?*
E16	*If yes to E15, howoften did it happen?*
E17	*Were your children ever hungry but you just couldn't afford more food?*
E18.	*Did any of your children ever not eat for a whole day because there wasn't enough money for food?*

2. Methodology

Food insecurity analysis was done using the Rasch Model. The Rasch model is capable of simultaneously measuring individuals' ability to respond to a set of score items, while also assessing difficulty levels of the score items.It is the only IRT model in which total score across items characterizes a person totally. The sum of all these item scores gives each individual a total score (summary of all item responses) which is used for comparison. The person with a higher total score is said to possess more of the variable being assessed. The summing of item scores to get a single score implies that it is intended to measure a single/unidimentional variable. The Rasch model is named after George Raschwho made a case for models based on the principle of invariant comparison. The principle of invariant comparison states that, "The comparison between two stimuli should be independent of which particular individuals were instrumental for the comparison; and it should also be independent of which other stimuli within the considered class were or might also have been compared"(Rasch, 1961).Since formulation of the model by Rasch in 1960, various generalizations have been developed (Mair and Hatzinger, 2007). In food security assessment for example, two households assessed by two researchers should be independent of the researchers (http://www.rasch-analysis.com/rasch-model-specification.htm).

2.1 Model Testing

The Rasch model analysis generates 2 model fit sets of statistics, the infit and outfit. The weighted Infit and/or outfit statistics represent difference between item performance as expected by model under the model assumptions and observed household responses. They are used to assess extent to which items conform to the Rasch model specifications. They are based on the conventional sum of squared standardized residuals and is given as:

$$\frac{z^2}{N} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

Where: $z^2 = \frac{(X-E)^2}{\sigma^2}$ is the squared standardized residual

N is the number of observations summed

X is an observation

E is expected value based on Rasch parameter estimates

σ^2 is the modeled variance of X about its expectation.

The Infit/Outfit good range is 0.8 – 1.2 but values 0.7 – 1.3 are considered acceptable. When an item fits the model perfectly, the Infit/Outfit value equals one. Infit value above 1.0 indicates that the item discriminates less sharply than the average of all items in the scale while Outfit value above 1.0 indicates a weaker than average association of the items with the underlying conditions. The item Outfit is an outlier-sensitive fit statistic which like Infit compares the observed household responses with responses expected under the assumptions of the Rasch Model (Obayelu, 2012). Hackett et al (2008) in their gender respondent effects on Brazilian food security scale used weighted item infitvalues, arguing that infit values were most commonly used in food security scale assessment. They did not use the outfit statistics because they were heavily influenced by extreme responses. Obayelu (2012) in his comparative analysis of householdfood security status in Kwara and Kogi states in Nigeriahad both Outfit and Infitstatistics that were within the range of 0.8 and 1.2. According to him and other scholars, values higher than 1.2 indicate questions that are not consistently understood and should be removed or omitted. Values lower than 0.8 are more closely associated with the underlying condition and are undervalued in an equal weighted scale.Connel, Nord, Lofton and Yadrick (2004) in their Rasch model analysis to determine the food security status of older children in schools also reported Infit/Outfit statisticsof between 0.86 and 1.11 except one question whose outfit and infit statistics exceeded the range but they included it in their analysis. This study assessed both infit and outfit statistics and considered the range 0.7 to 1.3 as acceptable. Yong quoted Wang and Chen (2005) as recommending a plot of the mean squares on a graph, checking them visually to identify a misfit (Chong Ho Yu, 2010).This study also used a Rasch model graphical check.

2.2 Rasch Model Analysis using R Programming

The extended Rasch model in R statistical package was used to analyse the 18 items responded to by 577 households in Tororo and 598 households in Busia. The probability of a household's reaction to a stimulus was a function characterizing the household's food insecurity level as a latent trait. The log odds of a household i correctly responding to an item j was a function of ability (β_i) and the item's difficulty (δ_j). The location of a household on the Rasch scale was determined using the IRT indicator distribution I_{ij} with

$$\Pr(I_{ij}=1 \mid \beta_i \delta_j) = \frac{\exp(\beta_i - \delta_j)}{1+\exp(\beta_i - \delta_j)} \quad \ldots\ldots\ldots\ldots \quad (2)$$

Where I_{ij} is a dichotomous random variable representing response of household i to item j

i = 1, 2, ……., n are the households ($n_{Tororo} = 577, n_{Busia} = 598$)

j = 1, 2, ……., m (m=18) are the items

β_i = i^{th} household's ability parameter for i = 1, … n

This is also referred to as the severity of household food insecurity

δ_j = j^{th} item's difficulty parameter

Responses to the 18 Rasch Model questions were coded into binary codes. For the often/sometimes/never responses, "often" or "sometimes" were coded as affirmative (value = 1), and "never" was coded as negative (value = 0). For yes/no responses, "yes" was coded as 1 and "no" as 0. For "how often?" responses, "almost every month" and "some months" were coded as 1 and "only 1 or 2 months" and never were coded as 0. Thus, the data structure looked like Figure 1;

respondent	E1	E2	E3	E4	E5	E6	E7	E8	E9	E10	.	.	.
1	1	1	1	1	1	1	0	0	1	1

Figure 1: Modified Data Structure

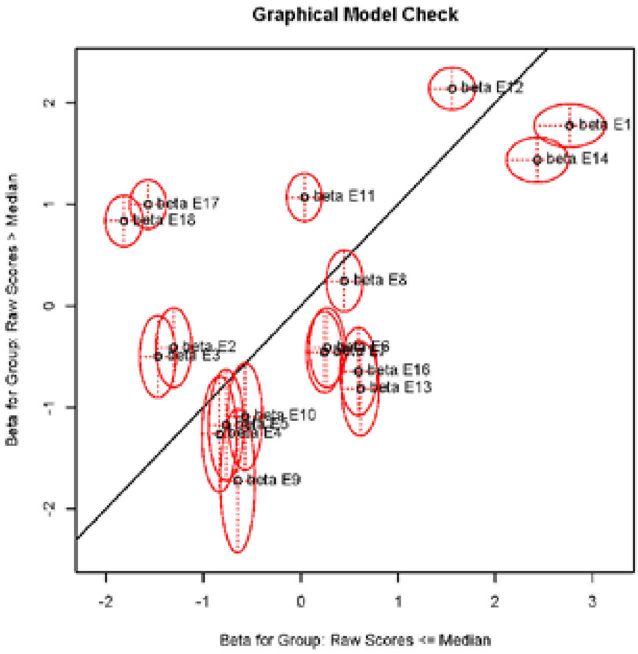
An algorithm for the Rasch model was developed and run using the R-programming software which also generated the Infit/Outfit statistics, Beta coefficients and probabilities for Busia and Tororo datasets.

The households were then classified using thresholds:Food Insecure (0.00-0.49); Moderately Food Insecure (0.50-0.79); Food Secure (0.80-1.00).

3. Results and Discussion

The graphical model check in Figure 2shows E9 and E13 to E18 to be outliers/misfits.Table 2 shows their outfit MSQs to be outside the acceptable range. However, their infit MSQ statistics except for E17 (infit MSQ 2.007) and E18 (infit MSQ 1.995) are within or close to acceptable range of 0.7 to 1.3.Therefore, given the infit statistics of E2 to E16 being within acceptable range, for the Rasch analysis we consider the 16 items E1 to E16. For Infit statistics for E17 and E18 (Table 2) are above 1.0 implying the item discriminate less sharply than the average of all items in the scale. Outfit statistics forE2, E3, E17 and E18 are above 1.0 indicating their weaker than average association with the underlying conditions.

Figure 2a - Graphical Rasch Model Check for all 18 Items



Generally, values higher than 1.2 indicate questions that are not consistently understood and should be removed or omitted. These include E2, E3, E17 and E18 that were earlier identified with outfit MSQ greater than 1. Values lower than 0.8 are more closely associated with the underlying condition and are undervalued in an equal weighted scale. These include E4 to E7, E9, E13 to E16 (see outfit MSQ, Table 2).

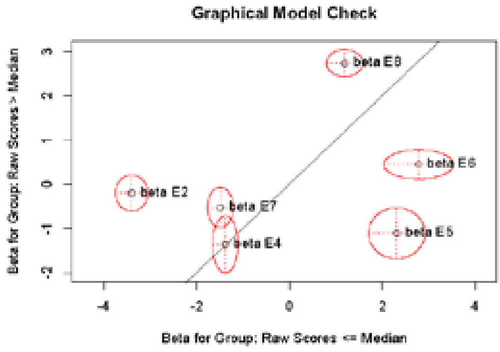
Considering the proposed interpretation of the infit/outfit ranges for parameter level mean square fit statistics by the website http://www.rasch-analysis.com/rasch-model-specification.htm, we have the following: Table 2showsvariables E17 and E18 with outfit MSQ↑2.0 implying theywould distort the measurements. Variable E3 has value between 1.5 and 2.0 and is therefore unproductive for construction of measurement. Most of the variables E2, E4 to E12, E15 and E16 have values between **0.5 and 1.5** and are therefore **good for productive measurement**. Variables E13 and E14 have values below 0.5 and are considered less productive for measurement, but not degrading and may produce misleadingly good reliabilities and separations. When we consider the infit MSQ, the variables all fit within the range 0.5 and 1.5 with the exception of E17 and E18. They can therefore be used for productive measurement.

Table 2 - Infit/Outfit Test Results for the 18 Items

	Chisq	df	p-value	Outfit MSQ	Infit MSQ	Outfit t	Infit t
E2	1286.13	1008	0	1.275	0.893	2.04	-2.32
E3	1530.81	1008	0	1.517	0.989	3.3	-0.21
E4	641.791	1008	1	0.636	0.726	-3.82	-6.63
E5	693.454	1008	1	0.687	0.824	-3.31	-4.11
E6	756.669	1008	1	0.75	0.754	-3.65	-6.36
E7	646.423	1008	1	0.641	0.833	-5.49	-4.17
E8	816.519	1008	1	0.809	0.924	-2.8	-1.86
E9	585.344	1008	1	0.58	0.689	-4.84	-7.75
E10	770.023	1008	1	0.763	0.78	-2.63	-5.32
E11	1265.53	1008	0	1.254	1.212	3.28	4.77
E12	1217.26	1008	0	1.206	1.187	1.67	4.37
E13	486.701	1008	1	0.482	0.618	-8.88	-10.59
E14	501.747	1008	1	0.497	0.685	-5.67	-8.87
E15	504.175	1008	1	0.5	0.71	-4.91	-7.92
E16	564.924	1008	1	0.56	0.67	-7.24	-8.94
E17	3125.6	1008	0	3.098	1.995	12.37	16.91
E18	3399.51	1008	0	3.369	2.007	11.72	16.53

Figure 2b shows that only two variables E4 (outfit MSQ 0.6, infit MSQ 0.7); and E7 (outfit MSQ 0.7, infit MSQ 0.7) were close to the line of model fit and would be considered to be within acceptable range as confirmed by their outfit MSQ/infit MSQ given in Table 3.

Figure 2b - Graphical Rasch Model Check for Children Items



Their values are within the productive measurement range of 0.5 to 1.5 when one considered both infit and outfit MSQs. Variable E6 infit MSQ of 0.5 also puts it within the productive measurement range. The other variables are misfits. Therefore, considering only the children factors for the Rasch analysis, variables E4, E6 and E7 can be used for food security analysis for household with children.

Table 3 - Outfit Infit Analysis for Households with children

Question	Chisq	df	p-value	Outfit MSQ	Infit MSQ	Outfit t	Infit t
E5	2501.445	614	0.000	4.067	1.178	5.49	2.42

E18	2161.368	614	0.000	3.514	1.142	5.25	2.46

3.1 Household Food Classification Using the Rasch Model

The probability of a household being food secure was derived from the Rasch Model with household food security status computed based on the following food security classification; Food Insecure (0.00-0.49); Moderately Food Insecure (0.50-0.79); Food Secure (0.80-1.00).

Table 5 - Household food insecurity status and the effect of number of household members by age category (<5 years; 5 to <18 years and 18 years and above)

Food Security Status/Characteristics	Insecure	Moderate	Secure	Total
Food Insecurity Distribution (%)	33.45	46.64	19.91	**1175**
HH average number of children <5 years old	1.61	1.64	1.74	**1.65**
HH average number of children 5 to <18 years old	2.7	2.47	2.45	**2.54**
HH average number with adults >18 years old	2.73	2.44	2.46	**2.54**

Table 5 shows that the largest percentage (46.6%) of households was moderately food insecure while one third (33.5%) were food insecure and only one fifth (19.9%) were classified as food secure. According to the analysis, food insecurity is more prevalent to households with more children aged 5 to 17 years, as it is with households having more adults compared to those with few children (5-17 years) and adult (18 years and above) household members. Children aged 5 through 17 years are classified as the most active whose bodies undergo various biological and physiological changes besides the intellectual growth (Kaiser et al., 2003). All these processes they undergo require a lot of energy as they form what type of adults they intend to be. Although, some of them may contribute to the household food production, their contribution is far less than their consumption since at most times, they are at school or involved in other activities that do not necessary contribute to the household food basket(Jyoti, Frongillo, & Jones, 2005).

Table 6 - Effect of Number of Children (less than 5 years and Less than 18 years) on Food Security Status in Uganda

Food Security Classification	Households with <5 year-old Children Status				Households with 5 to <18 year-old children status				Total
	With less than 5 year olds		Without less than 5 year-olds		With 5 to less than 18 year-olds		Without 5 to less than 18 year-olds		
	Frequency	Percentage	Frequency	Percentage	Frequency	Percentage	Frequency	Percentage	
Food Insecure	102	25.95	291	74.05	59	15.01	334	84.99	393
Moderate	137	25.00	411	75.00	119	21.72	429	78.28	548
Food Secure	57	24.36	177	75.64	47	20.09	187	79.91	234
Overall Total	**296**	**25.19**	**879**	**74.81**	**225**	**19.15**	**950**	**80.85**	**1,175**
	Pearson chi2 (2) = 0.2180 p= 0.897				Pearson chi2 (2) = 6.8066 p = 0.033				

When analyzed by age category of the children (Table 10), there is no significant difference in food security status for households with children under 5 years of age compared with those without this category of children (˙ 0.2180 2 Pearson s , p 0.897). However, a significant difference in food security status was found between households with children aged 5 to ↓18 years and households without this category of children (˙ 6.8066 2 Pearson s , p 0.033). It is possible that mothers tend to pay special attention to their very young children, providing for them required meals. When children grow older, they are expected to fend for themselves and may at times not be present for all the meals at home.When food is scarce, priority may be given to the younger children.

4.0 Conclusion

The effect of number of children in a household was studied(Owino, Wesonga, & Nabugoomu, 2014). Two main categories of children were thus hypothesized, those below five years and the 5 to 17 year olds with average household composition of 1.61 and 2.7 respectively for the sample of 1175 mainly rural-based households in the Eastern region of Uganda. Children 5 years to less than 18 years have a significant influence on the food insecurity status of a household. Attention needs to be given to understanding the food security situation of households with this category of children in order to plan for interventions.

ABSTRACT

This paper presents the methods for estimating comparable food insecurity prevalence rates across countries and time using the Food Insecurity Experience based Scale (FIES) or other similar food insecurity scales. Data are collected though the Gallup World Poll (GWP); however when data collected in national surveys using similar tools is available, those data are used to compute comparable prevalence rates. Results are provided regionally for 2014 and 2015.

Keywords: Food insecurity experience based scales, Rasch model, Voices of the Hungry project, global monitoring

PAPER

Introduction

The FAO Voices of the Hungry (VoH) project has developed methods to measure the access dimension of household or individual food insecurity based on the Food Insecurity Experience Scale (FIES), an 8-item questionnaire that elicits information on individuals' experiences and behaviours resulting from inadequate access to food (see World Summit (2009) for an official definition of this concept and United Nations (2015) to frame the project in the context of the post 2015 Sustainable Development Goals agenda).

The questionnaire was administered in 2014 and 2015 through the Gallup World Poll (GWP) in 147 and 140 countries, respectively. The GWP vehicle ensures continuous global monitoring; current plans are to continue including the FIES survey module (FIES-SM) in the GWP until at least 2018. The FIES-SM was translated into all major languages in each country where it was administered. The samples represent the adult population (15+ years) in each country, and sample sizes vary from 1000 up to 5000 individuals.

In parallel, several independent national surveys have fielded the FIES-SM or other similar food insecurity scales to monitor the food insecurity situation in the country. The samples collected in national surveys are representative at sub-national level, and sample sizes are much wider than in the GWP; therefore, when available, these data are used to calculate the prevalence of food insecurity in the country. The VoH methodology is based on the idea that it is possible to measure the severity of constraints on food access (an unobservable, or latent trait) based on people´s self-reported experiences. This is accomplished through the use of statistical techniques borrowed from Item Response Theory (IRT), commonly used in the educational and psychological testing fields, and in particular the Rasch Model (see Fisher & Molenaar, 1995 and Rasch, 1960). The model assumes that all questions refer to the same latent trait and form a scale of severity on which items (questions) and individuals (respondents) can be mapped. VoH developed a methodological extension of this model to ensure comparability among countries, surveys and from year to year. An R package to implement these methods can be downloaded from the FAO webpage.

The paper is structured as follows. Section 2 describes the FIES questionnaire and its rationale. Section 3 explains the methods to evaluate data quality, comparability across countries and time and scale stability across time. Sections 4 and 5 present some relevant results. Finally, Section 6 draws the main conclusions.

2. The Food Insecurity Experience Scale Survey Module (FIES-SM)

The FIES Survey Module (FIES-SM) is composed of eight questions1 with simple dichotomous responses ("yes"/"no"). Respondents are asked whether, at anytime during a certain reference period, they have worried about their ability to obtain enough food, their household has run out of food, or if they have been forced to compromise the quality or quantity of the food they ate due to limited availability of money or other resources to obtain food. (see FAO, 2013 for a description of the development of the FIES module).

In the version that has been applied globally through the GWP, questions are framed with reference to individuals and have a reference period of 12 months (Table 2-1). This is because the GWP is conducted in different months in different countries and a shorter recall period might result in lack of comparability across surveyed countries due to the possible seasonality of food insecurity.

Table

Questions in the Food Insecurity Experience Scale Survey Module for Individuals (FIES SM-I) as fielded in the 2014 GWP		
	Now I would like to ask you some questions about food. During the last 12 MONTHS, was there a time when… :	(label)
(Q1)	… you were worried you would not have enough food to eat because of a lack of money or other resources?	(WORRIED)
(Q2)	… you were unable to eat healthy and nutritious food because of a lack of money or other resources?	(HEALTHY)
(Q3)	… you ate only a few kinds of foods because of a lack of money or other resources?	(FEWFOODS)
(Q4)	… you had to skip a meal because there was not enough money or other resources to get food?	(SKIPPED)
(Q5)	… you ate less than you thought you should because of a lack of money or other resources?	(ATELESS)
(Q6)	… your household ran out of food because of a lack of money or other resources?	(RANOUT)
(Q7)	… you were hungry but did not eat because there was not enough money or other resources for food?	(HUNGRY)
(Q8)	… you went without eating for a whole day because of a lack of money or other resources?	(WHLDAY)

3. Data and methods

As outlined in Section 1, data analysed by the FAO VoH project are obtained through the GWP vehicle, with some exceptions where national data are available (USA, Mexico, Brazil and Guatemala). These national data were collected using tools that are similar to the FIES (see for instance Coleman-Jensen et al, 2015; IBGE, 2014; Tarasuk et al, 2014; Villagómez-Ornelas et al, 2014) and through equating procedure, it is possible to produce results that are comparable to the GWP results. In this section, we describe methods to test data quality, scale stability between years and comparability across countries and time. The data frame of reference is the GWP data, as national data require case-by-case considerations, and will not be described here.

3.1 Quality of Gallup World Poll FIES data

This section describes the methods to assess the quality of the FIES data. Data are analysed using the one-parameter logistic model (or Rasch model) which is used to estimate item (question) and respondent severity parameters along the same latent trait. This paper will not present a detailed description of the modeling framework applied to the FIES data, but further details can be found in FAO (2016), Section 4. Quality assessment statistics derived by the application of the Rasch model are briefly described below:

- **Missing responses** refer to cases where a respondent has stated that they do not know or have altogether refused to answer any of the FIES questions. Such cases are not considered in the analysis, but distribution of missing responses is reported as a general data quality indicator.

- **Item *Infit* and *Outfit* Statistics**: the FIES-SM was administered in close to 200 languages, in various countries throughout the world. Therefore, properly assessing the fit of all the items to the measurement model is crucial. The *infit* and *outfit* statistics assess the performance of the items included in the scale; that is the strength and consistency of the association of each item with the underlying latent trait. One of the Rasch model assumptions is that all items discriminate equally. Thus, ideally, all *infit* statistics should be 1.0;however, infit values in the range of 0.7 to 1.3 are considered acceptable. Similar standards may be applied to item *outfit* statistics. *Outfits* greater than 2.0 should be flagged for further assessment since outfit statistics are sensitive to even a few cases with highly improbable response patterns.

- **Rasch Reliability**: the standard Rasch reliability statistic is the proportion of total variance of severity of food insecurity in the non-extreme sample (omitting extreme raw scores 0 and 8) that is explained by the measure. A modified version of Rasch reliability that weights each raw score equally (rather than by the proportion of the sample in each raw score) is highly correlated with overall model fit across surveys using the same scale. This "Rasch reliability (equally weighted)" statistic is used as a proxy for model fit by VoH (see Nord, 2014).

▪ **Conditional Independence of items**: the Rasch model assumes that responses to any two items are correlated only because of their mutual association with the underlying latent trait. This means that we do not want two questions that ask about essentially the same behavior or condition caused by food insecurity (Nord, 2014). In general, conditional correlations greater than 0.30 between more than two pairs of items are flagged to identify the presence of a second dimensions in the data.

3.2 The updated global standard: how to ensure comparability across countries and time

Two potentially competing objectives of the Voices of the Hungry (VoH) project are to calculate prevalence rates of food insecurity that are comparable across countries and, for each country, comparable over time. The VoH report on the 2014 data (FAO, 2016) described the procedure for estimating prevalence rates that are comparable across countries. In order to calculate prevalence rates of food insecurity that are comparable over time in each country, it is desirable to have a fixed global standard scale and a fixed national scale for each country. Otherwise, if either of these changed over time, it would be difficult to distinguish real changes in national prevalence rates from changes due to random fluctuations in either the global standard or the country scale. Moreover, it is desirable that the global standard and national scales be quite precise. However single-year sample sizes of non-extreme cases (i.e., omitting cases that denied all items or affirmed all items) in the GWP are too small in most countries to provide sufficiently precise parameter estimates (cases with extreme responses are omitted when estimating the Rasch model through conditional maximum likelihood, as per Fisher and Molenaar, 1995). To overcome the small sample-size problem, three years of data will be used to calculate the final global standard and the final scale for each country. Thus, from year 3 onward, for each country, the national scales will be fixed. Prevalence rates will change only as the proportions in each raw score change. For 2014 and 2015, provisional national prevalence estimates will be based on a provisional global reference scale and provisional national scales. This will necessitate revising each country's prevalence estimates for 2014 in 2015, and for both 2014 and 2015 in 2016. Operationalizing this plan is straightforward. In the present paper, each country's scale is calculated based on aggregated data from 2014 and 2015 (when available, as a few countries did not have data collected in both years). Therefore, the calculation of country-specific item and raw score parameters, the global standard and thresholds on each country's scale are calculated using the pooled 2014-2015 data. Prevalence rates for each year are calculated by applying the same proportions-by-raw-score to each year's distribution of respondents across raw scores. From here on, we will refer to the country-data obtained by pooling data from 2014 and 2015 as "*pooled data*".

3.3 Scale stability between 2014 and 2015

The stability of the scale within the same country over time indicates that the meaning of the questions has been perceived in the same way by respondents over time. To test the stability of the scale we compare item severity parameters estimated for each country between 2014 and 2015. If, for one country, the difference between item parameter estimates is large enough and significant, we define the corresponding items as "unique". This implies that for that country those items have functioned differently between the two years. This may be due to the sampling framework, to a different interpretation of the items due to language adaptation or to poor fit of the Rasch model in one of the two years. If stability of the scale is observed in the large majority of countries, the VoH strategy is to consider the severity of the items estimated for the pooled data to calculate the global standard, estimate person parameters, measurement error and prevalence rates, and therefore to produce comparable results across countries and over time. The VoH approach to assess year-to-year stability of the scale considers three factors: absolute difference in item parameters, margin of error of item parameters, and the possibility that one or two items are unique but the rest are good.

4. Results

4.1 Quality of Gallup World Poll FIES data

In this section, we describe the results on the performance of the FIES in the 2015 round of the GWP, and in the pooled 2014-2015 data. A brief comparison with 2014 results is also included, but not described in detail (as already done in FAO, 2016). The **percentage of cases with any missing responses** is relatively low in the 2015 and pooled data. This percentage is higher than 5% for 13% of countries in 2014, 18% for 2015 and 14% of countries in the pooled data (results not shown). Table 1 includes a **summary of item infit statistics** for the 2015 and the pooled GWP samples. It can be noted that the infits improve considerably using the pooled data compared to 2015 and 2014 (this latter comparison is not shown). This result supports the use of pooled data to estimate item and person parameters rather than a single-year.

Table 1. *Summary of item infit statistics*												
	2015	*Pooled*	*2015*	*Pooled*	*2015*	*Pooled*	*2015*	*Pooled*	*2015*	*Pooled*
Item	Infit 0.8 to 1.2 (% of cases)	Infit 0.8 to 1.2 (% of cases)	Infit 0.7 to 1.3 (% of cases)	Infit 0.7 to 1.3 (% of cases)	Mean infit	Mean infit	Minimum infit	Minimum infit	Maximum infit	Maximum infit

Regarding the **outfit statistics**, the comparison between the single-year results and those based on the pooled data leads to less discrepant values (not shown). This is in line with the idea that possible anomalous response patterns need to be detected using single-year data. Mean **conditional correlation** is very low considering both the pooled and the year-by-year data (results not shown). Maximum conditional correlation instead improves considerably using the pooled data (Table 2 shows a comparison with 2015).

The mean **reliability** (equally weighted across raw scores) for the pooled data is 0.74 and ranges between 0.68 and 0.83. This result is consistent with the year-by-year analyses. In summary, the pooled data leads to improved item performance (and therefore the estimation of person parameters and prevalence rates) in terms of infits and residual correlation. This ensures that prevalence rates calculated according to parameters estimated on the pooled data are not only comparable, but also more reliable than those obtained using year-by-year parameters.

Table 2. *Maximum residual correlation (numbers in red refer to the 2015 samples while numbers in black refer to the pooled data)*

4.2 Comparability across countries and time

The updated global standard based on the pooled data (not shown) is only slightly different from the one calculated using 2014 data only (see FAO, 2016). The provisional thresholds for moderate or severe, and severe food insecurity considering the updated global standard change as follows: the threshold for the moderate or severe level is less severe (-0.29 versus -0.25 using the 2014 data only) while the threshold for the severe level is more severe (1.85 versus 1.83 using the 2014 data only). Items are considered common when their severity in a country differs from the one on the global standard by less than 0.35 units on the global reference scale. In 93 percent of the countries, a set of at least 5 common items was identified, thus allowing a robust equating procedure to be carried out. This result is in line with results of equating based on the 2014 data only.

4.3 Scale stability between 2014 and 2015

The stability of the scale between 2014 and 2015 was analyzed for countries where FIES data in the GWP were available for both years. Of 136 countries considered in the analysis, 99 (73.9%) have all common items between 2014 and 2015, 26 (19.4%) have only one unique item, 7 have two unique items and 2 have three unique items. No country has more than 3 uncommon items. The stability of the scale can be considered, overall, very good. It is worth noting that the instability observed in the GWP may be mostly due to differences in samples (possibly primarily different languages), and may reinforce the VoH plan to base the global reference scale on three years of data and revise prevalence estimates accordingly. A threee-year GWP sample is likely to be more representative of the population of interest.

5. Prevalence rates at country and regional level

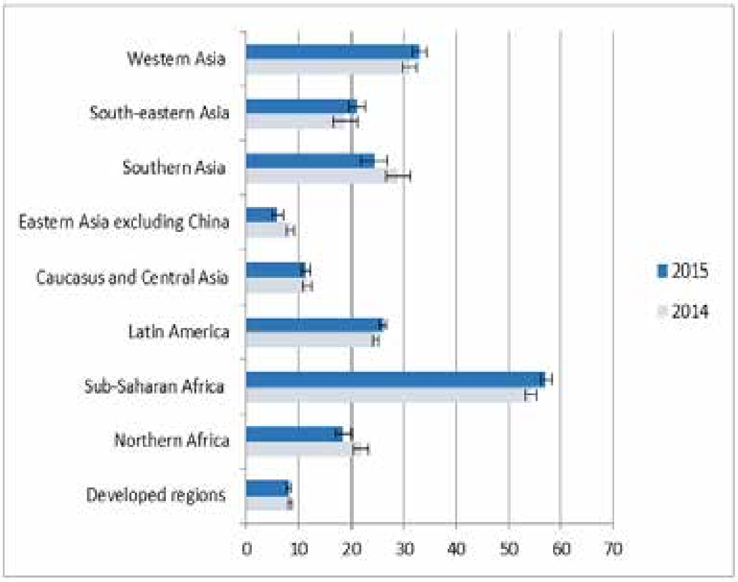
Table 3 shows the distribution of countries for different classes of food insecurity at moderate or severe and severe levels for 2014 and 2015. This distribution does not show particular changes in the two years, neither for the moderate or severe level nor for the severe level. Figure 2 represents the food insecurity prevalence rates calculated at moderate and severe level for the FAO regions, comparing 2014 and 2015. Margins of error are also included. It can be observed that the majority of the regions do not show a significant change infood insecurity prevalence rate over time.

Table 3. *Distribution of countries for different classes of food insecurity*

	Moderate or severe		Severe	
Range (%)	% of cases 2014*	% of cases 2015*	% of cases 2014	% of cases 2015
<5	8.2	8.6	17.0	15.7
5-14.99	32.7	35	33.3	32.9
15-24.99	17.7	12.1	14.3	15
25-50	21.8	22.9	16.3	17.9
>50	19.7	21.4	19.0	18.6

* Prevalence rates for 2014 and 2015 are calculated using the equating with the updated 2014-2015 global standard.

Figure 2 - Prevalence of food insecurity (moderate+severe) by FAO region, 2014 and 2015



6. Conclusions

The FIES provides a quick and reliable tool to estimate the prevalence of food insecurity at different levels of severity. The application of the FIES-SM in the GWP data in 2014 and 2015 has shown how comparability of the results is reached not only between countries, but also over time (using the pooled data approach). By pooling the data from 2014 and 2015 to estimate the Rasch model parameters corresponding to which prevalence rates are calculated, the reliability of the measure is increased. A three-year based analysis (using the 2016 GWP data) will provide a robust global standard for monitoring the evolution of food insecurity worldwide.

ABSTRACT

The objective of this paper is to summarize a set of state-of-the art analyses of the key issues involved in the measurement of food consumption in national household surveys. Food consumption data from household surveys are possibly the single most important source of information on poverty, food security, and nutrition outcomes at national, sub-national and household level, and contribute major building blocks to global efforts to monitor progress towardsthe major international development goals. This objective is achieved through a series of case studies from a diverse set of countries--including developing countries, the OECD, Canada and the U.S.--addressing the main outstanding research issues as identified by a recent assessment of 100 existing surveys (Smith et al., 2013). The individual research papers examine, both theoretically and empirically, how survey design options affect the quality of the data collected and, in turn, the implications of those options for statistical inference and policy analysis.

Keywords: Food Consumption; Household Surveys: Survey Methods

PAPER

1. Background and justification

Food constitutes a core component of a number of fundamental, broad-based welfare indicators, such as food security, nutrition, health, and poverty. It makes up the largest share of total household expenditure in low-income countries, on average accounting for about 50% of the household budget (USDA, 2011). Low levels of access to food was an important factor contributing to the estimated 850 million individuals who were chronically undernourished in 2012-14 (FAO, 2014). Proper measurement of food consumption is therefore central to the assessment and monitoring of the well-being of any population, and therefore is of interest to multiple international, national, and local agencies, and to several development domains – social, economic, and human. Data on food consumption are needed, for example, to monitor the achievement of the United Nations' First Millennium Development Goal, to eradicate extreme poverty and hunger, and may play an even greater role in monitoring the ambitious post-2015 sustainable development agenda. Similarly, its measurement is crucial to assess and guide FAO's mandate to eradicate hunger, food insecurity and malnutrition, as well as the World Bank's twin goals of eliminating extreme poverty and boosting shared prosperity. Sound food consumption data is also required by national and local governments, as well as non-governmental organizations, to guide their local and regional analysis, programming and policymaking. The lack of food consumption data or its mis-measurement may result in the mis-allocation of funding and may compromise the design, monitoring and evaluation of programs or policies.

The last two decades has witnessed unprecedented progress in the production and dissemination of household consumption and expenditure data across the developing world. In 1990, the World Development Report published by the World Bank was based on data from only 22 countries, and no country had more than one survey. Today there are 125 countries with consumption or expenditure information, and many of them have multiple surveys, adding to a total of more than 850 surveys (Ravallion and Chen, 2011). The number of countries with no poverty data over a 10 year period declined from 33 percent to 19 percent since the 1990s, whereas the share of countries with 3 or more data points over a 10 year period increased from 27 to 41 percent over the same period (Serajuddin et al., 2015).

Depending on their primary objective, the surveys collecting information on household consumption or expenditure take different forms, including Household Budget Surveys (HBS), Income and Expenditure Surveys (IES), or ‗multi-purpose' or ‗integrated' household surveys, like the Living Standards Measurement Study surveys. We refer to this family of surveys, which are usually nationally and sub-nationally representative, as Household Consumption and Expenditure Surveys (HCES).

While the variety of HCES purposes naturally translates into different designs, the dramatic increase in the number of household surveys in developing countries has been associated with a proliferation of approaches and methods used in the collection of food data that is not only due to their different purposes or country-specific considerations. While there exist international guidelines and recommendations for the design and implementation of each of the distinct types of HCES surveys, they are specific to each type of survey, are generally not prescriptive, lack coherency and usually leave much flexibility to national survey statisticians. Consequently, we observe heterogeneity in methods, even within the same type of survey, both across countries, as well as within countries over time.

The notion that survey design matters is not new, as the work of Mahalanobis and Sen (1954) and Neter and Waksberg (1964) more than half a century ago testifies. Despite the fact that consumer spending plays a central role shaping a variety of key economic behaviors—savings, earning processes, insurance, responding to shocks and tax policies among others (Browning et al. 2014)- the issue has traditionally been largely neglected by economists. The longstanding relative neglect of food consumption metrics has also contributed to the lack of guidelines and has been another source of the proliferation of variability in HCES questionnaire design, data collection methods and data processing practices. The lack of coherence is the outcome of limited and inadequate guidance, the lack of a body of conceptual, theoretical and empirical literature, including the lack of empirical examples of the tradeoffs involved in alternative available survey design options. In combination with the low level of funding that most low- and middle-income countries' national statistical organizations—which are the HCES implementing agencies of—have experienced over the past two decades, this confluence of factors has trapped many countries in a vicious cycle of statistical underdevelopment and underperformance which manifest themselves in many ways (Kiregyera 2014: 2). This situation is not unique to HCES: it is part of a broader, national statistics for development problem that has attracted increasing attention in recent years (Jerven 2013), and has spawned growing recognition of the need for a global strategy for improving statistics. This is encouraging. It makes for a more enabling environment for introducing change, suggesting the timing is good and the prospects for addressing common roots of these problems are promising. To date, much of the focus has been on agricultural and rural statistics (FAO 2010; World Bank, et al., 2011). While it is clear that there is a great deal of overlap between food and agriculture issues (Carletto et al., 2015), there remains a longstanding past due and increasingly urgent need to more directly address food consumption issues per se (Herforth & Hoberg 2014, Fiedler et al., 2012).

In recent years there has been a surge of interest in the measurement of household expenditure. Most of this interest has been generated by two factors: a) increasing evidence that changes in survey instruments over space and time compromise our ability to draw inferences and conduct trend analysis, and b) the persistent fall in the quality of Consumer Expenditure Surveys; particularly that related to under-reporting in developed countries. These concerns prompted two recent assessments of the current state of measurement of household expenditures. . One, initiated by the U.S. Bureau of Labor Statistics with the aim of producing recommendations for re-designing the U.S. Consumer Expenditure Survey, was undertaken by an expert panel formed by the National Research Council's Committee on National Statistics (Natl. Res. Counc., 2013). The second was the 2011 Conference on Research in Income and Wealth sponsored by the National Bureau of Economic Research, which focused on improving the measurement of consumer expenditures (Carroll et al, 2014). However, these initiatives were restricted to developed countries, only focus on total household expenditure - as opposed to food expenditure, and focus primarily on one particular type of survey - HBSs. Nevertheless, they provided useful lessons for all countries: they further demonstrated the enormous heterogeneity in methods and the growing urgency of a strategy, or at minimum criteria, for guiding countries through the diverse, oftentimes conflictive available possible approaches, while calling attention to the limited consensus as to how best to collect these data, and renewing the call for more research in these areas.

With respect to evidence from developing countries, Deaton and Grosh (2000) provided a comprehensive review of the issues and data needs for the measurement of consumption in household surveys, drawing on the lessons derived from LSMS surveys. The bulk of that work is now more than 20 years old. Since then a few other papers have analyzed the implications of particular aspects of survey design on total expenditures, poverty and inequality measures. For example, Jolliffe (2001) and Pradhan (2001) evaluate the impact of varying the length of the consumption list in El Salvador and Indonesia respectively; Gibson et al (2003) look at the effect of changing the length of the data collection period for the case of China; Beegle et al (2012) compare results from 8 questionnaire designs which include variations in methods of data capture, level of respondent, length of reference period, number of items in the recall list, and the nature of the cognitive task required of the respondent; and Backiny-Yetna et al (2014) compare different data collection methods, which include 7-day recall period, a 7-day diary, and a usual month'.

There is arguably a need for more systematic research on some topics before a general consensus about best practices on the collection of food consumption or expenditure data in household surveys can be derived. While the lack of broadly accepted practices affects all aspects of household consumption or expenditures, it is particularly pronounced in the case of food consumption: not only because there exist few papers that focus explicitly on food (e.g. the work by Backiny-Yetna et al, 2014), but also because the research has almost exclusively looked at only mean expenditures, and poverty or inequality measures.

The impact of survey design on other moments of the distribution is less-well understood., and as mentioned before, with increasing interest in using the data to analyze other dimensions of well-being, such as food security, health, diet quality, nutrition and the agriculture-nutrition nexus, which has given rise to the need for additional, more detailed information, The increased availability of HCES has sparked the use of these surveys in ways not conceived of when they were first designed. While some HCES—such as LSMS—were originally designed to be multi-purpose, others, such as HBSs, were originally more narrowly focused. HBS, for instance, originally had the clear goal of collecting the data necessary to (1) define and update the basket of commodities for the Consumer Price Index (CPI), (2) measure household consumption for the System of National Accounts (SNA), and, in some cases, (3) define the country's poverty line in order to track the living standards of the population, study the determinants of poverty and of other dimensions and dynamics of well-being, and to better understand public program coverage, participation and impacts. As they and other HCES have morphed into or become more multi-topic surveys, they have collected additional data. In some cases they have been modified to provide a more comprehensive picture of the household and, in some cases, of the individual household members' characteristics While still collecting the consumption data required to comply with their original mandate to measure economic conditions, poverty and inequality, they have come to collect more information on a wider array of topics, such as housing conditions, education, health, assets/wealth, employment, and income, among others. Moreover, as the data are being increasingly re-purposed by new stakeholders with altogether new interests, they have brought with them demands for altogether new types of data and new approaches to the surveys. HCES are now being used to for a host of new food consumption and nutrition-related analyses, which they were never intended to support. Among these new applications are the use of HCES to conduct subnational food security analysis, compile subnational food balance sheets; assess diet quality and dietary change (Monteiro et al., 1994; Nascimento et al., 2011; Levy et al., 2012, Coates 2013); analyze the relationship between household food expenditure and malnutrition (Campbell et al., 2010); estimate sodium intakes (Sarno et al., 2009); identify and monitor overweight and obesity (Kolodinsky & Goldstein 2011; Lobato 2009); to measure nutrient availability or proxy nutrient intakes (Pérez-Cueto et al., 2006; Bermudez et al., 2012; Fiedler & Helleranta 2010; Fiedler et al., 2012; Fiedler et al., 2013a; Fiedler et al., 2013b; Fiedler et al., 2013c; Fiedler et al., 2014a; Fiedler et al., 2014b; Fiedler & Lividini, 2014; Fiedler 2014); assess the adequacy of availability of fruits and vegetables to meet global health needs (Siegel et al., 2014); identify the most common food sources of specific nutrients (Bermudez et al., 2012; Fiedler et al., 2013a); to identify the number, percentage and location of households that acquire fortified or fortifiable foods, and model the impact of fortification programs (Fiedler & Afidra 2010; Nascimento et al, 2011; Marchioni et al, 2011; Claro & Monteiro 2010; Levy et al. 2012; Levy et al, 2009 Bermudez et al., 2012; Fiedler & Helleranta 2010; Fiedler et al., 2012; Fiedler et al., 2013a; Fiedler et al., 2013b; Fiedler et al., 2013c; Fiedler et al., 2014a; Fiedler et al., 2014b; Fiedler & Lividini, 2014; Fiedler 2014; Ricciuto et al., 2007; Beatty 2008; Kirckpatrick & Tarasuk 2008; Monteiro et al., 2000; Mondini & Monteiro 1994); to model the impact of biofortification programs (Fiedler et al., 2013; Fiedler & Lividini 2014; Lividini & Fiedler 2015; Fiedler & Lividini 2015), as well as to conduct feasibility and cost-benefit analyses of individual fortification, biofortification and supplementation programs, as well as of portfolios of combinations of programs (Fiedler et al., 2013; Fiedler & Lividini 2014).

This blossoming of the use of HCES to address food and nutrition issues reflects the intersection of three sets of events: (1) the growth in evidence-based policy, (2) the fact that food and nutrition issues have been at center-stage in international development for the past decade, and (3) the fact that there has long been a dearth of nationally representative dietary assessment studies which has severely constrained the nutrition evidence base and has throttled global progress in improving nutrition. Despite various shortcomings, household consumption and expenditures surveys (HCES) are increasingly being used to address the food and nutrition information gap because they contain a wealth of information about food acquisition and consumption; are being done with increasing frequency in an increasing number of countries (Serajuddin, 2015); have large samples; are statistically representative at subnational levels; and are much less costly than other dietary assessment data sources because these multi-purpose surveys are already being conducted and paid for by other government agencies (Fiedler 2013).

While there has been a surge of interest and HCES analyses of nutrition and food security issues, the potential of this particular type of repurposing of HCES has yet to be realized for several reasons. First, there is a lack of awareness of public nutritionists and food policy analysts about what these data contain. Second, there is a need for further research and action to improve the quality and utility of these data. To date, the nutrition community's HCES-related role has been overwhelmingly that of a passive user of HCES data from surveys that have already been conducted. Many HCES shortcomings, however, stem from design and implementation issues. If the nutrition community—with its unique skills and experiences—were to get more proactively involved in the design, implementation and analyses of HCES, they could be strengthened substantially as a tool for evidence-based food and nutrition programming and policymaking. At the heart of this Special Issue of Food Policy is the distillation of what we currently know about household survey design, the identification of better practices, the presentation of original, state-of-the-art research addressing the key methodological agenda items involved in strengthening HCES, which were recently identified in a review of 100 HCES (Smith et al., 2013). These are essential next steps to build global momentum and global consensus to enable exploiting this unique, shared, golden opportunity to re-purpose HCES and enable their better fulfilling this role, while at the same time making public nutritionists and food policy analysts more aware of what HCES have to offer.

A majority of the papers to be included in this Special Issue were initially prepared for a workshop jointly organized by FAO and the World Bank in Rome in November, 2014. They reflect a diversity of disciplinary approaches (statistics, economics, nutrition, food security analysis), and broad geographical coverage (with studies from African, Asian, Latina American and OECD countries – EC, US, Canada).

The main commonality linking the studies in the Special Issue is that they look at alternative or new methods from existing datasets, sometimes purposely collected for methodological studies, in order to identify the implication of survey design for measurement and analysis, and to translate those into recommendations for scalable approaches for future survey design.

The start of this work program was preceded and to some extent sparked by a desk review of the reliability and relevance of the food data collected in national household consumption and expenditure surveys, which was jointly leaded by the International Household Survey Network (IHSN), FAO and the World Bank (Smith et al, 2013). That assessment identified the multiple purposes these household surveys serve, proposed a method to assess the reliability and relevance of survey questions, and applied the method to 100 household surveys from low- and middle-income countries, a sample that resulted from selecting the most recent nationally representative household survey from each developing country, with the only condition of having enough documentation. The assessment points to many areas where survey design and questionnaires can be significantly improved, among which five were selected as key themes for the Rome workshop and this Special Issue. They are the following:

• Measuring food acquisition versus measuring food consumption. The term food consumption is interpreted in many ways. For the economists it is the amount of money spent to acquire food; for the food security analysts, it is the amount of food available for consumption; while for the nutritionists it is the amount of food actually eaten. Food data were initially collected in HCES simply to construct the consumer price indices or to inform national accounts. Therefore, the food data collected referred primarily to items acquired through purchase by the household during the reference period. Over the years, food items procured through own-production, barter, gifts and payment-in-kind were introduced into these surveys to better apprehend food acquisition in rural areas. These surveys aimed at capturing food that was acquired by the household in order to be consumed. However, with time, surveys have been also focusing on food items actually consumed by the household and the various sources from which food was acquired (purchases, own-production or gifts). Papers in the volume will address issues related to the differences between food data collected in acquisition type versus consumption type surveys and the use of these data to conduct specific analysis on consumer behavior.

• Measuring Individual vs Household Consumption. The food consumption/expenditure modules of household consumption and expenditure surveys (HCES) capture household, but not individual, level information. Yet, food and nutrition policies and programs often require information about which foods and nutrients are consumed by which groups of individuals, and in what quantity. While individual dietary intake data are often more appropriate for meeting these information needs, HCES are more widely available and conducted more regularly than individual-level dietary assessments. Furthermore, most dietary surveys do not assess the intake of all household members, making it difficult to plan programs, such as fortification programs, that are intended to benefit more than just one type of target individual. Until individual-level dietary data collection becomes routinely available, understanding whether and how household-level data can be used to approximate actual individual food and nutrient consumption is a worthwhile undertaking. Some of the papers in the volume will assess methodologies for deriving individual level estimates form household data.

• Recall and reference periods: benefits of bounding recall, and impact of length of recall periods on recall quality and telescoping. Nutritionists favor shorter recall periods (e.g. 24-hour recall) whereas expenditure surveys commonly use recall of 1 week or more. The impacts of recall period decisions on the quality of the data for different uses are far from being fully understood, and some of the papers in the volume will address some of the questions related to that. To assess usual consumption, how many times should data be collected from households and for what observation or reference period? What difference will extending reference periods and conducting repeat visits actually make to estimates of poverty and nutrient insufficiencies?

• Food consumed away from home (FAFH) and cooked/packaged meals. FAFH and prepared foods represent an increasing share of food consumption, and will continue to do so as GDP per person grows, and food systems evolve. This is an area where many surveys could improve, but where evidence on the robustness of alternative methods is weakest. A sub-set of the papers in this volume will look at the implication and methods for capturing FAFH, whether eaten in commercial or public establishments (e.g. restaurant, schools).

• Length and specificity of survey food lists. For many analytical purposes survey food lists need to be sufficiently detailed to accurately capture consumption of all major food groups making up the human diet. There are trade-offs in the decisions involved with coming up with a survey food lists of the 'optimal' length and specificity, that re not well understood. Some of the papers in the volume will attempt to provide evidence to help survey design practitioners and analysts address those concerns, and highlight the implications for policy analysis.

2. Research findings

The key aspects of the special issue are as follows:

1. The special issue brings together a collection of empirical studies on the implications of different survey design options for the measurement and estimation of different indicators and parameters of crucial importance to several development domains. The data used in these studies include nationally-representative data and detailed case studies across a range of countries from several of the main developing regions, as well as from developed countries. The results of the study will therefore be of interest to a global audience.

2. The special issue confronts the issue of survey design prioritized by a major international review, thus responding to the research needs and priorities reflecting the shared concerns of the main international experts on the topic. In addressing those concerns, the special issue will draw on expertise from a range of disciplines and institutional backgrounds, mirroring the diverse readership of Food Policy.

3. All the papers in the special issue have now been received and the findings will be summarized in the final version of this papers when it is submitted by the deadline of July 15.

THEMATIC SET

B11 FOOD AND NUTRITION SECURITY STATISTICS: METHODS AND APPLICATION

Session Organizer
C. Cafiero | | FAO | Rome | Italy

ABSTRACT

Food security at household and individual level is widely understood as the ability to access, on a continued basis, adequate amounts of food of the right quality in ways that do not otherwise compromise the overall welfare. Measures of household or individual access to food can then be used to inform indicators of access to food at local, national and global level to be used in monitoring progress towards the objective to ensure food security for all. How to measure food access though has been a long debated issue. Several methods have been proposed, ranging from the analysis of food expenditure data collected through household budget surveys to the analysis of quantitative food consumption data collected over short reference periods, that of individual dietary intake and nutritional status data, and including the analysis of experience-based food insecurity scales that look at the ability to access food as an individual or household latent trait. This session aims at tacking stock of existing methods to measure households and individuals' ability to access adequate amounts of food, and to discuss how such data can be used to inform food security assessments at local, nationaland global levels. Submission of papers that discuss methods for collection and analysis of data on food expenditure, food acquisition, food consumption, dietary intake, dietary quality, experience-based food insecurity scales, nutritional status, and welfare losses due to inadequate access to food is encouraged. We particularly encourage submission of papers discussing the statistical properties of the various indicators, and presenting methodological advances in the development of valid indicators of inadequate access to food, with reference to cost effectiveness, reliability, and the possibility to compare classifications at various degrees of severity of the inability to access food.

ABSTRACT

Using data from the third Cameroonian Household Consumption Survey conducted in 2007 by the National Institute of Statistics, this paper aims to estimate the food security status and identify the factors associated to food insecurity in rural households of Cameroon. It is found that the incidence of food insecurity in rural area is about 33.8% using the household caloric acquisition method of estimating food security status. Further analysis using the bivariate logistic regression method identified region of residence, landless status, and household-head's age as important determinants of food insecurity. Far-north's households are at least 1.5 times more exposed to food insecurity than other households of the country. Moreover, households who are sharecropper have 1.7 times more chance to experience food insecurity than those who are landowners. In addition, having a household head aged 40-49 and 50-59 increases the risk to be in food insecurity by 1.5 and 1.3 respectively, compared to households that head's age is less than 30. The region of the Far North should be preferred for eventual policies of fighting against food insecurity. Also, rural households that the head's age is high must have priorities, and resident rural population should be encouraged and helped to own land.

Keywords: Food Insecurity, Calorific contribution, Cameroon.

PAPER

1. Introduction

Due to its agro-ecological diversity[1], Cameroon shows great potentialities for agricultural production and livestock. Up till the late 1980s, the country was considered self-sufficient in agricultural production and played a role of food garret for its neighbouring countries (Gabon, Central African Republic, Chad, etc.). In the early 1990s, the country began importing massive quantities of cereals and other foodstuffs. This situation leads the Government and International Organisations to pay more attention to food security questions in the country.

In 2007 and 2011, the World Food Programme (WFP) conducted a Comprehensive Food Security and Vulnerability Analysis (CFSVA) in Cameroon in order to provide an understanding of food security and vulnerability situation of rural households. The results of these studies indicate that the particular case of rural households in Cameroon is not rejoicing. This situation is particularly weakened due to the level of poverty in rural area. Indeed, according to the results of the third Cameroonian Household Consumption Survey conducted in 2007 by the National Institute of Statistics, the rate of poverty in rural area was 54.5% against 11.9% in urban area.

It is then imperious to know for rural households, what are the socioeconomic and demographic factors that influence their food security situation. Accordingly, this paper aims to estimate the food security status and identify the factors associated to food insecurity in rural households of Cameroon.

The rest of the paper is organized as follows. Materials and methods are presented in section 2, results are presented and discussed in section 3 and section 4 concludes the paper.

2. Material and Methods

In this section, we give the definition of food security, and present the methodology that is used to measure it. We also describe the methodology that is used to identify the key determinants of food security status.

[1] The country is divided into five agro-ecological zones, with each of them suitable for specific agricultural production and livestock.

2.1. The food security concept

The standard definition of food security in use is that adopted during the World Food Summit held in 1996. According to this definition, "*food security exists when all people, at all times, have physical, social, and economic access to the sufficient food which meets their dietary needs and food preferences for an active and healthy life*" (FAO, 1996). This definition points out four distinct but interrelated elements of food security, which are essential to achieve food security: *food availability*, *accessibility*, *utilization*, and *sustainability of access*.

2.2. Instruments of measuring food security

In this paper, we use an indicator related to the calorific contribution approach of measuring food insecurity (see Kidane et al., 2005, and Muhoyi et al., 2014). The quantities of food consumed by households or individuals, recorded during a survey, are converted into calories using calories tables. The Household Calories Availability per adult equivalent (HCAeq) is then computed for each household as follows:

$$HCA_{eq} = \frac{\sum_{j=1}^{m} Q_j A_j}{\sum_{i=1}^{k} u_i}$$

Here, u_i is the number of adult equivalent of the household i, Q_j is the quantity of the product j (food) acquired by the household, and A_j is the quantity of calories contained in 100 grams of product j. Calories consumption per "adult equivalent" is needed to take into account the variation of individual dietary energy needs by age and sex and the difference between households in their demographic composition.

We now need a threshold to decide, given the value of the HCAeq, if a given household is food-secure or not. In this regard, we calculate the daily required calories for each household's member depending upon the recommended (FAO, 1996) caloric requirement for a person, considering its age and sex, and sum it up for each household. The household calories availability per adult equivalent is used to compute calorific indicator of food insecurity similar to a monetary poverty indicator:

$$P_\alpha = \frac{1}{N} \sum_{i=1}^{q} \frac{(Z - D_i)^\alpha}{Z}$$

Here, D_i is the threshold of calories consumption. When $\alpha = 0$, P_0 defines the food insecurity rate (headcount); when $\alpha = 1$, P_1 defines the food insecurity gap (depth); and when $\alpha = 2$, P_2 defines the squared food insecurity gap (severity).

2.3. Data

The Data used in this study are from the Third Cameroonian Household Consumption Survey (ECAM3) conducted from September to December 2007 by the National Institute of Statistic (NIS) of Cameroon. The survey, which main focus has been on measuring household"s living standards, concerned about twelve thousands households. With respect specifically to food, data are collected on all foods acquired by households, including their food purchases, foods consumed from their own farms or garden and food received in kind. The survey collected detailed information on daily expenditures of households in food consumption for two weeks. Our sample consists of 3,800 rural households.

The major difficulty encountered in calculating calorific contribution is the fact that in most cases, food items acquired by households was measured using Local Unit of Measure (LUM). The main operation done in data set has consisted to transform household"s food acquisitions in standard units (Kilogram) by using appropriate coefficients of conversion.

2.4. Determinants of food security

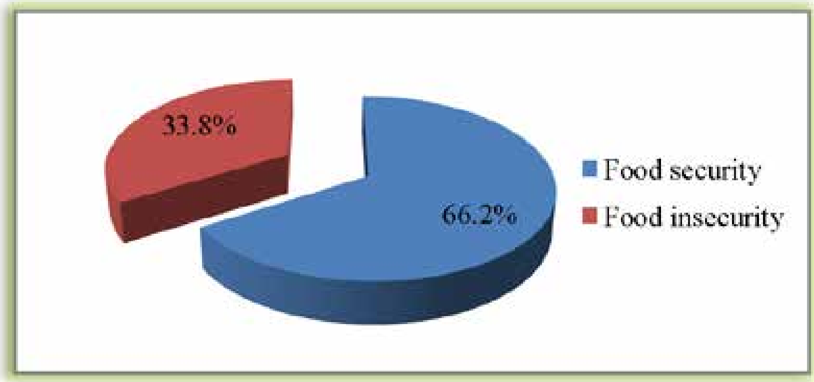
In order to quantify the probability of risk to food insecurity according to socioeconomic factors, we perform a logistic model. The binary form of the dependent variable i.e. „0" for food secure and „1" for food insecure, guided us to use this model (see for example Feleke et al., 2005; Babatunde et al., 2007 and Bashir et al., 2012). The explanatory variables in our model are: household head age, gender of household head, education of household head, household size, farmland size, region of residence, distance between households and the nearest market, household-head's socioeconomic group and diversification of household-head's activities.

3. Results and discussions

3.1. Descriptive statistics on food insecurity

Here, we present the mains results obtained from the computation of the proxy indicator of food insecurity. It is important to recall that threshold of food insecurity using calorific approach is variable[2] (see the section on materials and methods); that is two different households can have different thresholds according to their composition. For comparison, we also provide results obtained using a fixed threshold of 2,400 KCAL per person per day.

Figure 1 - Situation of food insecurity of Cameroonian's rural households



Source: Authors' calculations using CHCS 2007

From the Figure 1, we see that the incidence of food insecurity in rural area is about 33.8%, showing that more than one-third of rural households were subsisting on less than daily per capita calorie requirement during the survey period in 2007. This rate is not very far from the one that was found by the WFP during his Comprehensive Food Security Household Survey, using the Food Consumption Score to analyze food insecurity.

The results of the test performed to compare food insecurity incidences obtained using variable and fixed threshold respectively are reported in the last column of Table 1. They reveal at p↓5% that the two food insecurity incidences are significantly different for all regions. We also note a strong variation in the incidence of food insecurity across regions.

This can be explained by differences in eating habits from one region to another or by inequalities between regions in term of food accessibility.

Table 1 - Incidence and depth of food insecurity

Region	Variable threshold		Fixed threshold		p-value (test for comparison of incidences)
	Incidence	Severity	Incidence	Severity	
Adamawa	0.374	0.048	0.484	0.054	0.000
Centre	0.247	0.011	0.291	0.012	0.000
East	0.295	0.017	0.344	0.022	0.000
Far-north	0.512	0.036	0.642	0.044	0.000
Littoral	0.210	0.009	0.229	0.007	0.000
Nord	0.386	0.031	0.475	0.036	0.000
North-west	0.236	0.020	0.277	0.025	0.000
West	0.289	0.008	0.399	0.010	0.000
South	0.325	0.021	0.389	0.025	0.000
South-west	0.270	0.030	0.319	0.031	0.000
Total	**0.338**	**0.025**	0.418	0.029	0.000

Source: *Authors' calculations using CHCS 2007*

At the level of the different regions of Cameroon, it is evident that, the North and the Adamawa regions are the most exposed to food insecurity. The incidence of food insecurity in these regions is respectively 38.6% and 37.4%. This is expected considering that the northern part of Cameroon is confronted with harsh climatic conditions.

To know how far the food insecure households are below the recommended daily caloric requirement, food insecurity gap was calculated. Food insecurity gap provides the possibility to estimate resources required to eliminate food insecurity through proper targeting. Te calculated value of this indicator were found to be 2.25% (see Table 2) using variable threshold and 2.9% using fixed threshold. The gap is higher in the northern part of the country (4.8% and 3.6% for the Adamawa and Far-north regions respectively).

[2] Some studies often use a standard threshold of 2,400 kcal/capita/day.

3.2. Determinants of household food insecurity

The results of the binary logistic regression are presented in Table 2. Model evaluation is done by looking at Likelihood Ratio Test. The LR chi2 value is 318.09 with p-value of 0.00, so the model is fit and there is at least one variable that can describe household food security status. The coefficients are interpreted at 1%, 5% and 10% significance level.

The fact that household head has a secondary job or practices hunting, is not related to the food security status of the household. Nevertheless, practice of agriculture is related to food security status of the household. The fact for a household head to practice agricultural activities as sharecropper positively affects food insecurity of the household. The odd ratio in favour of food insecurity is increased by 1.70 as the household head is sharecropper as compared to the situation where he is land owner. This result can be due to the fact that farmers who are sharecroppers have to sell or offer part of their production to fulfil the land's rights of exploitation, which can limit their food supply.

The farmland size appears not to be related to the food security status of the household. This result is similar to that obtained by Babatunde (2007), in his study on the food security of rural households in northern Nigeria. In that study, as it is the case with this one, the unit of cultivated surface is hectare, which can be considered as huge for household for which access to land is not easy.

Our results highlight a link between region of residence and food insecurity. Except North and West regions, the effect of other regions on food security is significant at 5%. In light with our descriptive statistics, the sign (positive) of the coefficient related to the Far north region means that as compared to a household living in Adamawa, the risk for a household living in Far north to be food insecure is 1.54 times higher. In addition, this risk is 0.58, 0.55, 0.47, 0.36 and 0.26 times lower for the Littoral, Centre, North-west, South-west and East regions respectively. The order of vulnerability to food insecurity by region can be established as follows: Far north, Adamawa, Littoral, Centre, North-west, South, South-west and East.

Household size has a positive and significant relationship with the probability of being food secure. The magnitude of the effect decreases with the size of the household, ranging from 0.65 for households having 2-3 persons to 0.21 for those having more than 8 persons. Here, we can consider the size of the household as a factor of diversification of agricultural labor force and source of income at the household level.

Households headed by females have a higher probability of being food secured than their male counterparts. Indeed, the risk for a rural household headed by a woman to be food insecure is 0.57 times less than that of a household headed by a man. This result was not unexpected since most women are more adept than men in issues involving expenditure and calorie. There is another argument that food activities (purchasing, preparation, etc.) is most of time concerned with the female, so a household having female household head is more independent in these spending on food as compared to household headed by males.

The age of the household"s head seems to negatively influence the household food security situation. Two of the categories of this variable are significant (this is 40-49, and 50-59). Having household head aged 40-49 and 50-59, the chances of the household of being food insecure are 1.52 and 1.35 times respectively higher as compared to a household whose head is less than 30 years. The younger people are stronger than the elders and can perform tougher jobs in field. Moreover, households with older heads are the multigenerational households having more retired and/or older persons to feed. This may explain the negative effect of this variable on household food security. On the other hand, there is equal possibility that the older household heads have low tendency of adopting improved technology in agriculture and also economically not much active compared to younger one. In a related study, Bashir et al. (2012) found that an increase of one year in the age of household head decreases the chances of the household to become food secure by 3%. Similar relationship was observed by Titus and Adetokundo (2007) for Nigeria.

Summing up our results, the key determinants of rural household"s food insecurity, according to CHCS 2007, are the region of residence, mode of farmland ownership, household size, household head"s age and household head"s gender.

4. Conclusion and policy implications

This study has two main objectives: determine the food security status of rural households in Cameroon and identify the main determinants of household"s food insecurity. We used the household caloric acquisition method of estimating food security status. We also performed a bivariate logistic regression to identify key determinants of food insecurity.

The results reveal that 34% of the rural households were not able to meet the daily recommended caloric requirement. Concerning descriptive analysis, we noticed a considerable disparity of food insecurity distribution across regions. The northern part of the country is more vulnerable to food insecurity.

Further, the study has shown that the major factors affecting food security of rural households are: region of residence, mode of farmland ownership, household size, household head"s age and household head"s gender. More specifically, compared to a household living in Adamawa, the risk for a household living in Far north to be food insecure is 1.54 times higher. The econometric analysis allowed us to establish an order of vulnerability per region. It also allowed us to have some socioeconomic and demographics factors of food insecurity.

In the light of these results, we can make recommendations concerning policy of fighting against food insecurity, and give some orientations for future researches. The region of the Far North should be preferred for eventual policies of fighting against food insecurity. Rural households that the head"s age is high must have priority, and resident rural population should be encourage and help to own land. It is also suggested that income generating opportunities need to be created along with improvements in secondary and technical education systems.

Finally, we recommend that further studies should be conducted in the area of food insecurity by considering detail and accurate information on various variables including political, climatic and weather (rainfall and temperature), topology, natural disasters, ecological conditions and other factors that affect food insecurity.

Do Boys Eat Better than Girls In India? Longitudinal Evidence on Dietary Diversity and Food Consumption Disparities among Children and Adolescents

E. Aurino | School of Public Health, Imperial College London | London | United Kingdom

DOI: 10.1481/icasVII.2016.b11b

ABSTRACT

This paper examines the dynamics of gender-based disparities in the intra-household allocation of foodduringchildhood and adolescence in India by using three rounds of longitudinal data from two cohorts. While no gender-based disparities in dietary diversity occur at 5, 8 and 12 years old, a marked pro-boy gap emerges at 15 years old. Specifically, mid-adolescent girls tend to consume fewerprotein- and vitamin-rich foods such as eggs, legumes, root vegetables,fruit and meat.This result is robust to gender differences between adolescents in terms of puberty onset, time use and dietary behaviours. Finally, gender disparitiesin dietary diversityinmid-adolescence do not vary by maternal education, poverty or place of residence, whilst they are moderated by levels ofthe caregiver's educational aspirations. Specifically, the pro-boy bias is particularly marked amongst adolescents with 'academically aspiring' caregivers.

PAPER

1. Introduction

In India,undernutrition and micronutrient deficiencies are widespread, despite rapid economic growth (Deaton andDrèze 2009). Analysis of the latest national-level data available (from 2005)shows no significant differences in stunting between boys and girls under the age of 5 years (Tarozzi 2012;Corsiet al. 2015).Employing the same data, Tarozzi (2012) documents a gender-neutral situationin terms of anaemia for children under5 years old. The evidence on gender-based discrimination in feedingpractices, conversely, is mixed: while infantgirls appear to be systematically breastfed for shorter periodsthan boys (JayachandranandKuziemko 2012; Barcelloset al. 2014; Fledderjohann et al. 2014),there is no conclusive indication of a female disadvantage with regard to the intra-household allocation of foodin the case ofpre-schooland school-age children. For instance, Borooah (2004) demonstratesa pro-boy bias in dietary diversity only in the case of children aged up to 24 months born to illiterate mothers, whileDasGupta (1987) reportsthat infant girls and boys receive similar caloric intakes, although girls tend to be fed with more cereals while boys are given more milk and fats. In a more recent paper, Fledderjohann et al (2014) also report higher chances of milk consumption for under-5 boys as compared to their peers.Further, Kehoe et al. (2014) report no gender differentials in the dietary patterns of 10-year-olds in South India.

The absence of evidence related to gender-based gaps in anthropometric indicators[1] and the relativelynuanced picture with regard to feeding practicescontrasts to a wide literature documenting stark pro-boy biases in other dimensions of child development in India. Girls' disadvantage is systematically reflected in higher selective abortions and under-5 mortality rates (Jha et al. 2011; Tarozzi 2012), as well as in lower levels of immunisation (Prustyand Kumar 2014),worse educational outcomes (Derconand Singh 2013; Woodhead et al. 2013) and lower aspirations (Derconand Singh 2013; Beamanet al.2012).These pro-boy biases appearto start early – often even before children are born – and tend to increase as children are reaching adolescence (Pells 2011; Derconand Singh 2013).

In contrast to the evidence for young children, the 2005 nationally representative data revealsizeablegender inequalities in diets and nutrition indicators in the case of adults.

[1] Possible explanations for the absence of gender gaps in nutrition can relate to the mixed evidence on dietary practices or, as suggested by Marcoux (2002), to the higher biological resilience of girls.

Compared to males, Indian femalesaged 15–49 years old appear to be systematically consuming nutrient-rich foods less frequently and to be twice aslikely asmen to suffer fromanaemia,anon-communicable condition often caused by nutritionally inadequate diets (IIPS 2007; Arnold et al. 2009). The question of when such gender differentials in dietary and health outcomes emerge is, as yet, open, owingmostlyto adearth of large-scale surveys for groups other than pre-schoolers and adults (Kehoe et al. 2014). Longitudinal data are particularly scarce. In turn, the lack of systematic evidence on nutritional indicatorsdisaggregated by age and genderstands as a critical knowledge gap for the optimal design of policies that targetgroups at particular risk,such as adolescent girls and pre-pregnant women (Haddad et al. 1997; Coffey 2015).

This paper attempts to address this question for the first time by employingrich, longitudinaldata from Young Lives.Specifically, by using three rounds of survey data collected in 2006, 2009 and 2013 on two cohorts of children in Andhra Pradesh and Telangana, which together account for the fifth-largest population in any state in India[2], to document the associations between dietary diversity and gender at 5, 8, 12 and 15 years old, after controlling for a large set of child and household characteristics.

Individual dietary diversity is a synthetic measure of dietary quality(Ruel 2002). The indicator is associated with intakes of macro- and micronutrients, as well as with anthropometrics and health outcomes (Arimond and Ruel 2004). A diet that includes a balanced mix of foods rich in protein and vitamins – from items such as dairy products, eggs, meat and fish, and fruits and vegetables – is fundamental for the proper physical and cognitive development of children and adolescents, who are particularly vulnerable to malnutrition owing to their higher nutrient requirements and vulnerability to infectious diseases (Steyn et al. 2006). Qualitative evidence shows that both children and parents in theYoung Lives India sample attach intrinsic value to a varied and good-quality diet, beyond its role in promoting health outcomes (Aurino and Morrow 2015).

The analysis presented in this paper shows that while no gender disparities in dietary diversity existed at 5, 8 or 12 years old, or only slight ones, a pro-boy gap of almost half of a food group emergedat 15 years. Boys' advantage in dietary quality is mostly driven by the consumption of protein- and vitamin-rich foods, such as eggs, legumes, root vegetables, meat and fruit. The result is robust to the inclusion of indicators related to puberty, time use and dietary behaviours. Moderation analysis explores furtherwhether the pro-boy advantage during mid-adolescence varies by levels of maternal education, poverty, place of residence, orcaregiver'seducation aspirations as a proxy measure for parental attitudes towards the adolescent.

While no differences are detected along the maternal education, poverty orplace of residence axes,the treatment of adolescent boys and girls in respect of receiving a nutritious diet varied according to the levels of caregivers'aspirations.Specifically,the pro-boy gap is particularly marked amongst adolescents with 'academically aspiring'caregivers.Although the framework employed in this paper only allows for descriptive evidence and not full causal analysis, this result is suggestive that parental attitudes and aspirations towards the adolescent may constitute an exacerbating factor for gender differentials in diet during mid-adolescence. This evidenceis particularly relevant to the Indian context, for several reasons. First, the country is home tothe highest population of 10-to24-year-olds in the world (UNFPA 2014). Adolescent health, particularly that ofgirls, has been madea key policy priority in order to enable the country to benefit from the demographic dividend, as underscored by the 2014 National Youth Policy (Government of India 2014). Secondly, India bears one of the highest burdens of malnutrition globally, both for children and women (Coffey 2015). As child-bearing is concentrated in the age range in which Indian women are most likely to be underweight, improving dietary habits for adolescent girls and pre-pregnant women, beyond representing a development objective per se, can helpto break the transmission of malnutrition from one generation to the next (Black et al. 2013; Coffey 2015).

This analysis contributes to the literature in various ways. First, it adds to previous economicsresearch on gender-based inequalities in children's dietary practices in India (Borooah 2004; JayachandranandKuziemko 2012; Barcelloset al. 2014; Fledderjohann et al. 2014). In contrast to these studies, which focus on children under5 years of age (usually with cross-sectional data), this paper focuses on school-age children and adolescents, and presents adynamic picture of gender differentials in dietary qualityas children grow up and transition to adolescence.Further, by providing evidence from a large sample, it complements two strands of literature: on the one hand, it adds to the knowledge base on children and adolescents' dietary diversityin low-resource settings, which is still quite limited, and usually relies on rather small and cross-sectional samples (Kehoe et al. 2014).[3] On the other, it complements previous anthropological and demographicevidence that documents gender-based variation in the intra-household allocation of food to children ofdifferent ages in India and South Asia (Gittelsohn 1991; Dasgupta 1987, 1997;Palriwala 1993;Harriss 1991; Messer 1997; Mondal 2009).

The paper proceeds in the following way: Section 2 introduces the data, while Sections 3 and 4 respectively present the basic results and some possible explanations for the emergence of the gap during mid-adolescence. Section 5 explores the role of potential moderating factors in exacerbating or moderating gender differentials during mid-adolescence. Section 6 concludes.

[2] Thesestateswereuniteduntil June 2014, with a joint population of 84 millionpeople in 2011. Since the data I use werecollectedbefore the division, I will from nowongenericallyrefer to "AndhraPradesh".

[3] An exception is Woldehannaand Behrman (2013) who use data from the Young Lives Younger Cohort children in Ethiopia to analyse dietary diversity for children at 5 and 8 years old.

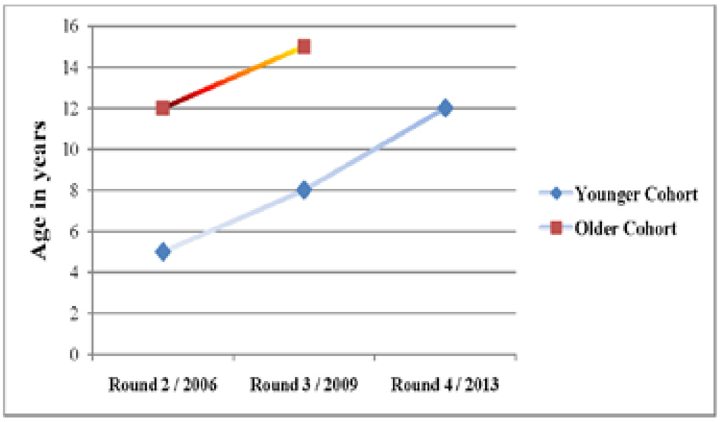
2. Materials and Methods

2.1. Sample

This paper draws on data on two cohorts of children collected by the Young Lives study in the state of Andhra Pradesh, India[4]. The sample was selected through a 'pro-poor' and multi-stage sampling procedure: first, local experts selected 20 'sentinel sites' or clusters per country whileoversampling sites covering more disadvantaged areas. Within each sentinel site, 100 households with a child born in 2001–02 and aged between 6 and 18 months (Younger Cohort) and 50 households with a child born in 1994–5 aged between 7 and 8 years (Older Cohort) were randomly selected (Barnett et al. 2012). For this reason, the sampleis not nationally representative, although careful comparisons with nationally representative surveys show that the variability in the Young Lives sample is comparable to the variabilitythat can be observed in the population as a whole (ibid.).

This analysis draws on data collected in Rounds 2, 3 and 4 of the survey, which took place in 2006, 2009 and 2013 respectively. Younger Cohort children were aged approximately 5, 8 and 12 years old in Rounds 2, 3 and 4, while Older Cohort children were aged 12 and 15 years old in Rounds 2 and 3 (see Figure 1). The first round of survey is not included in this analysis as it didnot includea section on dietary diversity, while the latest round of data for the Older Cohort sample is excluded for two reasons: first, this paper focuses on childhood and adolescence, and second, about half of the Older Cohort sample, at 19 years old,had left their households to get married, which could potentially lead to issues of comparability of dietary patterns with previous rounds. Attrition in the Young Lives sample is extraordinarily low: 95 per cent of the initially surveyed Younger Cohort children were still in the sample in Round 4, and 97 per cent of the Older Cohort sample was tracked until Round 3. Nonetheless, the analytical sample for this analysis was restricted to those children that were present in all the relevant rounds (n=1,915 for the Younger Cohort and n=976 for the Older Cohort) in order to address potential concerns that changes over time may be partially driven by different sample sizes and sample composition.[5]

Figure 1. Data structure, by cohort and round



2.2. Dependent variables

Dietary diversity relates to the number of food groups consumed by an individual in a given reference period (Ruel 2002). The Young Lives study collected data on the child's consumption in the previous 24 hours of 13, 17 and 15 food items in Rounds 2, 3 and 4 respectively[6]. Data werereported by the caregiver in the case of children aged 5 and 8 years old, and by the child in case of 12- and 15-year-olds.

Data on food items were rearranged into seven food groups in order to construct the dietary diversity measure proposed by Swindale and Bilinski (2006):(i) grains, roots or tubers; (ii) fruits and vegetables; (iii) meat, offal and fish,[7] (iv) eggs; (v) pulses and legumes; (vi) milk and dairy products; (vii) food cooked in oil or fat.

[4] Young Livesis an internationalstudy of childhoodpovertythatfollowstwocohorts of children in Ethiopia, India, Peru and Vietnam. More information isavailableat www.younglives.org.uk.

[5] Results are robust to the use of the full sample for each round.

[6] This information does not include quantities of food consumed, which implies that it is not possible to conduct any further analysis beyond consumption of the items.

[7] In Rounds 2 and 3, fieldworkers were instructed to code eggs meat and fish as 'not applicable' if the child was vegetarian. In practice they were however coded as missing values. In order to avoid the loss of information stemming from these missing values, meat and fish were recoded as if they had not been consumed if the following conditions held: (i) both variables simultaneously missing; and (ii) all the remaining questions related to the consumption of the other food items were not missing. The same was done in the cases of children having simultaneous missing values for eggs, meat and fish and all the remaining food groups not missing. This resulted in a recoding of 56and 40 observations in Round 2 and 106 and 54 observations in Round 3 for the Younger Cohort and Older Cohort respectively. A vegetarian variable was created following this recoding and used as a control in the analysis.

The dietary diversity measure accordingly ranges from 0 to 7, which respectively indicates whether the child has consumed any or all of the food groups in the past 24 hours. This index was selected as it is specifically validatedto provide a proxy of nutritional status of children and adolescents in low- and middle-income countries.[8]

In order to allow for an in-depth analysis of which food items would drivethe variation in the aggregate dietary diversity measure, dichotomous variables related to the consumption of the following ten food items were also constructed: (i) cereals, (ii) starchy roots; (iii) legumes; (iv) milk and dairy products; (v) eggs; (vi) meat; (vii) fish; (viii) oil and fats; (ix) fruit; and (x) vegetables.

Descriptive statistics regarding dietary diversity and the consumption of food items ineach round and by each cohort are reported in Table 1.In comparison to other studies conducted in low-resource settings,[9] dietary diversity in this sampleisrelatively low at all ages and for both cohorts, with an average consumption of about four food groups in the previous 24 hours. Most young peopletended to consume cereals, oil and vegetables, with substantial variation with regard to the consumption of animal-source foods or fruits, rootsand legumes.

Table 1 - Descriptive statistics: Dietary diversity and consumption of different food items among children at different ages and in both cohorts (mean withstandard deviation in parentheses)

	Younger Cohort			Older Cohort	
	Age 5	Age 8	Age 12	Age 12	Age 15

	(0.92)	(0.80)	(0.87)	(0.98)	(0.84)
Cereals	0.99	0.98	0.95	0.99	0.97
	(0.08)	(0.15)	(0.23)	(0.11)	(0.16)
Roots	0.30	0.36	0.41	0.30	0.37
	(0.46)	(0.48)	(0.49)	(0.46)	(0.48)
Legumes	0.45	0.29	0.24	0.39	0.33
	(0.50)	(0.45)	(0.43)	(0.49)	(0.47)
Milk	0.65	0.83	0.74	0.64	0.78
	(0.48)	(0.38)	(0.44)	(0.48)	(0.41)
Eggs	0.18	0.20	0.24	0.19	0.19
	(0.38)	(0.40)	(0.43)	(0.39)	(0.39)
Meat	0.10	0.11	0.14	0.10	0.13
	(0.30)	(0.31)	(0.34)	(0.30)	(0.34)
Fish	0.05	0.02	0.03	0.06	0.02
	(0.21)	(0.15)	(0.18)	(0.25)	(0.16)
Oil	0.96	0.94	0.97	0.92	0.90
	(0.20)	(0.23)	(0.18)	(0.27)	(0.31)
Fruit	0.42	0.31	0.44	0.41	0.34
	(0.49)	(0.46)	(0.50)	(0.49)	(0.47)
Vegetables	0.94	0.97	0.97	0.93	0.97
	(0.24)	(0.16)	(0.18)	(0.26)	(0.18)

[8] In contrast to Swindale and Bilinski, Round 2 data did not allow for the distinction between 'Vitamin A-rich plant foods' and 'Other fruits and vegetables', which resulted in the generation of seven food groups instead of the original eight groups, as it would not have been possible to compare dietary diversity between Round 2 and Rounds 3 and 4.

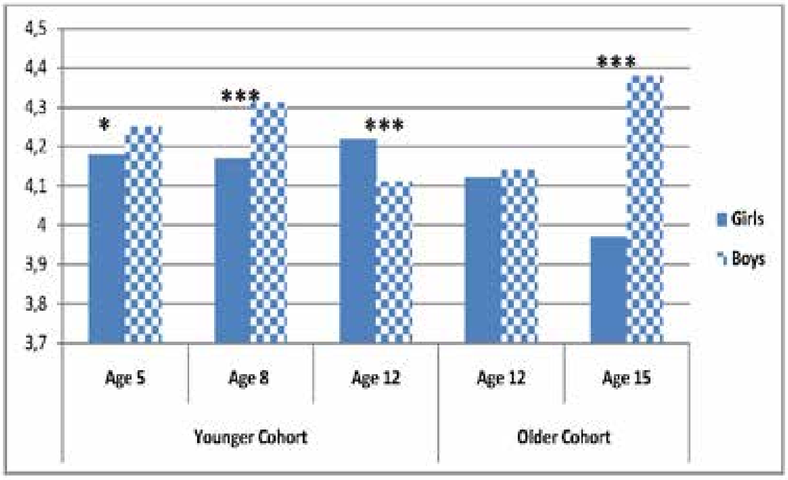
[9] See Steyn et al. (2006) for a review.

3. Results

3.1 Basic result: the emergence of gender-based gaps in dietary diversity during mid-adolescence

Figure 2 presents mean values of the dietary diversity measure disaggregated by child gender and cohort for each round of data.While genderdisparities are statistically significant at all ages except for 12-year-old Older Cohort adolescents, the gap is particularly marked at 15 years old. At this age, the pro-boy difference in dietary diversity accountsfor more than 40 percentage points of a food group.

Figure 2 - Mean of children's dietary diversity by gender, for each cohort and round



**p<0.1, ***p<0.01*

Would the observed gender-based gaps at different ages be significant even after controlling for child- and household-specific factors that are likely to influencedietary quality? To address this question, I rely on a standard multivariate set-up:

$$y_{ij,t} = \beta_0 + \beta_1 M_{ij} + \beta_2 X_{ij,t} + \gamma_j + \varepsilon_{ij,t} (1),$$

where$y_{ij,t}$ relates to dietary diversity of child i, living in cluster[10] $j$and measured at time t;M_{ij} is a dichotomous variable related to child gender, and $X_{ij,t}$relates to contemporaneous observable child, parental and household characteristics. Additionally, γ_j is a vector of time-invariant community characteristics and $\varepsilon_{ij,t}$ is the error term. The vector of child and household covariates$X_{ij,t}$ includesthe following covariates: child caste and birth order; maternal and parental years of schooling;[11]gender of the head of the household; and household's size and the logarithm of consumption per capita in rupees.The set of covariates also includes adichotomous variable related to whether the child wasvegetarian, another to whether an older brother was living in the householdand an interaction term between being a girl and having an older brother. The former controls for the lacto-vegetarian diet pattern, which is common amongst Hindu children (Kehoe et al. 2014), whilethe latter two control for the demographic characteristics of the siblings, which JayachandranandPande

10 Cluster and community are used as synonyms.

11 Religious and adult education were recoded as 0 years of education.

[a]Caste in India is divided into four official categories. Scheduled Tribes, Scheduled Castes and Backward Classes are recognised in the Constitution of India as historically disadvantaged, while Other Castes are the more privileged and socially and educationally advantaged castes.

Table 3 presents theempirical results based on the specification outlined above, where the relationship between dietary diversity and child genderfor each cohort and age is estimated through ordinary least square (OLS) regressions with community fixed effects.[12] Communityfixed effects are included in order to control for the set of environmental factors ""that are reasonablyconstant over time (e.g. agro-ecological characteristics, cultural preferences around food, etc.), as they may affect the diets of children living in differentcommunities.[13] A potential drawback of the OLS approach is that it may lead to biased estimates of the gender coefficient because ofthe potential correlation between child gender and unobservable child and parental characteristics that may affect the intra-household allocation of good food. While this issue is partially taken into account by the child and household controls included in the model, the present empirical strategy only aims at documenting patterns of associations between child gender, age and diet, and not at claiming causal findings.

[12] The use of the OLS model implies treating the dietary diversity variable as continuous, as in Amugsiet al.(2015) or Jones et al.(2014). This choice was motivated by the ease of the interpretation of the linear model as compared to alternatives such as ordered logistic regression. Sensitivity analysis undertaken through ordered logit models confirms that the choice of the linear model does not distort the findings (results available from the author).

[13] A similar approach is taken by Derconand Sánchez (2013), who use the terms 'community' and 'cluster' synonymously.The use of this technique however inevitably reduces theR-squared of the regression models. I use Round 2 as the reference sentinel site for the community fixed effects.

As compared to the difference-in-means approach presented in Figure 2, the male coefficient now provides a measure of the magnitude and statistical significance of the gender-based gap after controlling for child- and household-specific characteristics and community heterogeneity. With the exception of 12-year-old children in the Younger Cohort, the male coefficient is always positive, which indicates that boys tend to enjoy better diets at different ages. However, the association between gender and diet is only statistically significant at 15 years old, accounting for about half of a food group.

The coefficients of the childand household covariates reveal other interesting patterns. As expected, child dietary diversity is positively associated withincreases in household consumption levels, while the relation between caste and diet variesby age and cohort. Additionally, while at earlier stages of childhood, factors related to socio-economic status such as household consumption levels and caste seem to be driving most of the variation in children's diets, at 15 years old gender appears to be the most critical factor associated withimproved dietary diversity levels. Other potential explanatory factors such as household size and father's years of education do not seem to contribute strongly to children's dietary diversity, while maternal education appears to be weakly associated withbetter diet only at 12 and 15 years old.A similar lack of association between parental education and children's diets in South India is found in Kehoe et al. (2014). This may be explained by the correlation of parental education with household socio-economic status, which is controlled for by consumption levels, and/or by the widespread recognition amongst caregivers of the importance of nutritious diets for child development, irrespective of their education status (Aurino and Morrow2015). In contrast to Jayachandran and Pande (2015), whofind a strong birth order gradient and disadvantage in anthropometric indicators for second-born young girls who donot have elder brothers, no association with dietary quality is found in this sample.

The results presented so far show the emergence of gender-based gaps in dietary diversity during mid-adolescence. Gender- and age-specific gaps in dietary diversity are explored further by pooling data from the Younger and Older cohorts and treating them as repeated cross-sections. Specifically, I estimate the following model:

$$y_{ij,t} = \beta_0 + \beta_1 M_{ij} + \beta_2 X_{ij,t} + \beta_3 M_{ij} * Age_{ij,t} + \beta_4 Cohort_{ij} + \beta_5 Age_{ij,t} + \gamma_j + \varepsilon_{ij,t} \,(2).$$

Dietary diversity is now a function of the male dummy, the set of child and household characteristics introduced above, male–age interactions, and cohort and age dummies. Male–age interactions are included in order to capture gender-specific gaps in the way parents allocate foods at a given age. Cohort- and age-specific dichotomous variablesrespectively relax the assumptions that the relation between age and diet is the same across different stages of child development, and that structural patterns in diets are invariant across the two cohorts. Column 1 in Table 4 presents results from this pooled model, where only the coefficients related to male and the male–age interactions are displayed, as they constitute the parameters of interest of this model.[14] Estimates have been obtained through OLS,including communityfixed effects. In line with the results presented in Table 3, Column 1 shows that there are no statistically significant differences in thedietary diversity indicatorbetween being a boy at 8 and 12 years old as compared to the baseline category of 5-year-old girls. In contrast, the coefficient associated with15-year-old boys is strong and significant, accounting for about 35 percentage points of the dietary diversity measure, which corroborates the finding related to the emergence of gender differences in dietary quality during mid-adolescence.

With regard to the other controls, the key patterns of association between child and household covariates and dietary diversity do not substantially change from the ones shown in Table 3.[15] Specifically, the negative association with marginalised castes (as compared to the omitted category of Other Caste) and the positive association with household consumption levels become stronger. No statistically significant association between dietary diversity and age or cohort is found.

Which foods are driving the observed gender-based variation in dietary diversity during mid-adolescence? Columns 2–7 in Table 4 address this question, where the outcome variables now relate to the consumption of the differentfood items. Results related to the food itemsthat mostly relate to protein and micronutrient intakes are reported[16]. Estimateswere conducted through the use ofthe linear probability model (LPM) with community fixed effects.[17] At 15 years old, girls are systematically less likely to consume protein-rich foods such as legumes, eggs and meat, and vitamin-rich foods such as fruit and roots as compared to when they were aged 5 years old. At 15 years old, the male–age interaction is also positively associated withthe consumption of milk, although the coefficient is not significant. Additional gender–age gaps emerge from the analysis of the interactions at the other ages considered. Five-year-old boys are more likely to consume milk and vegetables, while at 8 years old boys tend to consume more legumes. In contrast, at 12 years old girls tend to eat more eggs. This last pattern is driven by the Younger Cohort sub-sample.

Notably some of the highlighted gender and age gaps relate particularly to the consumption of some 'unitary' food itemssuch as milk, fruit and eggs. In a context such as India, where meals are usually shared from the same pot, parents may be able to discriminate betweensiblings by providingan egg, a piece of fruit or a glass of milk to the preferred child at a given age.

14 Full results are available upon request.
15 Full results are available upon request.
16 No significant result emerged for cereals and oil.
17 Although the variables related to the consumption of each food group are binary, a linear model was preferred, as in the case of dietary diversity. This choice is due to its easier interpretability as compared to non-linear models, and as it usually provides a good approximation of the response probability for common values of the covariates (Wooldridge 2010).

These findings echo a body of literature in the social sciences that reports gender- and age- based differences in the allocation of higher-quality food in South-Asian households (Gittelsohn 1991; DasGupta 1991; 1997, Harriss 1991; Palriwala 1993). In particular, Harriss (1991) and Gittelsohn (1991), in India and Nepal respectively, report no preferentialtreatment of young children based on gender with regard to nutrition inputs, and the emergence of gender-based disparities during adolescence. This may relate to adolescence being a stage in whichgender norms – including those about food - may become more pronounced. In particular, Gittelsohn's description is rather suggestive:

- While differences were never as severe as for older household women, adolescent girls were disfavored in food allocation. It is at this stage of their lives that they begin to assume many household domestic responsibilities, such as water-fetching, wood collection and food preparation. No longer children, they were served later in the meal, often in the same eating group as the mother. ...On the other hand, adolescent boys were automatically served and frequently offered second helpings ...They were also given moderate-level preference in terms of substitution and channeling, occasionally receiving special foods, and they tended to receive a great amount of food proportionate to body size. (Gittelsohn 1991: 1152)

3.2 Is the gap explained by puberty, time use and dietary behaviours?

The results from the previous section highlighted the emergence of gendergaps in diet during mid-adolescence, after controlling for a variety of observable child- and household-specific characteristics that can influence dietary quality. Nevertheless, mid-adolescent boys and girls may differ systematically insome dimensions, which may represent potential explanations for the emergence of the gap at 15 years old.

Differencesbetweenthe timing of the pubertal growth spurt ofgirls and boys, which under optimal growth conditions usually occurs at 11 years old in girls and 13 years in boys (Rogolet al. 2000), can be one of those factors. Puberty is a phase of radical physical changes, including significant height and weight gain, and increased nutritional requirements. It may therefore beplausible that parents, by witnessing the rapid growth of the adolescent during this stage, would provide him/her with a more varied diet and with foods of higher nutritional quality. Following this line of reasoning, the pro-boy gap at 15years old would arise due to the lateronset of puberty for boys as compared to girls.

Similarly, the gendergap may be driven by systematic differences in time-use patterns between boys and girls that get more pronounced in adolescence, which may in turn influence how parents allocate foods within the household. Time use is highly gendered in India, with girls spending more time on unpaid domestic work and boys being more likely to be engaged in paid work and education (Beamanet al.2012). As genderinequalities in time use tend to widen after puberty (Pells 2011), the emergence of the gap at 15yearsold may be explained by parental bias in the intra-household distribution of food towards the adolescent that contributes most to the family budget through farm or off-farm employment, or that spends more time at school or studying, which in both cases is usually the male (Harriss 1991; Pells 2011; Derconand Singh 2013).

By the same token, adolescent boys and girls may differ significantly with regard to their dietary behaviours, as research from both advanced economies and middle-income countries shows that genderdifferentials along this dimension tend to appear during adolescence. Compared to boys, adolescent girls – even in middle-income countries such India -generally display higher levels of dissatisfaction with regard to their body weight, which in turn is associated withgreater prevalence of restrictive dietary practices among females (CardamoneCusatisand Shannon 1996; Mallicket al. 2014; Stuparet al. 2012). Accordingly, the observed gender-based gap at 15 years old may be the result of adolescent girls' deliberate choicestocontrol their dietary behaviours in order to curb body weight gain, instead of skewed parental allocation of food towards boys of the same age.

The presence of systematic gender differentials between adolescent boys and girls in these three dimensions seems to be corroborated by the data. Table 5 presents gender-based differences between boys and girls in terms of puberty onset, time-use patterns, and dietary behaviours at 15 years old.Puberty is proxied by an indicator of height differences between 15 and 12 years old, as one of the distinguishing features of puberty is the growth spurt, where girls peak height velocity at 12 years and boys two years later (Rogolet al. 2000). On average, Older Cohort boys gained about 15 cm between Rounds 3 and 2, while girls gained 9 cm. As hypothesised, significant gender-based differences can be noted in the time-use indicators. In particular, girls reported that they tended to spend almost twomorehours than boys on household chores or caring for other family members. By contrast, boys tended to spend an additional hour per day in school or studying compared to girls. Surprisingly, there wereno gender differences in the time spent on work on the family farm or for pay.Lastly, gender differences were noticeable with regard to two indicators ofdietary behaviour:(i) number of meals(including snacks) they reported having consumedin the previous day and (ii) days per week in which the adolescent had been engaged in at least one hour of intense physical activity such as running, cycling, etc. The patterns emerging from the data are consistent with the hypothesis that adolescent girls are more likely to adopt weight-control strategies such as skipping meals orundertakingintense physical activitymore frequently than boys (CardamoneCusatisand Shannon 1996; Mallick et al. 2014).

In order to investigate whether these factors explain the emergence of the gap in dietary qualityat mid-adolescence, two different approaches were adopted. With regard to puberty and time use, the basic cross-sectional model of Equation 1 was augmented by the relevantindicators in two separate modelsfor the sample of 15-year-olds. If puberty and/or time use are correlated withthegender-based gap, both a statistically significant association of these indicators withdietary diversity, and a change in the size and statistical significance of the male coefficient would be expected. Column 1 of Table 6presentsthe estimates for the baseline model for the reader's convenience, while Columns 2 and 3 present theresultsof the models that incorporate puberty and time use respectively. F-tests and Chow tests of equality of male coefficients in the different models (as compared to the estimate of the male coefficient from the baseline model) are also presented. Neither the puberty nor the time-use variablesare statistically associated withdietary diversity. Despitethe fact that the size of the male coefficient decreased slightly after the indicator of puberty was included, the Chow testconfirmedthe null hypothesis of the absence of statistical differences between the male coefficient from the augmented model and the baseline model. Similar results emerge when a different indicator of puberty (related to the age at which it occurs) was included, which are not shown here.

With regard to the hypothesis related to systematic gender differences in dietary behaviours, Columns 4 and 5 present the result of two models in which the two indicators of dietary behaviours were used as dependent variables in the multivariate model ofEquation 1. Once child and household characteristics are controlled for, no significant gender-based differences in dietary behaviours arenoticeable. Taken together, these results suggest that potential systematic differences between adolescent boys and girls in terms of pubertal growth spurt, time use and dietary behaviours are not able to explain the emergence of the gender gap in dietary diversity at 15 years old.

3.3. Extension: is the gap moderated by maternal education, poverty,locationor parental attitudes towards girls?

So far, the appearance ofa pro-boy gap in mid-adolescence has been documented across the whole sample. This section explores whether gender-based differentials in diet would differ across population sub-groups, as the question of whether gender inequalities in diet are exacerbated or mitigated by specific factors, such as maternal education or poverty status, has important policy implications. To this end, the modelling approach allows for gender to vary by maternal education, poverty, place of residence and parental educational aspirations. Following Dercon and Singh (2013), this is achieved in practice by augmenting the basic cross-sectional model usingan interaction variable between the gender dummy and each of those factors. A significance of the interaction term and a change in the gender coefficient would suggest thatthat specific factor magnified or mitigated gender inequalities in diet. Table 6 presentsthe coefficients for childgender and the interactions for the sample of 15-year-olds, after controlling for the set of child and household characteristics,[18] as well as F- and Chow tests. The latter compares the male coefficient from the baseline specification to the augmented models.

This analysis starts by examining the role of maternal education, as this factor emerges as critical in reducing gender inequalities in diet for young children (Borooah2004). This does not seem to be the case for adolescents, where the male coefficient is unchanged and the interaction variable is not significant. The next two models examine whether the gap varies for adolescents in the poorest tercile in terms of consumption per capita (as compared to the second and least-poor terciles)and for those living in urban areas, as povertyandplace of residencehave been shown to exacerbate discriminationagainst girls in India (Pells 2011; Derconand Singh 2013; Mukhopadhyay 2015).The empirical results show that neither financial constraintsnor place of residence contributes tointensifying the gender gap in dietary quality. Similar results are found when there is an interaction with caste is included (not shown here).

Finally, Column 5 reports the results from testing whether parental attitudes and aspirationsfor childrencan constitute a moderating factor for the gender differential in diet.For instance, Derconand Singh (2013) showed that caregivers' educational aspirations predicted both child educational aspirations and cognition, leading to increasing female disadvantage in education during adolescence in India, while Favara (2016) presented similar findings for Ethiopia. In the absence of a specific indicator related to parental attitudes towards the adolescent's health, these are proxied bya measure of the caregiver's aspirations for the adolescent's completed educational level. As in Beamanet al. (2012), the indicator assumes a value of 1 if the caregiver would like the adolescent to at least graduate from secondary school (Grade 12). This indicator is considered a good measure of parentalaspirations for the adolescent, as it is future-oriented and predictive of current behaviour (ibid.). Caregivers' aspirationswere onlyrecorded in Round 2for the Older Cohort, but this should not constitute a concern as parental aspirations and attitudestowards education are usually assumed as relatively time-invariant[19] (Rampinoand Taylor 2013). After the inclusion of the interaction between male and high parental educational aspirations, the advantage in dietary diversityis particularly marked for boys living with 'academically aspiring' parents, as compared to girls whose parents have equally high levels of educational aspirations, while the size and statistical significance of the male coefficient is less pronounced in the case of adolescents with parents with low aspirations. This result persists even after controlling for the adolescent's school enrolment status(Column 5) and time-use indicators (not shown here), as caregivers' preferences for educational achievements may be reflected in differences in those outcomes.

While this empirical framework only provides estimates of associations and not full causality, this evidence can be suggestive that, beyond educational outcomes, caregivers' educational aspirations may exacerbate gender inequalities in other dimensions, such as the intra-household distribution of food.

4. Conclusions

By using three rounds of data from the two cohorts in the Young Lives study, this paper provides original evidence on gender gaps in dietary diversity at different stages of childhood and adolescence in India. The empirical results showthat gender-based differentials in dietary quality are absent at 5, 8 and 12 years old, but that wide pro-boy gaps emerge at 15 years old. Disparities between mid-adolescent boys and girls are driven by the increased likelihood of boys to consume protein- and vitamin-rich foods. This result is robust to genderdifferentials in timing of puberty, in time use and in dietary behaviours. Moderation analysis shows that the magnitude of the gap does not vary by maternal education, poverty or rural/urban location. By contrast, once parental attitudes towards education are interacted with gender, there are smaller differences in dietary quality between boys and girls whose caregivers have low educational aspirations, and the pro-boy bias is mostly manifest amongst adolescents with 'aspirational'caregivers.

The documented variation in the intra-household distribution of highly nutritious (and generally higher-cost) foods underscores the advantages of adopting a longitudinal approach in the analysis of gender inequalities in dietary outcomes.This in turn can enhance the design and targeting of policiesaimed atimproving the nutritional status of groups at particular risk of malnutrition, such as adolescent girls in India.

[18] Full results are available from author.

[19] This is quite a standard hypothesis in the literature, although Beamanet al. (2012) showed that in certain conditions caregivers' aspirations can actually change.

Assessing Vulnerability to Food Insecurity in Mountain Areas of Ecuador: the Composite Vulnerability Indicator (CVI)

A. Borlizzi | FAO, Forestry Department | Rome | Italy

DOI: 10.1481/icasVII.2016.b11c

ABSTRACT

Mountain communities are particularly vulnerable to food insecurity, as they live in isolated areas and fragile ecosystems characterized by poor soil quality and high risk of natural disasters. According to a study by Huddleston et al. (FAO, 2003) almost 250 million people vulnerable to food insecurity were living in mountainous areas of developing countries. A new study, started in 2014 by the Mountain Partnership, aimed to update those results: the present article is part of that study. Household survey data are used to assess the vulnerability to food insecurity of mountain peoples from Ecuador, where mountains cover about the 40% of the national territory and host almost half of the total population.

Using data from the 2011-12 Household Income and Expenditure Survey of Ecuador (ENGHUR) and matching them with the geographic location and elevation of each interviewed household, a profile of mountain peoples of Ecuador is drawn. Vulnerability to food insecurity by elevation class is then analysed through the new "Composite Vulnerability Indicator" (CVI), which takes into account the food security dimensions relevant at the household level. The final figure of people vulnerable to food insecurity is obtained assuming that, if a household is vulnerable under one dimension of food insecurity, it is vulnerable to food insecurity as a whole. Different patterns between urban and rural areas are investigated, in order to distinguish the differential drivers of vulnerability in the two areas, and social safety nets are finally taken into account.

Keywords: Mountain, Vulnerability, Food Security, Sustainable Development Goals

PAPER

1. Vulnerability to Food Insecurity in the frame of the Sustainable Development Goals

Mountain communities are particularly vulnerable to food insecurity, as they live in isolated areas and fragile ecosystems characterized by poor soil quality – shallow soils, steep slopes, moisture and temperature constraints – and high risk of natural disasters such as avalanches, landslides, earthquakes and flash floods. In addition, migrations to major urban centres and lowlands caused over time the erosion of traditional livelihood systems and an increase in food insecurity among those who remained (FAO 2002). At the household level, vulnerability to food insecurity is related to the (in)ability to cope with external shocks that impact food and nutrition security, and to come back to the original conditions once the shock is over.

Vulnerability, on the other hand, can be reduced by building resilience of both people and communities (UNDP 2014) through safety nets that guarantee a minimum acceptable level of household food security over time. They are policy measures adopted to prevent vulnerable people from falling under certain minimum levels of livelihood because of a shock. In the framework of the Sustainable Development Goals[1], targets 1.5[2], target 2.1[3] and target 13.1[4] point to the direction of reducing vulnerability to food insecurity and building the resilience of vulnerable people. Building resilience is also implicitly acknowledged in several other targets (ODI, 2015).

[1] A complete list of the SDGs and their targets is available at: https://sustainabledevelopment.un.org

[2] Target 1.5: "Build the resilience of the poor and those in vulnerable situations, and reduce their exposure and vulnerability to climate-related extreme events and other economic, social and environmental shocks and disasters".

[3] Target 2.1: "By 2030 end hunger and ensure access by all people, in particular the poor and people in vulnerable situations including infants, to safe, nutritious and sufficient food all year round".

[4] Target 13.1: "Strengthen resilience and adaptive capacity to climate-related hazards and natural disasters in all countries".

According to a study by Huddleston et al. (FAO 2003) almost 250 million people vulnerable to food insecurity were living in mountainous areas of developing countries. The present article is part of a new study started in 2014 by the Mountain Partnership - and presented at COP 21, Paris, in 2015 - aiming to update the results obtained by Huddleston et al. To show the possibilities offered by household surveys in the analysis of vulnerability to food insecurity, household survey data are used to assess the vulnerability to food insecurity of mountain peoples of Ecuador, a country where mountains cover about the 40% of the national territory and host almost half of total population.

In order to estimate the number of mountain people vulnerable to food insecurity in Ecuador, a new "Composite Vulnerability Indicator" (CVI) is derived, which encompasses three food security dimensions relevant at the household level: physical access, economic access, and utilization. The final figure of vulnerable people is then tabulated by elevation class and by urban and rural areas of the country, as well as by ethnic group. Social safety nets are finally taken into account, obtaining the number of vulnerable people not benefiting from any form of aid.

Next sections are as follows: section 2 explains the newly developed methodology of the Composite Vulnerability Indicator; Section 3 describes the main characteristics of Ecuador people by elevation class, based on ENIGHUR 2011/12 data; Section 4 introduces the results of the application of the CVI to the Ecuador case study; Section 5, finally, concludes.

2. A new Methodology: the Composite Vulnerability Indicator (CVI)

Drawing from a global GIS-based analysis of mountain environments and populations, the study of Huddleston et al. (FAO, 2003) estimated that about 40% of mountain people across the world was vulnerable to food insecurity[5].

The 2015 FAO model (FAO, 2015) builds on the 2003 model adding more information to better capture the factors contributing to ensure food security in the specific mountain context[6]. The final figures show that nearly 330 million people, corresponding to 39% of the 2012 mountain population, with higher shares in Africa and Asia compared to Latin America.

To the aims of the present article, a new methodology is proposed which makes use of household survey data in place of spatial data. The unit of analysis is the household, whose vulnerability to food insecurity is analyzed under the lens of three food security dimensions[7]:

1. Physical access to food markets. For isolated households, access to food markets is made difficult by the poor conditions, or even the absence, of transport infrastructure. Consequently, isolated households' food security is more affected by extreme climatic conditions and environmental shocks. Moreover, the opportunities to market their own products are scarce, reducing the potential to improve their livelihoods and their economic access to additional food. Physical access to food is therefore a crucial issue for mountain population that has to be taken into account into the building of a composite vulnerability indicator. The present study considers access to improved ways of transportation like paved or cobbled roads as an indicator for the physical access dimension.

2. Economic access to food. Inadequate purchasing power is generally viewed as the main cause of food insecurity at the household level. As per survey data, the most reported causes of reductions in food expenditure were related with lack of good job opportunities and of health/job assistance: this combination is therefore used to identify vulnerable households under the perspective of the economic access dimension, along with the national poverty line[8]. In rural areas, on the other hand, land ownership is used as an indicator of household resilience[9]. Additional details are provided in paragraph 4.

3. Utilization. Sufficient energy and nutrient intake is the result of good care and feeding practices, food preparation, dietary diversity and intra-household distribution of food. When combined with good biological utilization of food consumed, this determines the nutritional status of individuals.

5 People were considered vulnerable in rural areas characterized by: cereal production less than 200 kg per person; low to medium bovine density index; closed forests and protected areas. 15% of urban mountain people was also considered vulnerable.

6 Yields were taken into account not only for the main cereal crops, but also for beans, cassava and potatoes. FAO Global Land Cover map was used to identify cultivated areas, while the Spatial Production Allocation Model (SPAM) provided information on the yield of the selected crops. Yields were then converted to calories available per hectare using the nutrient values adopted by the FAO Nutrition Division. A threshold of 1,370 calories and of 14 g of protein per person per day was taken as a threshold for vulnerability. For proteins, the production of meat and other products from cattle, sheep, goats and chicken was taken into account, rather than considering just bovine density. In urban areas, the World Bank "Poverty headcount ratio at urban poverty line" was averaged across developing countries, and the resulting value (23.6%) was used as the share of vulnerable people in mountain urban areas. People living in protected areas and closed forests, instead, are not considered vulnerable in this update.

7 A fourth dimension – Availability – is not taken into account, as it is more relevant at the country level, rather than at the household level. In addition, data on food availability are only available at the national level. A detailed description of the food security dimensions can be found in FAO, 2013.

Poor hygienic conditions and the consumption of contaminated water, on the other hand, are in most cases the main determinants of health problems that may impact food utilization. In this study, access to improved water sources and presence of improved sanitation facilities are used as indicators of the utilization dimension of food insecurity.

Each dimension described above is associated to an indicator that can assume values of either 0 or 1, with 1 indicating a vulnerable household under a particular dimension and 0 indicating a non-vulnerable one. The final Composite Vulnerability Indicator (CVI) takes into account the three dimensions in order to come up with a final figure of people vulnerable to food insecurity under the assumption that, if a household is vulnerable according to one dimension, it is vulnerable to food insecurity as a whole. This means that each dimension is given the same importance and is not assigned any weight.

It is to be noted, however, that the concept of vulnerability to food insecurity should not be confused with food insecurity itself. A household "vulnerable" to food insecurity, indeed, may be or may be not actually food insecure, depending on exogenous conditions and the presence of safety nets.

3. Ecuador Mountains: Main Characteristics

Ecuador is the most densely populated country of Latin America and the Caribbean, and one of the most "biodiverse" countries in the world. With a 2014 GDP of about US$100 billion and a population of almost 16 million, the World Bank ranks it in the "upper middle income" group. At the time of the household survey, however, food insecurity was still an issue for nearly 13 percent of its population, according to the 2015 SOFI report (FAO, 2015). The Ecuadorian territory can be roughly divided into three geographic regions: the Pacific coast in the west, characterized by plains and coastal hills; the Amazon in the East, covered by rainforest; and the Andes in the Centre. Galapagos Islands are also part of the national territory.

The Andes are the longest mountain range in the world and the highest range outside Asia; they are made up of parallel ranges interspersed with high plateaus crossing the country from north to south, and covering about 40 percent of the national territory. More than one third of the mountainous territory is characterized by an elevation of 2,500 meters or more; however, due to their proximity to the Equator and hence to the lack of harsh climatic conditions, elevated plateaus have been chosen throughout history as locations for major urban settlements: nearly half of the total population of Ecuador live in mountain areas. In particular, twelve out of the 38 cities with 50,000 or more inhabitants are located in elevation class three, which is also the class with the highest value of population density (table 1). The capital Quito, located at an elevation of 2 850 m (Elevation Class 3[10]), is an urban area with infrastructure and subsidiary activities uncommon to most of the mountain areas around the world.

Table 1 - Population density and number of major cities per elevation class

Elevation class (Kapos et al., 2000)	Population density (people/km^2)	Number of cities with 50,000+ inhabitants
Class 1 (> 4,500 m)	.	.
Class 2 (3,500 – 4,500 m)	1.8	0
Class 3 (2,500 – 3,500 m)	**163.9**	12
Class 4 (1,500 – 2,500 m)	45.6	2
Class 5 (1,000 – 1,500 m)	15.7	0
Class 6 (300 – 1,000 m)	30.8	2
Class 0 (0 – 300 m)	44.9	22

Credits: Author's elaborations on data from Population Census 2010; INEC data on elevations.

Household Income and Expenditure Surveys (HIES) are a rich source of information on household livelihood. Matching survey data with the location of each household and its elevation[11] allows us to derive household statistics by elevation class and to identify patterns of living conditions and exposure to food insecurity along the different elevation classes.

8 The National Statistical Office of Ecuador (INEC) provides estimates of the national poverty line every 3 months by comparing per capita income with the consumption poverty line (línea de pobreza por consumo). All the individuals whose income is below poverty line are considered poor. As of December 2011, poverty line was set at $72.87 per month, corresponding to $2.43 per day. Using data of ENIGHUR 2011/12, per capita income of each interviewee was derived and deflated with base December 2011. Hence, while the original study used a urban poverty line averaged over the developing countries, here a national poverty line, specific for the country under analysis, is adopted.

9 See for instance: Skerrat, 2013.

10 To the aims of this article the UNEP-WCMC classification is used, described in Kapos et al. (2000).

11 No data were available on the slope of each household location, which is an important element to determine the elevation classes 4, 5 and 6; the results shown here may therefore slightly differ from those that would be obtained in presence of that piece of information. 12 Encuesta Nacional de Ingresos y Gastos de Hogares Urbanos y Rurales. Since the survey was not designed to be representative at the level of the mountain versus non mountain areas, the expansion factors have been recomputed to derive statistics representative of the population of the different elevation classes, based on the 2010 Census data.

Data presented in this case study were gathered by the Ecuadorian National Statistics Institute (INEC) in 2011–12 through a Household Income and Expenditure Survey (ENIGHUR[12]) that involved almost 40 000 households and about 150 000 people. Matching survey data with the location and the corresponding elevation of each surveyed household allowed the study to derive household statistics by elevation class and to identify patterns in the change of living conditions and vulnerability to food insecurity in the different classes. Food security statistics were derived using the ADePT-FSM tool[13], jointly developed by FAO and the World Bank.

A main feature of Ecuador mountain areas is that, while elevation Classes 2 and 5 have a strong rural character, with low population density and low number of cities, Classes 3 and 4 show the opposite characteristics. Classes 2 and 5 have the lowest percentages of dwellings with improved water sources and sanitation facilities, a high dependency ratio and the highest percentage of women among the elevation classes, suggesting that many adult men leave their families in search of better employment and economic conditions. This preliminary conclusion is supported by the results of the survey's "self-evaluation of living standards" module, which included questions on the causes of household poverty. In answering those questions, "unemployment" and "lack of good jobs" were the causes most frequently reported by respondents of those elevation classes.

The more urbanized elevation classes 3 and 4, on the contrary, are characterized by higher per capita income and a lower percentage of people working in the primary sector. Class 3 has the highest percentage of people holding a University degree and the highest standards of water and sanitation facilities among the elevation classes, but is also characterized by higher income inequality and higher food prices.

The main agricultural products by elevation class are reported in table 2. In the highest elevation class, roots, tubers and pulses compensate for the lower availability of cereals. In particular, potato is the most frequent crop in class 2, preceded by maize in the immediately lower class and also by beans in class 4. At lower altitudes, cash crops are more frequently cultivated.

The average number of cattle per household is much lower at higher elevations than at lower altitudes, while the opposite is true for sheep. Consequently, the average value of animals per person is lower (table 2).

Table 2 - Main agricultural products (based on the frequency of positive answers by respondents) and average value of sold and own consumed animals by elevation class.

Source: author's elaborations on ENIGHUR 2011-12 data; INEC data on elevations.

The food group "cereals and products" contribute the most to the dietary energy and protein consumption in all elevation classes, with white rice being the biggest energy contributor among the single food items. However, the share of energy derived from cereals on total dietary energy is lower in mountains than in the country as a whole, while the share of roots, tubers and pulses is higher. In quantitative terms, milk is the most consumed food item in Classes 1 through 5, while in Class 6 and in lowlands white rice is followed by green plantains. Meat and meat products contribution in total dietary energy, finally, are substantially lower in rural classes 2 and 5 if compared to more urbanized classes 3 and 4.

Households in the rural Classes 2 and 5 spend the highest income portion on food and are characterized by the lowest dietary diversity, measured in terms of total number of food items reported during the interview. The share of dietary energy obtained from own-produced food on total dietary energy in rural Class 5 is higher than in all other classes. The mostly urban Class 3, on the other hand, obtained its highest share of calories from purchased food.

12 Encuesta Nacional de Ingresos y Gastos de Hogares Urbanos y Rurales. Since the survey was not designed to be representative at the level of the mountain versus non mountain areas, the expansion factors have been recomputed to derive statistics representative of the population of the different elevation classes, based on the 2010 Census data.

13 Available at: http://www.fao.org/economic/ess/ess-fs/fs-methods/adept-fsn/en/

As to the food consumed away from home, an important component is represented by food received free by children at school. School feeding programs are aimed at addressing the issue of food insecurity in the more vulnerable areas; the higher shares of children receiving food at school are observed in rural elevation classes 2 and 5, although in absolute terms the greatest number of children receiving food is found in the urbanized class 3.

4. Vulnerability to food insecurity in Ecuador

The first question of the ENIGHUR 2011-12 questionnaire asks about the "main access" to the dwelling. This piece of information was used to derive an indicator reflecting the "physical access" dimension of food security. For values of the variable "main access to dwelling" ranging from 1 to 3[14] the household was categorized as non-vulnerable under the physical access dimension, while it was considered vulnerable for values of the variable ranging from 4 to 6[15]. The "Physical Access" Vulnerability indicator can therefore assume two values: 1 for vulnerable households and 0 for non-vulnerable households. Main results are shown in table 3; household weights[16] were used to expand the results to the entire population. About 650,000 mountain people, corresponding to 9% of mountain population, have poor or no access to improved roads and hence difficulties in accessing markets, against a share of 6% in lowlands. The percentage of household with poor or no access to roads is higher in elevation classes 2 and 5 although, in absolute terms, the highest number of people with poor access to markets is found in class 3. Clearly, isolation is a typical rural problem: while in urban areas the share of "isolated" mountain people ranges between 1 and 3 percent, in rural areas twenty to thirty percent of the population can be considered isolated (table 3).

Table 3 - Vulnerable people by elevation class and area - Physical Access dimension

Source: author's elaborations on ENIGHUR 2011-12 data; INEC data on elevation and population.

Reducing food expenditures is one of the possible coping strategies adopted by vulnerable households in a period of food/market crisis or after being hit by an external shock. The share of households adopting such strategy can therefore be used as a benchmark of vulnerability at the household level. The adoption of such coping strategy was surveyed by ENIGHUR over a period of one year preceding the interview. About 1.6 million mountain people[17] reduced their food expenditures, corresponding to about 23% of total mountain population[18]. About 1 million of these vulnerable people are located in elevation class 3, although the highest share of population that reduced food expenditures is located in elevation class 2 (about 40%).

The main causes behind the food expenditure reductions, as reported by the interviewees, were:

1. Lack of more rewarding job positions for the household head;
2. Death/illness of a household member;
3. Job loss (in urban areas) and failure of family business (in rural areas).

Based on the answers of respondents on the causes of reduced food consumption over the previous year, households are identified as „vulnerable" under the Economic Access dimension if the following situations occurs (see table 4):

14 Corresponding to (respectively): 1: Highway/paved road; 2: Cobbled Road; 3: Road (not paved).
15 Corresponding to (respectively): 4: Path; 5: River/sea/lake; 6: Other.
16 See note 13.
17 Without considering people of the highest income quintile. As explained in note 13, all the figures on population are referred to the 2010 Census of Population.
18 In mountain urban areas 20% of people reduced food expenditures, while in rural areas the share was 26%. At national level, around 4 million people - 28% of national population - reduced food expenditures in the previous year.

a) In rural areas: per capita income below national poverty line, and the household does not own land nor it benefits of any health/job insurance scheme[19].

b) In urban areas: per capita income below poverty line or, for the lowest two income quintiles, households not covered by any kind of health or job insurance.

Results are displayed in table 4 below.

As to the Utilization dimension, finally, the following water sources have been considered „unimproved": truck delivery; well; river, ditch; other sources; on the other hand, "public aqueduct"; "public tank, fountain"; and "pipeline – untreated water" were considered as improved water sources. For the sanitation facilities, all the different types of "toilet" were considered „improved", while "latrine" and "no sanitation facility" were considered as indicators of vulnerability.

Main results are shown in tables 5 and 6. Eight percent of mountain population, corresponding to about 0.5 million people, lack of improved water sources (table 5): this result reflects a better condition of mountain versus lowland populations in Ecuador, as lack of access to improved water sources mainly regards rural areas. As to sanitation, about 0.6 million of mountain people (8%) lack of improved sanitation facilities, against a national average of 10% (table 5).

Thus, also for sanitation facilities the situation in highlands is better than in lowlands, although in the rural elevation classes 2 and 5 about one quarter of the population do not have access to improved sanitation facilities. Similarly to the previous indicator, indeed, the lowest standards are observed in rural areas, where 19% of the population is vulnerable under this dimension, while only 1% of urban mountain population lack of improved sanitation facilities.

Once created the indicators of the single dimensions, CVI is derived as follows:

$CVI = \max(PA, EA, U_W, U_S)$

Where: PA is the indicator of the Physical Access dimension;

EA is the indicator of the Economic Access dimension;

U_W is the indicator of the Utilization dimension related with access to safe sources of drinking water;

U_S is the indicator of the Utilization dimension related with access to improved sanitation facilities.

As previously discussed, each of the above mentioned indicators can assume values of 0 and 1. Accordingly, the CVI is equal to zero when all the indicators are equal to zero, indicating a situation where a given household is not vulnerable to food insecurity, and is equal to 1 when at least one of the indicators is equal to 1, i.e. when a household is vulnerable under one of the food security dimensions.

According to this **Composite Vulnerability Indicator (CVI)**, about 5.8 million people in Ecuador are vulnerable to food insecurity, representing the 40% of national population[20] (table 7).

In mountain areas, the number of vulnerable people is 2.1 million, corresponding to 31% of mountain population. Hence, vulnerability to food insecurity is more severe in Ecuadorian lowlands than in mountain areas. As explained in previous sections, this is mainly due to climatic conditions that favor the presence of mountain urban areas served by many infrastructures, which does not represent a common situation in mountain areas all over the world.

The elevation classes with the higher prevalence of vulnerability are the mostly rural classes 2 and 5, although more than half of the mountain vulnerable people are located in the urbanized class 3. About 19 percent of mountain people have insufficient economic access to food (table 4), making of **economic access** the food security dimension that contributes the most to the final figure of vulnerable people in Ecuadorean mountain areas.

Table 7 - Vulnerable people by elevation class in Ecuador estimated with the Composite Vulnerability Indicator (CVI)

Elevation	Vulnerable People, National (%)	Vulnerable People, National (000)	Vulnerable People, by area (%)	Vulnerable People, by area (000)

20 See notes 13 and 18: population figures refer to the 2010 Population census data.

In mountain urban areas, the share of people vulnerable to food insecurity is 23%, mainly due to high income inequality, higher prices of food, and lack of job or health assistance: a percentage substantially higher than the value estimated by Huddleston et al. for urban areas, but in line with the World Bank indicator used for the study update. In mountain rural areas, on the other hand, vulnerability to food insecurity affects 43% of the population. Indeed, as discussed in the previous sections, isolation, poor quality of water and sanitation facilities, and lack of good job opportunities mainly impact rural mountain areas. Migration in rapidly expanding mountain urban areas, on the other hand, has determined poverty conditions for a substantial number of urban people.

Table 8 below compares the results obtained with the new CVI approach against the results obtained with: the spatial approach of the 2015 update; the FAO indicator "Prevalence of undernourishment" (PoU); and the share of people declaring to have reduced food consumption in the year prior to the survey (ENIGHUR 2011/12 data). At the national level, while 13% of people are estimated to have a caloric consumption below the minimum level for a healthy life, 28% of total population had to reduce food consumption in the year prior to the survey, and 40% are considered vulnerable according to the CVI approach. These results confirm that being vulnerable to food insecurity does not necessarily mean that a particular household is actually food insecure: only about one third of the vulnerable people is below the threshold of minimum dietary energy consumption, and only two thirds of the vulnerable people actually had to reduce food consumption in some way. As to mountain areas, CVI results are in line with those obtained through the spatial approach considering the LAC region, and are slightly higher than the results obtained for the South America sub-region.

Table 8 - Comparison of food security indicators in Ecuador

	National	Mountain areas
Prevalence of undernourishment[21] (PoU, 2010-12)	13%	.
Reduced food consumption (benchmark; ENIGHUR 2011/12)	28%	23%
Vulnerability to Food Insecurity (Spatial approach)	.	31% (LAC[1]) 27% (S.A.[2])
Vulnerability to Food Insecurity (CVI approach)	40%	31%

1: Latin America and Caribbean (Including: Caribbean, Central America and South America).
2: South America

Based on self-declared ethnicity, the two groups with the lowest share of vulnerable people (about 35 percent) are *Mestizo* and *Blanco*, which account for about 75 percent of the total population.

Among indigenous people, which account for about 7% of total population, vulnerability to food insecurity is about 60 percent, and among other minorities[22], the prevalence is higher than the national average as well. Indigenous people - almost 1 million - are mostly located in mountain areas, where they account for about 13 percent of the mountain population, and in rural areas. Vulnerability therefore shows differential patterns among different ethnic communities.

Vulnerability can be reduced by building resilience of both people and communities (UNDP 2014). Social safety nets are an important tool in order to guarantee a minimum acceptable level of household food security over time. They are policy measures adopted to prevent vulnerable people from falling under certain minimum levels of livelihood as a consequence of a shock, allowing households to stay food secure over time. To the aims of this study, a household is benefiting of social safety nets if it benefits of at least one of the following:

- Free breakfast at school (for children aged 5-14);

- Free lunch at school (for children aged 5-14);

- Received "Mi papilla"[23] (for children aged less than 5);

- Received food bags and/or fortified food and/or food education;

- Have been visited by a health care team.

Out of the 2.1 million vulnerable people living in Ecuadorian mountain areas, about 1 million belong to households benefiting from some form of social safety nets. This leaves out about 1.1 million mountain people who are vulnerable to food insecurity and do not benefit from any social safety nets, corresponding to 16 percent of total mountain population.

21 The methodology to estimate the prevalence of undernourishment can be found in SOFI 2015 (FAO, 2015).
22 *Negro, Mulato and Montubio.*
23 Complementary food with high nutrient density.

Again, in mountain areas the share of vulnerable people not benefiting of safety nets is lower than in lowland, with the higher shares observed in classes 2 and 6, and the higher share of people benefiting of safety nets living in class 5 (table 9).

Table 9 - Social safety nets and vulnerable people by elevation class

5. Conclusions

The present study introduces the use of household survey data in the analysis of vulnerability to food insecurity in mountain areas and a new composite indicator called Composite Vulnerability Indicator (CVI). While the spatial approach is mainly based on the presence of given crops and farm animals, and hence on the availability dimension of food security, the new approach takes into account the dimensions of physical and economic access to food, and utilization, which may affect stability of a household"s food security over time.

Based on indicators reflecting the dimensions of food security more relevant at the household level and using ENIGHUR 2011/12 survey data, around 31% of Ecuadorian mountain people - corresponding to 2.1 million people - are estimated to be vulnerable to food insecurity. Two different patterns of vulnerability to food insecurity can be identified in mountain areas of Ecuador: one of the rural areas and one of the urban areas. While in rural contexts vulnerability is often linked to isolation, poor water and sanitation infrastructures, and lack of good job and education opportunities - which in turn causes outmigration to urban areas - in urban settings vulnerability to food insecurity is driven by high income inequality and higher prices of food. In addition to that, the lack of any job or health assistance causes the inability of a household to cope with food related or economic shocks. The majority of vulnerable mountain people live in rural areas, although vulnerability to food insecurity also interests the 23% of the urban mountain population, corresponding to almost 1 million people. This is the reason why in Ecuador, as opposed to many other developing countries, mountain areas are better-off compared to lowlands, because they host densely populated urban areas served by infrastructure generally not available in mountain areas of other developing countries. Almost half of mountain vulnerable people belong to household benefiting from school feeding or other nutrition and health care programs. This means that about 16% of total mountain people, besides being vulnerable to food insecurity, do not benefit from any social safety net, and is therefore at a greater risk in case of a food or market-related shock. This new approach has the advantage of allowing for a precise characterization of vulnerable areas, describing where each of the different vulnerability factors play a major role not only at regional and sub-regional level, but also at national and sub-national level. It also allows to understand who the most vulnerable people are, and for a precise localization of vulnerability hotspots. This, in turn, has a huge potential to help target and facilitate policy interventions.

The results obtained with the new CVI methodology are consistent with those obtained with existing FAO and World Bank methodologies, encouraging to apply this new methodology to other country of different regions and income level[24], provided survey data and geographic location of the interviewed households are available for the analysis.

[24] Another case study, of Malawi, has already been published in the same FAO 2015 publication, although other countries should be analysed to test the robustness of the CVI methodology.

Determinants of dietary Diversity in Namibian Children: Evidence from 2013 DHS

L. Pazvakawambwa | University of Namibia, Department of Statistics and Population Studies | Windhoek | Namibia

N. Nickanor | University of Namibia, Department of Statistics and Population Studies | Windhoek | Namibia

DOI: 10.1481/icasVII.2016.b11d

ABSTRACT

This study aimed at establishing levels and factors influencing dietary diversity in Namibian children as a proxy of food security. The study made use of secondary data from the Namibia 2013 Demographic and Health Survey, from a cross-sectional representative women in the reproductive age group (15-49) from all 14 provinces. Dietary data was used to come up with a dietary diversity score (DDS) that was calculated by counting each of 11 food groups. A DDS ↓5 was regarded as reflecting poor dietary diversity and poor food security. A generalized linear regression model was fitted to model dietary diversity with independent variables such as socio-economic status, region, mother's level of education, religion, ethnicity, marital status and place of residence. Results indicated that dietary diversity was low in rural areas. There were significant differential in dietary diversity with socio-economic status, marital status, place of residence and ethnicity. Generally the majority of Namibian children consumed a diet which varied less.

Keywords: Dietary diversity, Food security, Children, Namibia

PAPER

1. Introduction

The three major components underlying food security are food availability, accessibility and utilization. Critical to ensuring adequate intake of essential nutrients that promotes good health and well-being is the intake of a variety of foods and food groups (Ruel, 2002). Dietary diversity is not only viewed as a proxy measure of food security (Hoddinott and Yohannes, 2002), but has become an important measure of the diverse diet and by implication an indicator of nutritional adequacy and quality (Foote, et al., 2004). Consumption of a higher number of food items and food groups is associated with positive health outcomes such as birth weight, child anthropometric status (Hoddinott and Yohannes, 2002); improved nutritional adequacy (Hatloy, et al., 1998) it also highly correlated with caloric and protein adequacy. Among adults, diversified diet is associated with reduced complications of diabetes (Wahlqvist, et al., 1989), reduced incidence of cancers (Fernadez, et al., 1996; Lucenteforte, et al., 2008). A number of studies have shown, using Dietary diversity score (DDS) which counts the number of food groups consumed over a specified reference period to assess dietary diversity, that DDS is positively associated with overall dietary quality (Steyn, et al., 2006; Kennedy et al., 2007).

In developing countries, deficiencies of selected micronutrients prevalent among young children and women of childbearing age were found to be associated with birth defects, growth restriction, impaired cognition and increased morbidity and mortality (Black, et al., 2008). A limited or lack of dietary diversity is primarily responsible these deficiencies particularly among population groups of concerns in developing countries. Understanding dietary intakes among children is important in order to develop evidence-based strategies. The purpose of the present study was to assess dietary diversity among children under five in Namibia as a proxy of food security. In addition, we examined the relationships between dietary diversity and socio-demographic variables.

2. Methods

Secondary data from the Namibia Demographic and Health Survey NDHS (2013), from a cross-sectional sample of representative mothers from all the regions was used. The woman responded to dietary questions regarding the feeding of their children. The responses were used to compute a dietary diversity score (DDS) given by the total number of food groups consumed by the children out of the recommended 12 (Bread, noodles, other made from grains; Potatoes, cassava, or other tubers; Eggs; Meat (beef, pork, lamb, chicken, etc); Pumpkins, carrots, squash (yellow or orange inside); Dark green leafy vegetables; Mangoes, papayas, other vitamin A fruits; Any other Fruits.

Liver and heart organs; Fish or shell fish; Food made from beans, peas, and lentils; and Cheese, yorghut, and other milk products). A DDS of ↓5 was regarded as reflecting poor dietary diversity and poor food security. A binary logistic regression model was fitted to model DDS (1=DDS of at least 5, 0=DDS↓5) with independent variables such as wealth index, region, mother's highest educational level, religion, ethnicity, marital status and place or residence, to establish the determinants of dietary diversity in

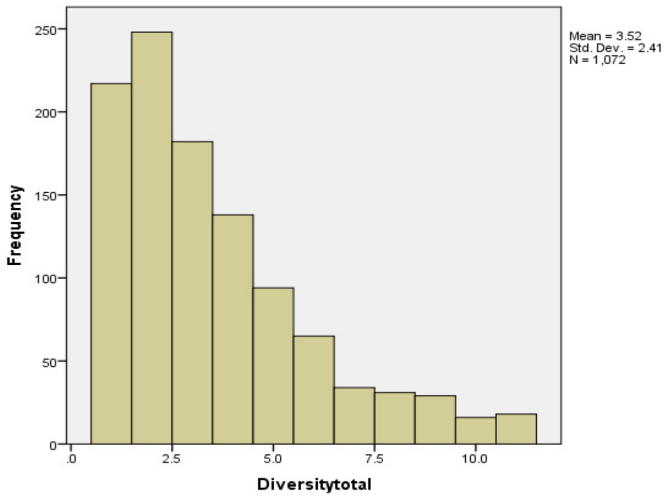
3.Results

Background characteristics of the sample

The composition of respondents by age-group was 15-19 (4.4%), 20-24 (16.4%), 25-29 (19.6%), 30-34 (17.8%), 35-39 (16.9%), 40-44 (13.7%) and 45-49 (11.1%). Their distribution by region was Zambezi (7.5%), Erongo (9.0%), Hardap (6.7%), !Karas (9.0%), Kavango (8.9%), Khomas (9.4%), Kunene (7.4%), Ohangwena (7.3%), Omaheke (6.5%), Omusati (7.1%), Oshana (6.4%), Oshikoto (6.6%) and Otjozonjupa (8.1%). Most of the respondents resided in urban areas (51.6%). With regard to their highest educational level, 7.6% of the respondents had had no formal education, 22.9% had primary education, 63.4% secondary education, and only 6.1% had higher education. Their religious affiliations ranged from Roman Catholic (21.1%), Protestant/ Anglican (23.2%), ELCIN (40.2%), Seventh Day Adventist (5.8%), no religion (1.4%), and others (8.3%). Most of the households were female headed (54.0%). The socio-economic status of the respondents (measured by the wealth index) ranged from poorest (17.2%), poorer (19.5%), middle (21.8%), richer (23.5%) to the richest (18.1%). Their distribution with regard to marital status was as follows: never in union (42.3%), married (25.9%), living with partner (22.5%), widowed (2.9%), divorced (1.3%), no longer living together / separated (4.9%). Their cultural diversity (measured by the main language spoken at home) ranged from Afrikaans (9.8%), Damara/Nama (16.2%), English (1.3%), Herero (10.3%), Kwangali (9.4%), Lozi (7.1%), Oshiwambo (41.5%), San (1.3%) and others (3.1%).

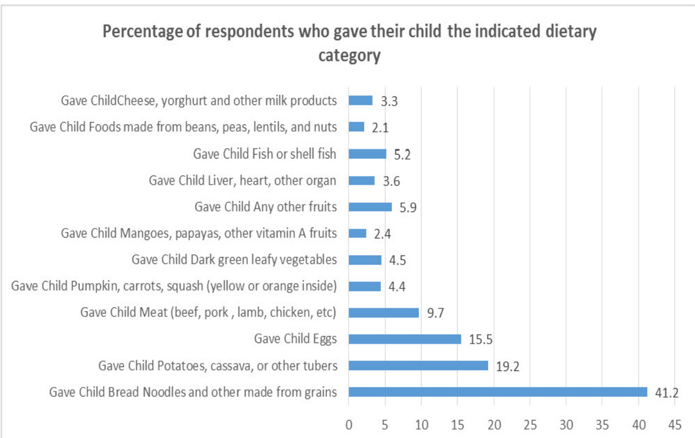
From the food groups proposed by FANTA (Swindale and Bilinsky, 2006), the dietary diversity score, which is the sum of the different food groups consumed by each child, ranged from 1 to 11 with a mean of 3.52 with a standard deviation of 2.41 [95% CI: 3.38 – 3.67]. The histogram of the dietary diversity scores are presented in Figure 1. The dietary diversity scores were skewed towards very few food groups.

Figure 1 - Histogram of Dietary diversity scores for children



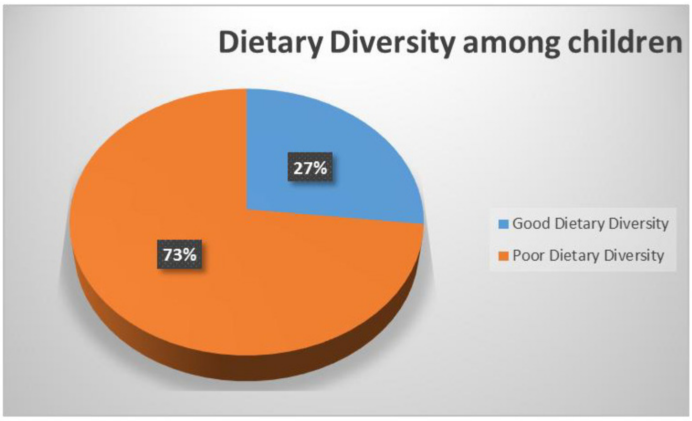
The proportion of children consuming foods from the various groups are presented in Figure 2. It was worrying to note that there was very little consumption of foods all other groups except for the Bread, Noodles and ... group (41.2%); and Potatoes, cassava, or ....(19.2%); and to a lesser extend eggs (15.5%).

Figure 2 - Percentage of respondents who gave their child food from the indicated dietary food group



A dietary diversity score of less than 5 was considered poor. The pie chart in Figure 3 shows that only 27% of the children had a good dietary diversity. The rest of the children had a poor dietary diversity (73%).

Figure 3 - Pie chart showing percentage distribution of dietary diversity in children



Bivariate analysis results

Chi-square tests of association between the dietary diversity score and potential predictor variables are given in Table 1.

Table 1 - Results of Chi-Square Tests of Association between the dietary diversity score and potential predictor variables.

Independent Variable	Pearson Chi-Square Statistic	P-value
Respondent Age-group	7.972	0.240
Region	95.077	P<0.001***
Place of residence	49.716	P<0.001***
Highest educational level	53.322	P<0.001***
Religion	4.315	0.505
Sex of Household Head	2.848	0.091
Wealth Index	72.753	P<0.001***
Marital Status	19.083	0.002
Main Language spoken at home	30.326	P<0.001***

The results of Chi-square tests of association at 5% level of significance indicated that dietary diversity in children was significantly associated with region (Chi-square=95.077, p<0.001); place of residence (Chi-square=49.716, p<0.001); highest educational level (Chi-square=53.322, p<0.001); wealth index (Chi-square=72.753, p<0.001); marital status (Chi-square=19.083, p=0.002); and main language spoken at home (Chi-square=30.326, p<0.001). There was no significant association between dietary diversity in children with the mother's age-group (Chi-square=7.972, p=0.240); religion (Chi-square=4.315, p=0.505) and the sex of the head of that household (Chi-square=2.848, p=0.0.091). Those potential indicator variables with significant associations were input into the binary logistic regression model to establish the extent of their effects on dietary diversity in children.

Results of logistic regression are presented Table 2. The regression results showed significant differentials in dietary diversity with respect to region. Children from Erongo (OR=2.073 ,CI:1.010-4.253, p=0.047); !Karas (OR=2.286 ,CI:1.120-4.665, p=0.023); and Khomas (OR=2.360 ,CI:1.158-4.811, p=0.018) regions were about twice more likely to have a good dietary diversity compared to their counterparts in the Otjozonjupa region. With regard to the highest educational level, children of mothers with no formal education (OR=0.150 ,CI:0.043-0.516, p=0.003); and those whose mothers had primary education (OR=0.337,CI:0.143-0.794, p=0.013) were less likely to have a good dietary diversity compared to those of mothers with higher education. Results also revealed that children from the poorest households (OR=0.387 ,CI:0.183-0.817, p=0.013) were less likely to have a good dietary diversity compared to those from the richest households.

Significant differentials were also observed with respect to the main language spoken at their homes (a proxy for cultural effects). Children from Afrikaans (OR=0.274, CI:0.101-0.743, p=0.011); Damara/ Nama (OR=0.270, CI:0.104-0.704, p=0.007); Herero (OR=0.334, CI:0.116-0.961, p=0.042); Kwangali (OR=0.217, CI:0.087-0.541, p=0.001); and Oshiwambo (OR=0.368, CI:0.146-0.924, p=0.033) speaking homes were less likely to have a good dietary diversity compared to those speaking other languages. However, the marital status of the mother, and the place of residence did not have a significant effect on dietary diversity among the children.

4. Discussion

In this cross-sectional analysis, we examined the dietary diversity of children under-five regardless of breast feeding status. Overall, our results of the regression tend to confirm the findings of previous work in neighbouring South Africa, as measured in the NFCS in 1999, where DDS had a mean of 3.6. Comparing it to Namibia, although different dietary methods were used, it should be recognised that the majority of children in Namibia have a very limited dietary variety. The adequacy of intake of some specific food items (especially lentils, Vitamin A rich fruits) implied means that micronutrients was particularly low. Folate intakes were also very low due to the limited quantities consumed by the children in lentils and green leafy vegetables (2.1% and 4.5% respectively). Only 3.3% of children consumed milk or milk products which are essential for providing Calcium. The children's diet consist primarily of starchy foods and by implication certain micronutrients were deficient. These children should be regarded as being at risk of undernutrition. DDS.

5. Conclusions

Our study shows dietary diversity among young children in Namibia is alarmingly low and primarily starch based. This limits the consumption of essential micronutrients leading to lack sufficient nutrient-dense foods to achieve micronutrient adequacy as shown by the limited dietary diversity. Although a small number of children did consume from a diverse food group this study was not able to determine the sufficiency and frequency of the quantities in order to assess the adequacy, as a limitation of the study. Another limitation was that the foods consumed by the children was based on the recall from their mothers who may not recall some food items consumed in between meals.

ABSTRACT

Food balance sheets as comprehensive food and agricultural statistics play an important role to provide information on patterns, levels and trends of national diets in a country and it measures the food supply of the population. In this paper, tried to prepare the Food balance sheets of Iran for two years (2013-2014) .Firstly, built the Supply Utilization Accounts to enable comparison of food availability with food use and secondly prepared other measures and outputs including: Import dependency ratio (IDR), Self-Sufficiency ratio (SSR), and after standardization of commodities food balance sheets for analysis of the pattern of per caput food supply.

Keywords: Food balance sheets, Import dependency ratio (IDR), Self-Sufficiency ratio (SSR), Per Caput food supply.

PAPER

1. INTRODUCTION

The interest in food balance sheets in Ministry of Jahad agriculture increased considerably after focusing duties and authorities of commercial and industrial of agricultural sector to Ministry of Jahad agriculture in 2013, then access to Information of the food and agricultural situation like: production, utilization, stocks & trade were the major source of data to increase food market transparency and reduce volatility of the food prices and forecasting for raising standards of living and providing the policy analysis and decision-making needed to ensure food security.

National Food balance sheets were prepared by Agricultural Planning, Economic & Rural Development Research Institute in Iran from 1989 to 2012 and the latest two Food balance sheets were prepared by Information Technology and Communication Center. In constructing the Food balance sheets, both official and unofficial data available in ITC Center and missing data have been estimated on basis of surveys and other information as well as technical expertise. The purpose of this study is to provide comprehensive information on patterns, levels and trends of national diets.

The paper discusses about nature of food balance sheets, data sources, commodity coverage, supply and utilization elements, preparing and standardization of food balance sheets, analysis of the pattern of per caput food supply and Import dependency ratio (IDR), Self-Sufficiency ratio (SSR).

1. NATURE OF FOOD BALANCE SHEETS

Food balance sheets present a comprehensive picture of the pattern of country's sources of supply and utilization for each food item during a year. The total quantity of foodstuffs produced in country added to the total quantity imported and adjusted to any change in stocks that occurred since the beginning of the year, gives the supply side of the food balance equation. On the utilization side a distinction is made between the quantities of exported, fed to livestock, used for seed, processed for food use and non-food uses and lost.

The per *caput supply* of each food item available for human consumption is obtained by dividing the respective quantity by the population partaking of it. Data on per caput supply are expressed in terms of quantity and energy, protein and fat. They are an important element for projecting food demand, together with such other elements as income elasticity coefficients, private consumption expenditure and population. A comparison of the quantities of food available for human consumption with those imported will indicate the extent to which a country depends upon imports (Import dependency ratio (IDR)) to feed itself (Self-Sufficiency ratio (SSR)).

1.1. DATA SOURCES

Food balance sheets are assembled form a variety of sources. Production data are based on annual surveys, trade data are register based, information on stock changes and industrial uses is available from marketing authorities, feed rates are obtained from government agencies, seeding rates are obtained from cost of production surveys, lost rates and composition factors are obtained from FAO documents and the total population is register based.

1.2. COMMODITY COVERAGE

All potentially edible commodities were taken into account in preparing food balance sheets. Generally, food balance sheets are constructed for primary crops, livestock and fish commodities up to the first stage of processing in the case of crops and to the second stage of processing in the case of livestock and fish products. The major food groups were: Cereals, Roots and products, Sugars and Syrups, Pulses, trees nuts, Oil crops, vegetables and products, Fruits and products, Meat, Fish and products, Milk and Cheese, oil and Fats.

2. SUPPLY AND UTILIZATION ELEMENTS

Production - For primary crops, production is related to the total domestic production at the farm level and livestock items in terms of live weight for primary fish items. Production of processed commodities relates to the total output of the commodity at the manufacture level (it comprises output from domestic and imported raw materials of originating products).

Changes in stocks - This comprises changes in government stocks. Increases in stocks of a commodity reduce the availability for domestic utilization. They are indicated by the (–) sign and decreases in stocks by the (+) sign since they increase the available supply.

Imports - It includes commercial trade of all movements of the commodity in question into the country during the year.

Exports - It includes commercial trade of all movements of the commodity in question out of the country during the year.

Supply - The elements involved are production, imports, exports and changes in stocks then the definition for supply was:

Production+ imports- exports + changes in stocks = supply for domestic utilization

Feed - This comprises amounts of the commodity that are fed to livestock during the year, whether domestically produced or imported.

Seed - This comprises all amounts of the commodity used during the year for reproductive purposes such as seed whether domestically produced or imported.

Food Manufacture - The amounts of the commodity used during the year for manufacture of processed commodities.

Waste – This comprises amounts of the commodity lost at all stages between the level at which production is recorded and the household.

Food – This comprises the amounts of the commodity that are available for human consumption during the year.

Per caput food supply – These estimates are provided of per caput food supplies available for human consumption during the year in terms of quantity, caloric value, protein and fat content. The caloric value, the protein and fat content were calculated in base on FAO's food composition factors for Islamic republic of Iran.

3. PREPARATION AND STANDARDIZATION

The utilization of all the information which was assembled for construction of a food balance sheet often ends up in a rather long list of food commodities and standardization can be achieved by showing only primary commodities and processed commodities (except for sugar , oil and fats) are converted into their originating primary commodity equivalent. This procedure facilitates the analysis of food balance sheets with no loss of pertinent information.

4. IMPORT- DEPENDENCY RATIO (IDR)

An important aspect in assessing the food situation within a country – including food security –is the extent to which supply is dependent on external imports. The Import Dependency Ratio (IDR) measures precisely the percentage of a country's supply that is derived from imports, defined as:

*IDR = Imports / (Production + Imports – Exports) * 100*

The value of 100 indicates 100% of the country's supply for a given commodity is dependent on imports; value of 40 indicates 40% of a country's supply for a given commodity is dependent on imports or conversely, 60% of the country's supply for the commodity is produced within the country. The IDR can be calculated for individual commodities, groups of commodities of similar nutritional values, or even the aggregate of all commodities.

5. SELF- SUFFICIENCY RATIO (SSR)

The Self-Sufficiency Ratio (SSR) expresses the magnitude of production in relation to domestic utilization, defined as:

SSR = Production / (Production + Imports – Exports) * 100

The value of 100 indicates 100% of the country's supply originates from the country's own production; the value of 30 indicates 30% of the country's supply originates from the country's own production. In the context of food security, the SSR is often taken to indicate the extent to which a country relies on its own production and higher ratio, the greater the self-sufficiency.

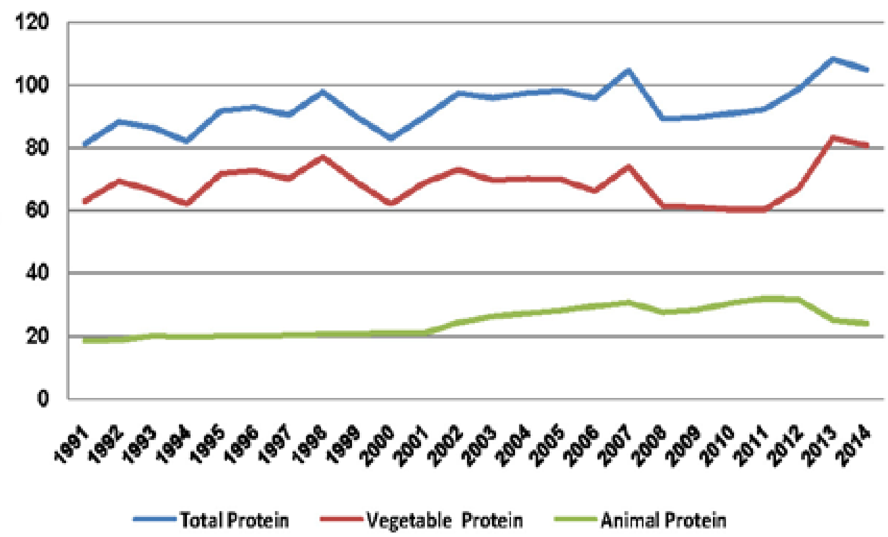
Figure2- Daily Protein Per caput supply in 1991-2014



Conclusions

The study of food security by food availability index during the period 1991-2014 in Iran shows that the average of total energy supply is 3506 kcal and it is more than the population average per capita requirement of 2870 kcal in the general case in the world and the average total calories supply is 93 grams and it is more than the population average per capita requirement of 80 grams in the general case. The average percent of vegetable products energy supply during the period 1991-2014, is 89% and the average percent of animal products energy supply is 13%. The average percent of vegetable products protein supply is 74% and the average percent of animal products protein supply is 36%. Increase of the annual growth rate of energy supply per capita of vegetable products (1.09 percent) from animal products (0.55 percent) and accordingly, Increase of the annual growth rate of protein supply per capita of animal products (1.14 percent) from vegetable products (1.09 percent) . In 2013, the main sources of calories are cereals 48%, fruits 13% and oils 7%. The main sources of proteins are cereals 47%, vegetable 15% and meats 13%. The main sources of fats are oils 41%, nuts 16% and meats 14%. In 2014, the main sources of calories are cereals 50%, fruits 14% and oils 8%. The main sources of proteins are cereals 51%, vegetable 12% and milks 6%. The main sources of fats are oils 45%, milks 11% and nuts 10%.

Statistical trends in agriculture in light of the future sustainable food security in Slovenia

Š. Gale | Statistical Office of the Republic of Slovenia | Ljubljana | Slovenia

DOI: 10.1481/icasVII.2016.b12b

ABSTRACT

The concept of a sustainable food security on the national or global level includes the availability to provide sufficient amount of food also in exceptional and critical circumstances, as well as a higher level of potential rates of self-sufficiency and traceability of safely produced agricultural products. The primary purpose of this paper is to outline the state and the importance of the Slovenian agriculture and to link the available statistical data with the academic assumptions.

Agriculture in Slovenia is carried out as a traditional industry in a specific geographical and climatic situation and has therefore certain specific characteristics. At the latest agricultural census in 2010 there were just over 75,000 agricultural holdings in Slovenia, of which 61% were smaller, with less than 5 hectares of utilised agricultural areas and were cultivating 22% of total utilised agricultural areas. Larger agricultural holdings represented only 2% of all agricultural holdings in Slovenia.

The dominant type of agricultural holdings were family farms, similarly to other European countries. Slovenia is also one of the European countries with the smallest area of arable land per capita and one of the countries with above European average share of permanent grassland. Economic accounts for agriculture data on agricultural subsidies, labour input and investments also enable more in-depth knowledge of the agricultural specifics.

Slovenia is traditionally a net importer of food, since domestic production does not meet the needs for agricultural products. Data of the national supply balance sheets show that the annual domestic agricultural production varied over the past decade, partly due to changes in the area set aside for individual agricultural products and partly due to the increasingly unreliable weather conditions and the increasingly unreliable yield per hectare. Domestic consumption, which can be consumed for various purposes (food, further processing, industry, animal fodder), was mainly gradually declining in the same period, but mostly exceeded the domestic production. Rates of self-sufficiency, which show to what extent domestic production covers domestic consumption, were mostly lower than 100%. Slovenia has higher self-sufficiency rates for animal products than for crops; the rates are the lowest for vegetables (38% in 2014), potato (68% in 2014) and cereals (78% in 2014).

Nevertheless, some expert and academic assessments show that Slovenia has sufficiently big potential in availability of agricultural land to improve its food security by 2030. To ensure greater food security in the future academics propose the increase of the agricultural areas and agricultural yield, conversion to organic farming, reduction of the quantities of food waste and a change of eating habits, especially the reduction of meat consumption.

The aim of the paper is therefore to show the statistical agricultural trends of the selected agricultural indicators with the purpose to support or reject the current academic positions and proposals for the future improvement of the national food security. The paper further aims to target the potential development areas of the Slovenian agriculture in this light and offer some suggestions for the potential future improvement of some segments of food security in Slovenia.

Keywords: agricultural holdings, indicators, supply balance sheets, self-sufficiency rate

PAPER

1. Introduction

Key problems of global so-called commercial (conventional) agriculture today are unequal distribution of globally (still) sufficient food production, "chemisation" of activity, soil erosion (on more than 900 million hectares of agricultural land in the world), large water consumption, building up of agricultural land, and a rapidly growing world population. On many agricultural areas consumption of mineral fertilisers per hectare represents an environmental burden. Conventional agriculture is distinctly capital and energy intensive, albeit productive, employs few people (in developed countries less than 5% of the population) and presents a large environmental burden (Stutz, Warf 2005). Fossil fuels are used for production and sustainable economy of local communities is neglected, since agricultural products are usually sold on distant markets.

Sustainable development model, which is a multi-layered growth of well-being among people, involves permanent protection of available natural resources. Sustainable development is development consistent with the capacity of the environment both in terms of permanent supply of the population with natural resources and in terms of the capacity to neutralise various environmental burdens (Plut 2014). It is characterised by the use of local natural resources and decentralisation of production due to the need for greater self-sufficiency (Stutz, Warf 2005).

In expected uncertain conditions of unstable food supply[1] at the global level due to climate change, local, regional and national self-sufficiency in food is becoming a very important issue. Slovenia cannot cover its needs for agri-food products on its own, but experts assess that Slovenia has sufficient potential of agricultural land to improve its food security by 2030 (Plut 2012). Due to many environmentally positive consequences, it is appropriate to treat the increase in self-sufficiency as one of the key areas of sustainable development. The concept of food security includes the ability to provide food even in exceptional and critical circumstances, secure level of potential self-sufficiency and traceability of safely produced agricultural products (Perpar, Udovč2010). Food security and own food production at the national level are again becoming the issues of strategic importance.

2. Global agricultural trends

The reasons for lack of food on the global and regional markets are negative consequences of climate change (more frequent droughts and floods), increasing prices of mineral fertilisers, use of larger agricultural area for producing biofuels (ethanol, biodiesel), extensive conversion of agricultural land into building sites, erosion, and growing wheat consumption for meat production. Large energy consumption and large emissions of greenhouse gases from traffic during the transport of food over large distances are key wider negative environmental impacts (Nierenberg, Halweil 2005). Agricultural systems contribute significantly to water consumption, to climate change, to reducing biodiversity and to soil depletion (Sage 2012). Production of 1 kilogram of wheat namely requires 900 litres of water, 1 kilogram of maize 1,400 litres of water, and 1 kilogram of beef as much as 15,000–20,000 litres of water (Nierenberg, Halweil 2005, p. 77).

In the opinion of environmental and agricultural experts, in the next few decades it might be possible to influence the expansion of agricultural land, an increase of yields on existing agricultural area, usage of new food sources, a decrease of food waste in developed countries, to distribute food more fairly and to change eating habits by not increasing the share of meat from animal farms (use of cereals) in the diet of people in developing countries and by constantly decreasing meat consumption in developed countries. Due to energy and environment reasons, meat consumption and the share of meat should decline in developed countries, while in globally and geopolitically strained conditions of food supply the consumption of wheat for meat production should be drastically limited. For a meat-based diet, on average four times more resources are necessary than for a vegetarian diet. Due to the lack of food and environmental reasons, some experts point out the need to move to a more vegetarian diet in developed countries (Maxey 2007). The predominance of the vegetarian diet of the world population would require 700–800 m2 of intensively farmed agricultural land per capita, while the predominance of the diet based on meat and dairy products would require up to 4,000 m2 per capita. To meet the average daily intake of 2,500 kcal per capita with 30% of animal products, around 1,500 m2 intensively farmed agricultural land per capita would be needed, while a high share of meat would require around 3,000 m2 per capita. To feed 10 billion people, in mid-21st century we would thus need 880–3,000 million hectares of land, most probably 1,100–1,300 million hectares. This means that in the case of a lower share of meat and dairy products in the global diet, no additional agricultural land would actually be needed (Sage 2012).

3. Slovenian characteristics in terms of sustainable development and agricultural trends

In terms of sustainable development, Slovenia is characterised by the stabilisation of the population and population pressures on the environment, smaller cities, large dispersion and small settlements, rich water resources, very well preserved nature and high-quality living environment on most of its territory. Our country is distinguished by exceptional landscape and biodiversity, but also by excessive consumption of natural resources and various forms of environmental burdening, including the existence of spatially delineated areas of intensive and multilevel landscape degradation.

[1] Food includes a set of agricultural products (meat, eggs, cereals, potato, vegetables, sugar and rice) in basic or processed form.

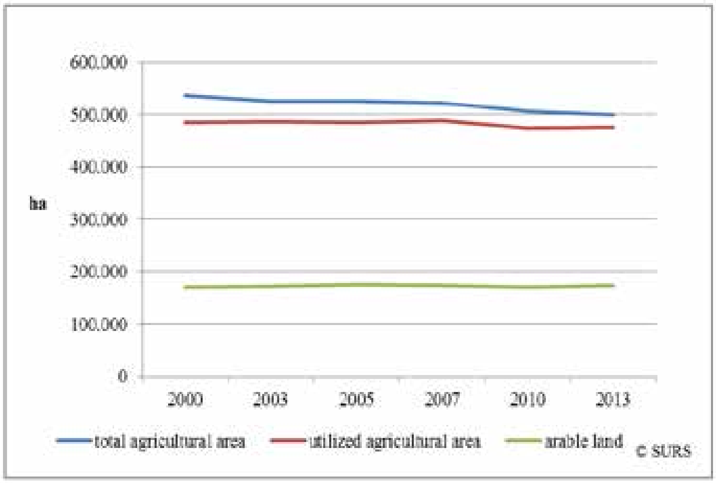
Between 2002 and 2007, 19,712 hectares of Slovenian's territory were built up, of which 65% was agricultural land (Odnos do kmetijske zemlje 2010; Perpar, Udovč2010). The draft Slovenia's Development Strategy for the 2014–2020 period points out increasing development differences among Slovenian regions.

Even though agriculture contributes only 1.2% of total GDP in the EU-27, and also in Slovenia in 2010, it is one of the most important industries. In addition to its most important task of providing people with high-quality food, agriculture takes care of preserving the cultural landscape, has a positive impact on rural development, on preserving settlement, particularly in demographically endangered areas, and creates jobs. The integration of agriculture into the environment and factors related to environmental protection – such as preservation of biodiversity, improving the well-being of livestock, sustainable farming, etc. – are being increasingly emphasized. Agriculture is an important part of the economy since it provides inputs for agro-industry, supplements tourism industry, performs municipal services, etc. The Common European Agricultural Policy focuses its increasing attention on comprehensive treatment of agriculture and rural areas and spends a considerable share of the total EU budget for these purposes (Agriculture in Slovenia and in the Rest of the EU 2014).

An average agricultural holding in Slovenia is less than half the size of an average agricultural holding in the EU-27 (according to 2010 data just over 6 hectares of utilised agricultural area). Half of agricultural holdings in Slovenia have less than 5 hectares of utilised agricultural area. Smaller agricultural holdings (less than 5 hectares of utilised agricultural area) represented 61% of all agricultural holdings in Slovenia; they were cultivating 22% of total utilised agricultural area in the country. Larger agricultural holdings (more than 30 hectares of utilised agricultural area) represented only 2% of all agricultural holdings in Slovenia; they were cultivating only a fifth of total utilised agricultural area in the country.

According to statistical data for 2010, utilised agricultural area in Slovenia represented less than a quarter of total area. Slovenia was thus one of the four EU-27 Member States with less than 0.1 hectare of arable land per capita. The most widespread crop in Slovenia was maize, which was sown on almost 37% of arable land (59% as maize for grain and the rest as green maize). Wheat was sown on almost 19% of arable land, but because the share of arable land is low, Slovenia is not self-sufficient in wheat. Cattle and milk production are the most important part of livestock production representing 58% of the total value of livestock production. Cattle breeders in Slovenia breed on average 13 cattle per agricultural holding. Pig breeding represents only 12% of the total value of livestock production in Slovenia. 23% of sheep and goats are bred on agricultural holdings having the status of organic farms or farms in transition to organic farming. In Slovenia there are more than 2,000 organic farms (Agriculture in Slovenia and in the Rest of the EU 2014). In 2014 the share of organically farmed utilised agricultural area was just over 8%.

Figure 1 - Agricultural area, utilized agricultural area and arable land, Slovenia



1) Due to rounding, the sum specified may not match.
Source: Statistical Office of the Republic of Slovenia

Around 1960 there were around 300,000 hectares of arable land and kitchen gardens in Slovenia; by 1991 the number dropped to 200,000 hectares, mostly on account of overgrowing and building up of agricultural land. In 1991 there were 246,000 hectares of arable land, which is 1.242 m2 per capita and in 2010 only 170,000 hectares (in 2011 only 168,700 hectares) or only 830 m2 per capita. As regards the area of arable land and kitchen gardens, Slovenia is among EU Member States with lowest values. More than half of arable land was used for producing cereals, particularly maize for grain and wheat, and almost a third was used for producing green fodder, mostly green maize, and grasses and grass-clover mixtures. Maize fields are also used for producing silage as the basis for an increasing number of biogas plants. The European provision on the necessary extent of biogas production reduces the production of crops for food (Perpar, Udovč2010). In 1991, there were 561,295 hectares of utilised agricultural area in Slovenia, which is 2,833 m2 per capita; in 2000 the number was 508,960 hectares or 2,571 m2 per capita, and in 2009 only 468,496 hectares or 2,297 m2 per capita, which is well below the EU-27 average (3,510 m2 per capita) (Keyfigures on Europe 2010). According to SURS's data and the agricultural census, in 2010 there were 474,432 hectares of utilised agricultural area in Slovenia or 2,350 m2 per capita. In geographically and climatically similar conditions, secure food supply in Slovenia would require at least 3,000 m2 of utilised agricultural area (arable land, permanent grassland, orchards and vineyards) per capita (Hrustel Majcen 2004).

In 2007 the global average area of cereals was 1,000 m2 per capita; at that time cereals in Slovenia were sown on around 100,000 hectares, which is only 500 m2 per capita; in 2010, 152,000 tons of wheat grain was produced on 7% smaller area (75 kilograms per capita), which is 8% more than the 2005–2009 average (140,000 tons). The yield per hectare of wheat (4.8 t/ha) was among the best in the five-year period. Maize output in 2010 was 300,000 tons, i.e. an average result in recent years. As regards the share of agricultural holdings breeding livestock, Slovenia is among the top EU-27 Member States (79%). As regards the intensity of livestock production, which is measured by the number of livestock units per hectare of utilised agricultural area, Slovenia is among the top ten EU-27 Member States. In Slovenia the average is 1.1 livestock units per hectare of utilised agricultural area, just above the EU-27 average of 0.8 livestock units per hectare of utilised agricultural area. To cultivate a hectare of utilised agricultural area, farmers in Slovenia spend on average a lot more hours per year (286) than farmers in the EU-27 (102).

The self-sufficiency rate, which shows the extent to which domestic production meets domestic consumption, depends on the weather conditions in an individual year, particularly for crops. In 2014, self-sufficiency in wheat was 70%, and for cereals in general 77%. Self-sufficiency was the lowest in vegetables; only 38% in 2014. As regards animal products, self-sufficiency rates were higher: meat 80%, milk (2006–2011) between 115% and 120%. Per capita meat consumption has declined over the past ten years; in 2005 it was 97 kilograms and in 2014 85 kilograms.
The most obvious reason for the strategically low self-sufficiency rates in Slovenia is decrease in arable land (and thus the area of cereals); also important is the low level of exploitation of the entire natural agricultural potential. The general decrease in agricultural land due to abandoning agricultural production and building up the most fertile flatland areas had a negative impact on self-sufficiency (Plut 2012).

Due to rich water resources, Slovenia is one of the countries that use very low shares of available water resources for water supply and is in this respect comparable to Austria, Switzerland and Finland. In the 2005–2007 period on average only 2–3% of all available water was abstracted (so-called water stress is practically non-existent) (The European Environment 2010). Nevertheless, due to climate change and expected larger needs for irrigation, it is expected that particularly in the western and north-eastern parts of Slovenia the problems with seasonal hydrological and agricultural lack of water in the vegetation period will become worse.
Among the mentioned national priority sustainable self-sufficiency issues, in the opinion of national experts (Plut 2012), achieving a secure rate of food self-sufficiency, production and consumption of locally produced, high-quality and healthy food will most probably be the most demanding strategic sustainable development task at the national level. We should also decrease the amount of food waste. According to SURS's estimate, in 2013 40% of food consumed in Slovenia was produced in Slovenia and 60% was imported. In 2013, 4 percentage points less locally produced food was consumed in Slovenia than in 2010 (44%); most of the food was imported from the neighbouring countries (Hungary, Austria, Italy and Croatia). According to SURS's rough estimates[2] the amount of waste food was falling in the 2010–2014 period. In 2014 a person in Slovenia generated on average 59 kilograms of food waste[3]; in 2010 the figure was 88 kilograms. Large enough agricultural land and preservation of natural soil fertility on around 75,000 agricultural holdings will be the key natural conditions for preserving food security in Slovenia at the time of the stabilisation of its population.

[2] The rough statistical estimate of the amount of food waste (food waste per capita) is the first attempt to calculate the indicator, so data should be used with caution. The national methodology for a more realistic calculation is being prepared.

[3] Food waste covers the following types of waste:

02 01 02 Animal-tissue waste (wastes from agriculture, horticulture, aquaculture, forestry, hunting and fishing)
02 01 03 Plant-tissue waste (wastes from agriculture, horticulture, aquaculture, forestry, hunting and fishing)
02 02 02 Animal-tissue waste (wastes from the preparation and processing of meat, fish and other foods of animal origin)
02 03 01 Sludges from washing, cleaning, peeling, centrifuging and separation (wastes from fruit, vegetables, cereals, edible oils, cocoa, coffee, tea and tobacco preparation and processing; conserve production; yeast and yeast extract production, molasses preparation and fermentation)
20 01 08 Biodegradable kitchen and canteen waste (municipal waste)
20 01 25 Edible oil and fat (municipal waste)
20 03 01 Mixed municipal waste
20 03 02 Waste from markets

4. Strategic expert proposal for improving the level of food security for Slovenia

Despite relatively low self-sufficiency rates, in the opinion of experts, Slovenia has sufficiently large agricultural land potentials to be able to significantly increase the self-sufficiency rates (Plut 2013). The experts propose:
... Stabilisation of the extent of built-up areas
... Remediation of degraded agricultural area
... Preservation of biodiversity and landscape ecosystems
... Increasing the importance of hilly areas for food
... Protection of irreplaceable fertile agricultural area
... Increasing the extent of agricultural area by a third or at least a quarter of the current extent
... Increasing utilised agricultural area to around 600,000 hectares to achieve the strategic minimum of 3,000 m2 of utilised agricultural area per capita
... Increasing arable land to around 250,000 hectares (or 1,250 m2 per capita) instead of the current 170,000 hectares (less than 900 m2 per capita)
... Increasing the area of cereals to 140,000 hectares (by 2030) to achieve 700 m2 of area of cereals per capita instead of the current 500 m2 per capita
... Streamlining agricultural production into producing food in an integrated and organic way (despite lower yields), with the emphasis on cereals (particularly wheat, not so much maize)
... Increasing the self-sufficiency in vegetables; reducing local production and consumption of meat
... Limiting the production of fodder in flatland areas
... Focusing on orchards, vineyards, pastures and traditional livestock production in hilly areas
... Limiting the production of biofuels on agricultural land (rape seeds and maize for biofuel) to degraded areas

Organic farming responds to key challenges by providing a high level of public goods such as soil quality and biodiversity. It also contributes to the sustainable development of rural areas by creating a larger number of jobs and acting as a promotor of innovation in rural development. In 2004, the EU adopted the European Action Plan for Organic Food and Agriculture and the Government of the Republic of Slovenia adopted the Action Plan for Development of Organic Agriculture in Slovenia by 2015, with the help of which the following goals should be achieved by 2015: 15% of utilised agricultural area with organic farming, 20% share of organic farms and 10% share of organic food in total food supply. The stated goals have not yet been achieved (Slabe 2010).

The share of utilised agricultural area with organic farming is increasing (in the structure of organic farming in Slovenia grassland prevails with a 90% share). Between 2005 and 2012 the share increased from 4.5% to 7.3%, but it is still far from the goal of 15% of utilised agricultural area with organic farming (Green Growth Indicators 2014). Organic food production is an important opportunity for creating new jobs, revitalising agriculture and rural areas, and improving the quality of life. Fresh organic vegetables in particular are imported from Italy, Spain, the Netherlands and Austria. The Institute for Sustainable Development and the Biotechnical Faculty (Slabe 2010) found that in 2009 the share of organic food in Slovenia was only 1% of total food market, but that the demand for organic food has been growing in the past five years at an annual rate of 10–15%. The two institutions also found that organic farming in Slovenia covers only about 20% of the current (still growing) needs of the Slovenian market (Slabe 2010).

5. Conclusion

There are some key obstacles facing sustainable development: bad conditions for sustainable mobility (public transport is not functional), despite some measures *still insufficient support for organic farming and the resulting insufficient quantities of locally produced organic food, unsustainable construction of tourist facilities, marginalisation of the importance of fair relations in supply chains, general ignorance of sustainable practices* (Plan B for Slovenia 2012). Slovenia has low self-sufficiency rates and downward trends in a number of key crops (vegetables, cereals, potato, etc.), while in bovine meat and milk domestic needs are covered or even exceeded. Connected to declining self-sufficiency rates, Slovenia is facing a question of current agricultural land use. Does it really make sense that livestock production expanded from mountainous regions, with mostly grassland, to more favourable but limited fertile plains on which fodder (mostly maize) for animals is grown. On flatland there is a constant conflict with other activities (e.g. transport and other infrastructure, industry, construction of dwellings), particularly protection of drinking water (Slabe 2010).

Of all expected impacts, in Slovenia extreme weather conditions (floods, droughts, storms) will probably have the most negative impact on well-being in the coming decades, since as regards the damage in recent decades they are already here. The strategy of adjusting agriculture and forestry in Slovenia points out the following key measures (KajfečBogataj et al. 2008):
... Making the construction of water reservoirs and irrigation systems one of the most important targets of agricultural policy (including the provision of food security)
... Sustainable provision of economic security of farms at extreme weather events – via insurance companies and co-financing of premiums
... Providing the possibility of implementing supplementary activities that reduce the vulnerability of farms at extreme weather events
... Changing land use due to repeated droughts (also due to floods and landslides)

From the point of view of the potential of natural resources, key and recommended economic direction for Slovenia is reduced consumption of energy and material and decentralised regional use of domestic resources (Plut 2014). Additional national sustainable development projects for sustainable existence should be prepared and implemented by supporting the pilot sample eco-villages and urban eco-neighbourhoods, increasing food and energy self-sufficiency of its regions and municipalities (pilot sample self-sufficient municipalities), sustainable management and use of local resources in various types of protected areas, and eco-remediation of living and management at national, regional and local levels (Plut 2014).

In the opinion of ecological and agricultural experts, in the next few decades it will be actually possible to expand agricultural land, to decrease food waste in developed countries, and decrease the consumption and share of meat in the diet in developed countries, particularly due to energy-environmental reasons. The general decrease in agricultural land in Slovenia, which is shown by statistical data, due to abandoning of farming and extensive building on the most fertile flatland areas increased its food dependency (Plut 2012).

By 2030 the extent of agricultural land should be returned to the situation around 1960. In view of geographic conditions and ownership, a large share (two thirds) of agricultural area with limited natural conditions from food production (more difficult conditions for production), the large share of protected and water protection areas (on more than half of the national territory), priority water supply role of gravel plains (mandatory subsidies to farmers for lower yields) and other reasons, agricultural production should be focused on producing integrated and organically produced food (despite the slightly lower yield) for supplying the population with a significantly larger emphasis on cereals (particularly wheat, not so much maize), as well as much larger production of vegetables (currently only around 40% self-sufficiency), fruit and partly grapes. In the next 20 years utilised agricultural are needs to be increased from 470,000 hectares to around 600,000 hectares. In this way we would achieve the strategic minimum of utilised agricultural area, which is in our geographic conditions around 3,000 (3,500) m2 per capita. With a view to increasing the self-sufficiency rate of Slovenia, the key issue is increasing the area of arable land (including gardens), where at least 250,000 hectares are needed or at least 1,250 m2 per capita instead of the 170,000 hectares or less than 900 m2 per capita in 2010. Production of animal fodder should be limited, particularly in the flatlands; in the hilly part of the country in addition to orchards and vineyards, grassland should enable traditional, humane livestock production (cattle, sheep) (Plut 2012). The market situation shows that the supply of organic food in Slovenia is still lower than the demand; statistics shows increased share of utilised agricultural area with organic farming. The possibility to engage in such production is still not fully exploited (Perpar, Udovč2010).

A higher self-sufficiency rate (particularly in wheat) could be achieved by taking into account the assumption of reducing local production and consumption of meat (Potočnik Slavič2010). In 2014 the self-sufficiency rate in wheat was 70% (for all cereals in general 77%), which is more than in recent years. Per capita meat consumption has declined over the past ten years; in 2005 it was 97 kilograms and in

2014 85 kilograms. According to SURS's estimates, in the 2008–2013 period the amount of food waste in Slovenia decreased. In 2013 a person in Slovenia generated on average 72 kilograms of food waste; in 2008 the figure was 197 kilograms. These statistical data (some of them should be used carefully) indicate favourable trends and changes in eating habits and draw near to expert proposals.

In view of the needs for food, very limited production of agricultural crops for biofuel would only be possible on poisoned or otherwise degraded areas. The existing forms of pollution, particularly in urban ecosystems, are not irreversible, the quality of air and water resources can be significantly improved, and more effort should be invested in financially demanding recultivation of land poisoned by heavy metals. In the opinion of environmental experts, these areas could be built up, which should in the long run be stabilised (Plut 2014).

In view of the existing knowledge, economic structure and experience, Slovenia has the greatest opportunities in the following low-carbon technologies and value added chains (Climate Change Act 2010): sustainable management of forest, wood as a construction material, wood products and use of wood residues for energy production, and organic farming. In the entire forest-processing chain in particular, Slovenia could build a "green valley" image and could be a role model for how it is possible to sustainably manage national wealth. In the 2010–2020 period, the amount of logs processed in Slovenia could be increased by 70%, i.e. from 1,125,000 m3 to 2,100,000 m3 (Humar, Kutnar, Piškur 2013).

Large effort would be needed also for very important remediation of environmentally degraded areas (e.g. gravel pits, industrial, mining and coal areas), which are usually on flatland. Together with sustainable forestry and rural tourism, increase in importance of hilly areas for food production is essential for the implementation of harmonised, sustainable regional development in Slovenia.

Based on statistical data, the article tries to indicate current agricultural trends and in light of national expert proposals for improvement of food security in Slovenia point out some potential development areas of agricultural activities in the country. Some favourable statistical trends show convergence with proposals to improve food security, while others point out the urgency of future more comprehensive and complex treatment of all stakeholders in planning one of the most important industries.

ABSTRACT

Food consumption refers to the amount of food available for human consumption. The knowledge of food consumption is crucial to set production and food supply policies, to compare eating habits with other countries, to assess the nutritional status of a population and to study the relationship between diet and health. In the last years all these aspects have taken an increasingly important interest because epidemiological studies have indicated a possible association between high consumption of meat and an risk of several forms of cancer as well as metabolic and cardiovascular diseases.

Unfortunately meat consumption is often estimated by methods that are inappropriate for this use because they do not represent the actual amount of meat consumed or, better, eaten by the consumers. The actual food consumption may be lower than the quantity shown as food availability depending on the magnitude of wastage and losses of food during the slaughtering, in the household, e.g. during storage, in preparation and cooking, as plate-waste or quantities fed to domestic animals and pets, thrown or given away The consumption estimated by FAO and by statistical offices of the various countries through the national food balance sheets does not indicate the amount of meat, ie the weight of the skeletal muscles of animals with included or adherent tissues, but the amount of the weighted carcass at the slaughterhouse, including bones, tendons, connective tissues and fat.

This paper discusses a method of estimating the real per capita consumption of meat in Italy with accuracy comparable to that of individual consumption, developed by the Study Commission of Animal Science and Production Association (ASPA). This action responds to the need of producing statistical indicator related to health food, as recommended by many international organizations (FAO, Eurostat).

Keywords: Consumption, Meat, Estimation

PAPER

1. Introduction

There are different methods for estimating the per capita consumption of meat, highlighting the importance, purposes, advantages, disadvantages and uncertainty. They may be grouped into three categories: Food Balance Sheet, Household Budget Surveys, Individual Dietary Surveys.

1) Food Balance Sheets

Food Balance Sheets (FBSs) are annually published by FAO (2015b). They shows for each food item i.e. meat for human consumption which corresponds to the sources of supply and its utilization. The total quantity of meat produced in a country added to the total quantity imported and adjusted to any change in stocks that may have occurred since the beginning of the reference period gives the supply available during that period. On the utilization side a distinction is made between the quantities exported, fed to livestock + used for seed, losses during storage and transportation, and food supplies available for human consumption. The per capita supply of each such food item available for human consumption is then obtained by dividing the respective quantity by the related data on the population actually partaking in it. Data on per capita food supplies are expressed in terms of quantity and by applying appropriate food composition factors for all primary and processed products in terms of dietary energy value, protein and fat content. It is an apparent consumption because includes non-edible parts, such as tendons, cartilages and all the waste.

The estimated consumption of foods based on availability is the most popular method because it allows to derive the annual per capita consumption without difficulty and almost inexpensively. Another strong point if compared with other methods as detailed hereafter, is the ability to estimate the availability of food for the population in all the points of consumption: home, restaurants, canteens, community hospitals, prisons, barracks, etc. Moreover, the consumption can be estimated regardless of how foods are consumed: raw or cooked, fresh or processed.

At the same time FBSs presents some weak point. The method leads to a significant overestimation of the consumption compared to the amount actually eaten due also to the difficulty or impossibility of separating the product for human consumption from the amount of product given to animals. Another critical issue of FBSs regards the population participating in available consumption for human use. The apparent meat consumption is helpful to know the total amount of meat available in a country for human consumption.

2) Household Budget Surveys

Household Budget Surveys (HBSs) are national surveys mainly focusing on consumption expenditure. They measure the household expenditure to buy food and other goods and services, and in some cases also the quantity.

HBSs are used to compare expenditure and indices of consumer prices for different foods among states, regions or different socio-economic groups, to monitor the consumption of various foods over time and eventually to take decisions in social, agricultural and food policies. The consumption data measured by HBSs are also used to study the relationship between consumption of a particular food or group of foods and human diseases. But this use requires precautionary measures because the estimated consumption does not express what a person really eat but simply what a person buy. Meat consumption measured by a HBS is a less coarse index compared to that obtained with the FBSs because the meat bought at retail is already deprived of most of the bones, tendons and the separable fat and do not include waste.

However, HBSs do not provide the real consumption of meat, but the available amount for consumption; furthermore, the method is more complex and expensive. Another point of weakness of this method is represented by eating meals outside home. In addition, Household Budget Surveys do not take into account guests in the family, food purchased but not consumed during the survey period or those purchased before the reference period.

3) Individual Dietary Surveys

Individual Dietary Surveys (IDSs) are carried out by research institutes on a sample of individuals representative of the population. Individual surveys provide data on the amount of foods or food categories consumed by the selected individual over the period covered by the survey. The survey may also retrieve some information, such as the daily episodes when specified foods have been consumed, whether they were home-produced or bought and, in such cases, also the commercial label, the way in which foods were cooked, the place where they were consumed, whether there was any edible wastage and so on. Tables of food composition are used to calculate the energy and nutrient content of the consumed foods.

Basically, the methods for assessing individual dietary intakes can be classified into two main categories: the retrospective reporting of intake from the recent or remote past and the prospective recording of consumption. Some methods only measure consumed foods and the frequency of consumption, others also measure the weight scale or the standard weight portions. Food can be weighted raw or cooked. The costs are high and the diversity of methods makes no fully comparable data from different surveys. Data from these surveys are more appropriate than those obtained with FBSs or HBSs to describe the eating habits and to study the relationship between food intake and human health. The limitations and uncertainties concern the weight check, the study of domestic waste in the kitchen and on the plate, the conversion from raw to cooked food, the conversion of processed products into meat, the separation of meat in compound feed. They are very expensive and therefore they are occasionally carried out or with a multiannual periodicity and not in all countries.

Definitively, all methods overestimate the real meat consumption because they include non-edible parts, processing losses and waste. In IDSs the overestimation is minimum, but in FBSs it can reach values higher more than twice the actual food consumption. It is necessary to take into account the limitations and uncertainties that each method presents, to know the objectives and reasons for which they were designed and to interpret and use the data on consumption correctly.

To overcome this situation, the Scientific Association for Science and Animal Production (ASPA) has set up a committee of professors and researchers belonging to some Faculties of Agriculture and Veterinary Medicine, experts in the meat of different animal species, plus an ISTAT expert on animal production to develop an economic, fast and reliable estimative method to assess the real per capita consumption of meat and fish. In this paper we reported the results on the meat.

2. Method

To achieve the aim, the committee used the Food Balance Sheets (FBSs) method, the same with which in Italy is estimated the apparent consumption The method is even used in Italy to estimate the apparent consumption. This The actual per capita consumption of meat has been is calculated subtracting from the availability in kilogramms of carcass weight the processing losses as well as the parts that are not edible (bones, cartilages, connective tissue, etc) and excess fat, which is normally not eaten and is not currently classified on the nutritional and dietary plan as meat but it is considered as fat. In other words, the definition of the level of meat consumption was changed from equivalent carcass to fresh meat by conversion coefficients specifically determined. First of all it is necessary to have a wide knowledge of national availabilities. This was taken from surveys on the slaughter and records of imports and exports made by ISTAT.

Then it is of fundamental importance a detailed analysis of the losses that occur between primary production and the actual consumption (Table 1). The total losses and waste were estimated using data from scientific literature on slaughtering procedure and meat yield of carcass and several joints.

Table 1 - Losses that occur in the reduction of the animal's carcass to meat

Cold carcass

- ✓ **Processing losses**
- ✓ **Removing most of bones, cartilages, ligaments, tendons and aponeuroses**
- ✓ **Separable fat removal**
- ✓ **Partial or total skin removal in pigs and poultry**

Salable meat

- ✓ **Retail processing losses**
- ✓ **Retail scrap material**
- ✓ **Retail wastes**

Consumable meat

- ✓ **Scrap material at consumption in the kitchen and on the plate**
- ✓ **Consumption wastes**

Actually consumed meat

The estimates of losses at various levels of the supply chain are almost inexistent in Italy. Information are often inaccurate and confused: for example, no distinction is made between waste carried to a level as those carried out at previous levels, etc. In particular estimates of consumption losses both at home and outside home are scarce or non-existent.

Faced with this situation, the Committee has used a completely different approach to estimate with a good degree of approximation losses, scrap material and waste The processing losses are liquid losses and small body parts not recoverable that occur in the sectioning of the carcass, in the preparation of the cuts and of the portioned meat. The scrap materials are parts not edible (bones, cartilage, tendons and ligaments), or diverted from human consumption (separable fat with a knife, aponeurosis, glands, nerve tissue and blood vessels). Wastes include fresh or transformed meat discarded due to impairment, presence of defects, overcoming expiration date, lack of acceptance or because purchased or cooked in excess. With this approach the total of processing losses and scrap material waste, regardless of the stage of the supply chain in which they occur, were quantified using data from the scientific literature on livestock slaughtering, consulting experts in the field and in the case of cattle performing carcass dissection trials.

For processed products the determination of conversion coefficients was more complex because it was also necessary to take into account the weight loss due to processing and seasoning and the addition of fats and other ingredients in order to transform them into fresh meat. as defined above.

3. Results

The ASPA Committee calculated the conversion factors of the carcass, quarters, cuts and all meat products imported and exported of various animal species in consumable meat. An example of these coefficients is shown in Table 2.

The availability of consumable meat without considering retail waste was obtained multiplying the apparent availabilities by these conversion coefficients. The per capita availability of the retail consumable meat is achieved dividing the total availability by the population of Italy).

Table 2 - Conversion coefficients of carcass in consumable meat by species

Red meat	Conversion coefficients (%)	**White meat**	Conversion coefficients (%)
Lambs	0,573	Broilers less than 2 kg	0,610
Lambs >15 kgs	0,536	Broilers over 2 kg	0,620
Ewes and rams	0,565	Turkeys	0,621
Piglets	0,494	Guinea Fowls	0,582
Light pigs	0,528	Ducks	0,520
Heavy pigs	0,492	Gooses	0,520
Steers	0,593	Quails	0,452
Female bovine animals aged less than 15 months	0,575	Pigeons	0,501
Calves <8 months	0,524	Rabbits	0,553
Wild boars	0,707	Red deers	0,738
Fallow deers	0,722	Roe deers	0.789
Mouflons	0,632	Chamois	0,713
Horses, donkeys and mules	0,700		

Table 3 shows the amount of meat consumable obtained for the different animal species in the period 2010-2014.

Obviously the per capita availability of consumable meat, comprising the waste to the detail is much lower than the availability in carcass equivalent calculated for example by the FAO. In fact the latest figures published by the FAO, which for Italy relate to the years 2010 and 2011, respectively report an apparent consumption of 89.51 and 86.65 Kg (FAOSTAT). However the amount of available meat thus calculated provides an index much more close to the actual consumption.

Table 3 - Estimates of consumable meat per capita in Italy without considering retail waste in the period 2010-2013 (Kg)

Meat	2010	2011	2012	2013	Average
Bovine[1]	13,75	12,73	12,30	11,69	12,62
Pigs	20,57	19,97	19,52	19,47	19,88
Poultry	10,93	11,59	12,07	11,60	11,55
Sheep and goats	0,65	0,61	0,58	0,49	0,58
Horse	0,66	0,63	0,64	0,56	0,62
Rabbit	0,35	0,35	0,34	0,32	0.34
Wild animals [2]	0,06	0,06	0,06	0,06	0,06
Total	46,97	45,94	45,51	44,19	45,65

[1] It includes buffalo meat; [2] equal estimate all years

The accuracy of the estimate, which is a derived statistics, is dependent on the reliability of the statistics of supply and determination of the conversion coefficients. The data on national production, imports and exports are those collected by ISTAT. Therefore the accuracy of the estimate of the per capita availability of meat should be the same as that of the apparent consumption calculated by FAO, for example. As well as retail waste, the consumable meat still includes scrap material at consumption in the kitchen and on the plate and consumer waste (meat and meat products eliminated on the garbage for impairment, exceeded expiration date or because purchased or cooked in excess). In order to get the real meat consumed the waste produced at retail and the scraps and wastes at consumption level must be subtracted from the availability of consumable meat.

For retail waste some information obtained from a number of stores of a great distribution chain were taken into consideration. The retail wastes were calculated on the difference in value between the total receipts of meat put on sale and the amount of meat actually sold. Based on this information the retail wastes were estimated to be about 2% regardless all species. Taking into account these losses, it has been obtained the true consumable meat.

For consumer losses (scrap material in the kitchen and on the plate and wastes) both at home and away from home (restaurants, fast foods and services institutions,) the only information came from some researches carried out abroad. For European countries according to a study (2011) performed by FAO the meat losses at consumption amount to 11% of the quantity purchased. The same proportion of waste has been found in UK by WRAP (2009) for the group of food comprising meat and fish, The Economic Research Service of United States Department of Agriculture estimated the losses at consumer level to 23% for meat and to18% for poultry (USDA ERS, 2016), but in USA the losses include some inedible material, such as bones.

Based on these data, taking into account that bones have already been eliminated from the consumable meat estimate in this research, it was assumed as consumer losses a value equal to 10%. Subtracting this value to the meat consumable has been obtained the real consumption of the meat.

Table 4 shows the real meat consumption per capita in Italy in 2010-2013 The real consumption per capita obtained are almost identical to those observed in the years 2005-2006 in Italy by CRA-INRAN with the method of individual dietary survey (IDS) (Turrini et al. 2013).

Table 4 - Real meat consumption per capita in Italy in the period 2010-2013 (Kg)

Meat	2010	2011	2012	2013	Average
Bovine[1]	12,12	11,23	10,85	10,31	11,13
Pig	18,14	17,61	17,22	17,17	17,53
Poultry	9,64	10,22	10,64	10,23	10,18
Mutton and goat	0,57	0,54	0,51	0,43	0,51
Horse	0,58	0,56	0,56	0,49	0,55
Rabbit	0,31	0,31	0,30	0,28	0.30
Wild Animasi [2]	0,05	0,05	0,05	0,05	0,05
Total	41,41	40,52	40,13	38,96	40,25

[1] It includes buffalo meat; [2] equal estimate all years

This is particularly interesting because it shows that the method proposed by us, based on FBS but changing the definition level of meat, estimates the actual consumption with the same precision of IDS on individual consumption, but without the complexity and high costs of this. Obviously the method only provides the average consumption of a country and does not allow for the breakdown of consumption by different group population differing for socio-economic, geographical, age class, sex and other demographic characteristics. Therefore our method cannot replace individual dietary survey, but can be useful for monitoring the nutritional status of the population of a country in the long range of years that usually separate the IDS.

Table 5 - Apparent and actual per capita daily consumption (grams) of meat in Italy.

Meat	2010	2011	2012	2013
Bovine				
real consumption	12,12	11,23	10,85	10,31
apparent consumption	23,8	22,1	21,3	20,2
real/apparent %	50,9	50,8	50,9	51,0
Pigs				
real consumption	18,14	17,61	17,22	17,17
apparent consumption	38,4	37,3	36,9	36,7
real/apparent %	47,2	47,2	46,8	46,8
Poultry				
real consumption	9,64	10,22	10,64	10,23
apparent consumption	18,0	18,6	19,4	18,8
real/apparent %	53,6	54,9	54,8	54,4

In the four years period considered the real meat consumption per capita decreased by 2,45 kg, equal in relative terms to about 6%. The decrease has mainly affected the beef (1,81 kg) and pig (0,97 kg).

Table 5 shows the apparent and real daily consumption of meat of the three main species. The apparent consumption values are those calculated and published by ISMEA.

The actual consumption is compared to those apparent about 51% for beef, 47% for pork and 54% for the poultry. The method provides an estimate very close to that of the quantity of ingested meat and therefore may be a more suitable index for the studies on the relationship between meat consumption and human health.

Conclusion

The method allows to estimate the per capita real consumption on annual basis with the same precision of the individual dietary survey, but without the complexity and the high costs of the latter.

The developed method provides an estimate very close to that of the quantity of ingested meat and therefore may be a more suitable index for the study of the relationship between meat consumption and human health.

The method may represent a paradigmatic example to estimate real consumption of all foods, similarly to what it is done in the US by the economic statistics service of the Department of Agriculture (USDA ERS,2016).

THEMATIC SET

B13

CAPTURING THE ENVIRONMENTHAL IMPACT OF AGRICULTURAL ACTIVITIES

Session Organizer
R. Smith | TIES | Edinburgh | United Kingdom

ABSTRACT

Agricultural activities have effects on the surrounding environment and often on a wider environment, through a number of pathways. Locally there is runoff of pollutants to neighbouring land and water bodies, with pesticides, use of excess fertilisers for whatever reasons, and hormones and medications from livestock production being some examples. There can be also other by-products of the agricultural practices, such as ammonia gas from intensive units, and greenhouse gases (carbon dioxide, methane and nitrous oxide) from various agricultural activities. Downstream impacts of agricultural include effects of use of water changing drought and flooding frequencies and water availability for other purposes. Many of these effects are now being modelled using statistics available, but the example of the local scale modelling of greenhouse gases under IPCC encouragement shows that our data sources may not be detailed enough for the tasks ahead. The session will look globally at some examples of data requirements for assessing agricultural impact and explore to what extent the current statistical base provides us with the information required

ABSTRACT

Spatial monitoring of soil quality especially in terms of soil organic carbon (SOC) content for the purpose of evaluating the effects of C-stocking practices at different spatial scales, is critical for both stakeholders and public authorities. Various studies have recently demonstrated the usefulness of hyperspectral satellite images for faster and cheaper prediction of SOC compared to standard soil chemical analyses. In this study we combine both sources of information by means of hierarchical modelling accounting for different spatial scales to provide an accurate map of SOC over a broad regional scale in a peri-urban region.

Keywords: SOC content, Hierarchical modelling, Multi-scale, Spatial statistics

PAPER

1. Introduction

The overall decrease of soil organic matter in peri-urban croplands has become a threat for soil sustainability in Europe (Ciais et al., 2010). The COP21 conference recently held in November 2015 in Paris resulted in adopting a "4p1000" initiative aiming at favouring C storage practices to mitigate greenhouse gas emissions. Among possible storage practices, the recycling of exogenous organic matter (EOM) issued from organic waste treatments originating from urban, industrial and agricultural activities provides a promising source of C stocking amendments which may also substitute synthetic fertilizers (Houot et al., 2014; Noirot-Cosson et al., 2015). This study, as a part of the French TOSCA-"PLEIADES-CO" project, basically aims at spatially simulating the effects of such practice at the regional scale of a 221 km² peri-urban area close to Paris, where animal breeding has declined. The spatial simulation of such effects of EOM use practice (Noirot-Cosson, 2016) requires spatially explicit and updated information about initial soil organic carbon (SOC) stocks. SOC stock, defined as the carbon mass per unit area for a given depth, is the product of SOC content by considered depth (for a given horizon), soil bulk density, and the percent volume of soil out of rock fragments. Goidts et al. (2009) identified SOC content variability as one of the main sources of predictions uncertainty of SOC stocks and whatever scale, from global to local (Minasny et al., 2013), most studies considered SOC content as the main target variable, and this mainly for the topsoil layer comprised between 8 and 30 cm, being most often the ploughed layer for cropland, i.e. the layer directly modifiable by C-stocking practices such as EOM use. At such detailed scale such as our study area, accurate predictors of SOC content are required: error uncertainties shall be specified to each potential end-user so that, jointly to the map of SOC contents, a map of prediction uncertainty should be provided.

Whatever scale, environmental covariates are the most commonly used to predict SOC content. Depending on the context, either terrain attributes derived from a DEM (Orton et al., 2012a, 2012b; Lacoste et al., 2014), land use/land cover (Lacoste et al., 2014), satellite images (Normalized Difference Vegetation Index (NDVI) derived from remotely sensed images, (Wu et al., 2009)), remotely and proximally sensed visible to near infrared (NIR) reflectance (Peng et al., 2015), geological data (Lacoste et al., 2013), or gamma radiometrics (Malone et al., 2009), may be considered in the modelling. Numerous methods have been developed for mapping soil properties generally using one or a combination of environmental covariates. They mostly rely on statistical modelling and can be classified into three categories: (i) remote-sensing methods, predicting SOC content by means of a regression from hyper/multi-spectral image reflectance spectra (Selige et al., 2006; Stevens et al., 2010, 2012; Gomez et al., 2012; Vaudour et al., 2013, 2016); (ii) geostatistical methods, based on a network of soil sampled sites and a set of environmental covariate data being mostly terrain attributes derived from a DEM (Marchetti et al., 2010; Hamiache et al., 2012; Conforti et al., 2015) and/or soil types (Kempen et al., 2011) and/or an airborne gamma radiometric image (Malone et al., 2009); a spectral or vegetation index band of a multispectral satellite image (Wu et al., 2009); (iii) machine learning methods, such as random forest (Grimm and Behrens, 2010), regression trees (Lacoste et al., 2014; Peng et al., 2015; Somarathna et al., 2015) or support vector regression (Somarathna et al., 2015).

In this study, we aimed at mapping SOC contents of agricultural topsoil over a 221 km² peri-urban area, the EOM sources of which need to be spatially managed across the 106 km² cropland area (Noirot-Cosson et al., 2014). The further use of this map into a soil plant model and for practical decision for end-users dictates the need for uncertainty assessment, as well globally as locally, at the scale of each cultivated field.

A previous study (Hamiache, 2012) provided maps of SOC content by means of multivariate geostatistical methods, from soil measurements and DEM variables. Here we aim at integrating all kind of available information, at different scales and from various sources : hyper/multi-spectral image reflectance spectra, remotely and proximally sensed visible to near infrared (NIR) reflectance, terrain attributes derived from a DEM and soil measurements, in a single hierarchical model to provide an as precise as possible map of SOC content together with its uncertainty assessment.

The core of the hierarchical model is a latent spatial random field representing the SOC content, which is linked to the available data through several relationships that take into account the scale change, and the measurement and modelling uncertainty.

2. Hierarchical modelling

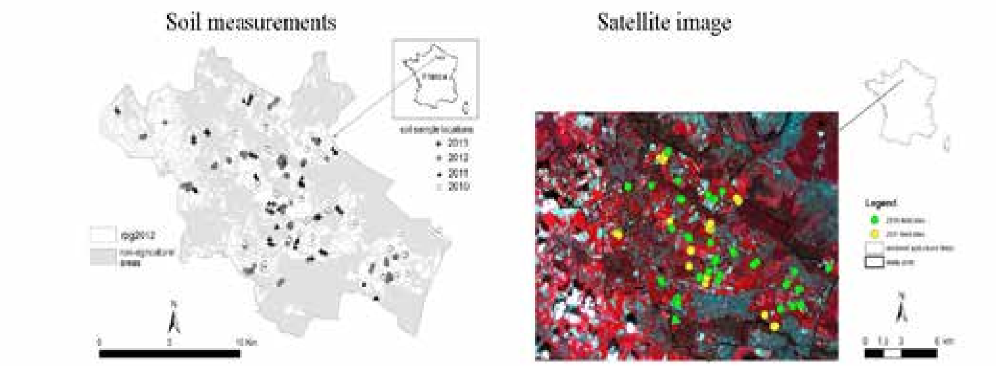
Let $C(s)$ the SOC content at location s, s in a domain S. We assume that C can be written as $C(s)=X(s)\beta+\varepsilon(s)$. $X(s)$ is a vector of covariates at position s and $\varepsilon(.)$ is a stationary Gaussian random field with covariance function $\rho(.)$. Covariates X stem from a DEM (elevation, slope, …) available at different resolution grids.

We have at our disposal two observation families that can be linked to the SOC content.

- $(Y_1^1, Y_2^1, \ldots, Y_{n_1}^1)$ are the values of a satellite image acquired on March 2013, at pixels of size $\delta_x \times \delta_y$ centred on sites $(s_{11}, s_{12}, \ldots, s_{1n_1})$ selected because the corresponding areas were bare soils at the moment the image was taken. Usually the Y^1s are vectors with dimension nb, the number of spectral bands, but here we consider only the first one (infra-red). We assume that a value Y_i^1 is a noisy affine transformation of the SOC average on the pixel centred on s_{1i}.
- $(Y_1^2, Y_2^2, \ldots, Y_{n_2}^2)$ are values of soil chemical characteristics, including Organic Carbon, acquired from 2010 to 2013 at locations $(s_{21}, s_{22}, \ldots, s_{2n_2})$.

Figure 1 shows the Plaine de Versailles region together with the locations of the soil measurements and a satellite image of the region acquired on 27 April 2010

Figure 1 - Plaine de Versailles: locations of the soil measurement by year and 2.5 m-SPOT5 image of 27 April 2010. SPOT/ISIS programme. Copyright CNES.



We consider a grid of mesh $\delta_x \times \delta_y$ so that the we can write $Y_i^1 = \frac{1}{4} \sum_{s_j \text{ neighbour } s_i} C(s_j) + \varepsilon_i^1$, $(\varepsilon_i^1)_i$ are i.i.d zero-mean Gaussian random variables with variance σ_1^2 .

If we assume that the measurement noise for SOC is normally distributed with variance σ_2^2 and considering an affine transformation of the DEM covariate elevation E , then the hierarchical model is written :

$$C_g \sim N(\mathrm{a}+\mathrm{bE}_g, \sigma_0 \Sigma_g)$$
$$Y^1 \mid C^1, \mathrm{c}, \mathrm{d}, \sigma_1 \sim N(\mathrm{c}+d\overline{C^1}, \sigma_1^2)$$
$$Y^2 \mid C^2, \sigma_2 \sim N(C^2, \sigma_2^2)$$

C_g and E_g are the vectors of the latent variable and the elevation on the grid, Σ_g the covariance matrix for C_g, C^1 is the vector of the C_g involved in the averaged calculation $\overline{C^1}$ linking the image and the SOC content, C^2 is the latent variable at locations $(s_{21}, s_{22}, \ldots, s_{2n_2})$ are not on the grid). The covariance function $\rho(.)$ is given by an exponential model and the matrix Σ_g can be written as $\Sigma = \sigma_0^2 \Sigma_0$ with $\Sigma_0(s, s') = \exp(-\|s - s'\| / \alpha)$. The range α parameter is estimated previously by usual geostatistical methods from the SOC measurements.

After straightforward calculations the two last equations of the model can be resumed as a linear model $\Upsilon = MC_o + \varepsilon$, Υ gathers vectors Y^1 and Y^2, and C_o is the vector of the latent variable C at all the locations involved in the observational layer.
Inferring the whole model consists then to infer the latent variable C at all the grid points and the parameter vector $\theta = (a, b, c, d, \sigma_0, \sigma_1, \sigma_2)$.
The inference is driven in a Bayesian framework, by means of a Gibbs algorithm from classical prior distributions to provide good conjugate distributions. Updating the parameters θ and the C^1 is given by the standard formulas for linear models, and the component of C on the grid that are not included in C^1 are obtained by Gaussian conditional simulation.

2. Simulations

To evaluate the algorithm performances and to evaluate to what extent the chains convergence hold, a simulation study is driven on a fine small size grid.
The size of the grid is 100×100, the scale parameter is $\alpha = 10$, and the θ parameters are $a = -4$, $b = 2$, $c = 10$, $d = 5$, $\sigma_0 = 5$, $\sigma_1 = 2$, $\sigma_1 = 2$. We pick at random $n_1 = 400$ and $n_2 = 300$ values of the corresponding simulated Y^1 and Y^2.
The inference algorithm is performed on several chains in order to enable a control of convergence of the distribution with several values for hyper-parameters to investigate the sensivity to the priors.

Figure 2 - Posterior distribution for $\theta = (a,b,c,d,\sigma_0, \sigma_1, \sigma_2)$

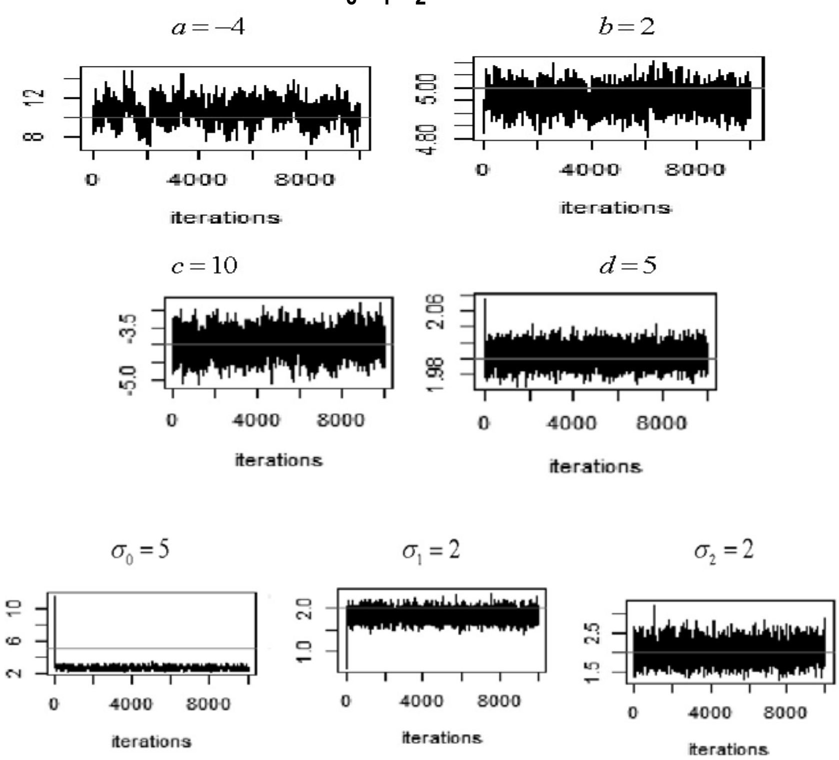


Figure 2 displays the posterior distribution for parameters 0. For all the parameters except 0_0 the convergence toward the real value is reached quite rapdly. The lack of convergence of 0_0 may be due to an identifiability issue, common for spatial fields although the scale is not inferred, and must be investigated.

Figure 3 - Latent field and averaged posterior fields

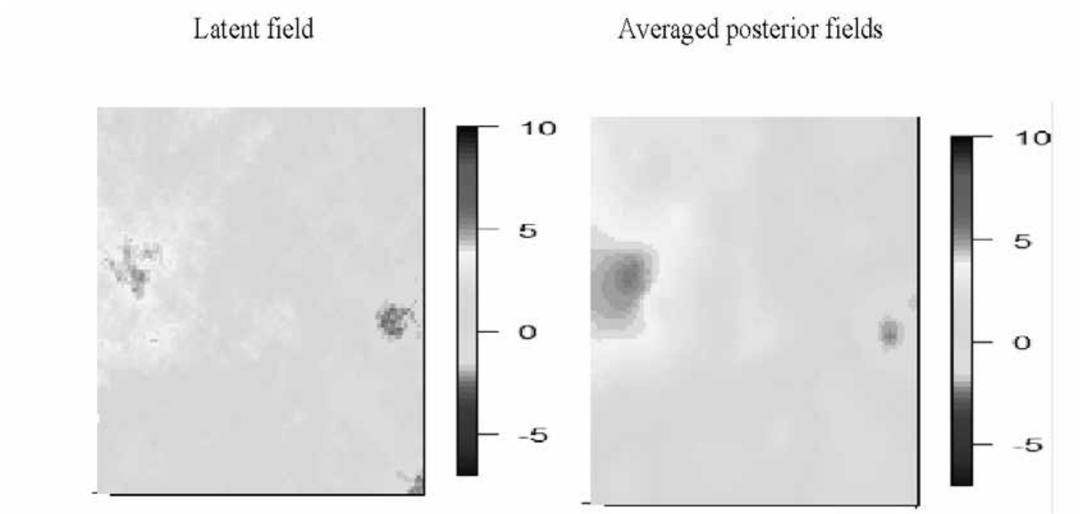

Figure 3 displays the simulated latent field C , together with some draws of the posterior distribution and the averaged posterior fields showing that the main features of the latent field are recovered in average.

3. Real data

The simulation study shows encouraging results, but it is driven for a small dataset size. The dataset we are faced with in an operational framework is an image on a grid of 243x407 cells, n_1 10192 cells representing bare soils and n_2 253 top soil measurements.

This leads to severe computational issues, as the conditional simulation step of the Bayesian algorithm needs the inversion of a matrix of size $n_1 x n_1$. Using specific packages for very big matrices and storage utilities could help to carry out the inference, still it remains very time consuming. Making recourse to approximation methods seems unavoidable.

Figure 3 shows a map for the SOC content and the map of its standard deviation obtained with the same dataset except the image, but using geostatistical methods. This map will serve as a reference, to investigate to what extent data from satellite images may improve the mapping of SOC content and what would be the degraded performance using images instead of soil measurements.

Figure 4 - Mapping for the SOC content and its standard deviation by geostatistical methods

Increased quality in statistics on crop residues and lime used as input to greenhouse gas inventories

DOI: 10.1481/icasVII.2016.b13b

ABSTRACT

Updated and well documented agri-environmental statistics are key for the evaluation of national and international environmental goals and targets. The annual National Greenhouse Gas (GHG) Inventories according to the UNFCCC is one such example, and requires great amounts of input data. This paper focuses on methodological improvements of the statistics on crop residues and lime, which are needed to estimate the GHG emissions from the agricultural sector. Statistics Sweden conducts several surveys in the agri-environmental area and is the responsible government agency for the statistics on crop nutrients and cultivation measures in agriculture in Sweden. In a previous pilot study, coefficients for nitrogen in crop residues were reviewed, and compared with those used in the Swedish GHG calculations. Within the same project, updated official statistics were produced on the utilisation of crop residues, presented as shares of crop areas with different management in terms of crop residues. However, to make use of the new data in the GHG gas calculations, the areas need to be converted into quantities. This requires coefficients for the ratio between crop residue and yield. Stubble heights also need to be considered. A desk study was carried out to obtain updated coefficients for ratios between straw or tops and crop yield as well as for nitrogen content in the crop residues. The updated coefficients will increase comparability between the GHG inventories and other environmental reports, such as the OECD/Eurostat nutrient budget for nitrogen.

Regarding the estimation of GHG from lime used in the agricultural sector, annual sales statistics were used until the National Inventory Report for Sweden 2015 was submitted. However, indications of increased agricultural use of lime in the form of by-products that are not distributed through the ordinary market imply that sales statistics may no longer fully reflect the amount of lime applied to arable land. A test to move from sales statistics to statistics on farmers' actual use of lime has been conducted, utilising the existing sample surveys on fertiliser use and cultivation measures in agriculture. Data on farmers' application of lime to arable land were collected for the years 2010, 2012 and 2014. The questions covered type and amount of lime product and size of land area where lime had been applied. Results were compared with sales statistics for the years 2010 and 2012. It showed that for well-defined products available on the ordinary lime market, data from the sales statistics and from the sample survey were comparable and relatively similar. However, the sample survey showed larger total amounts of lime than the sales statistics. This was due to the application of lime products in the form of by-products from e.g. the paper and concrete industries, which were not completely accounted for in the sales statistics. Hence, for environmental monitoring, such as the GHG inventory, the statistics of farmers' lime application constitute a better basis for calculations, as it reflects the actual amount that is applied to soil and hence affects the natural environment.

Keywords: crop residues, nitrogen, straw, greenhouse gas, nutrient budgets, lime, sales statistics, sample survey, mixed mode

PAPER

1. Introduction

Updated and well documented agri-environmental statistics are crucial as they form the basis for several environmental reporting systems that in turn are needed for the evaluation of national and international environmental goals and targets. The annual National Greenhouse Gas (GHG) Inventories according to the United Nations Framework Convention on Climate Change (UNFCCC) is one such example, and requires great amounts of input data. Statistics Sweden conducts several surveys in the agri-environmental area and is the responsible government agency for the statistics on crop nutrients and cultivation measures in agriculture in Sweden. Statistics Sweden is also part of the consortium Swedish Environmental Emissions Data (SMED), which conducts the inventory and reporting of GHG.

This paper focuses on two of the input variables needed for the inventory of emissions from the agricultural sector, namely: estimates on the amount of crop residues that are left on the field and the amount of lime applied to soil. The specific aims are to:

- i) update the coefficients and the method to convert shares of land areas into quantities of nitrogen in crop residues

- ii) present a new methodology to collect data on the use of lime that reflects current situation in agriculture.

2. Crop residues

In a previous pilot study, coefficients for nitrogen in crop residues were reviewed (Andrist Rangel et al, 2013a; b). It was also observed that coefficients used in the Swedish calculations for the GHG inventory and for the OECD/Eurostat's nutrient budgets requested from all European Member states (MS) differed. Within the same project, updated official statistics were produced on the utilisation of crop residues, presented as shares of crop areas with different management in terms of crop residues. However, the areas need to be converted into quantities of nutrients before they can be applied in the GHG and nutrient budget calculations.

2. 1 Share of removed crop residues – definitions and source data

Crop residues are defined as dead biomass according to 2006 IPCC Guidelines (IPCC, 2006). In the model used in Sweden for estimating flows of nitrogen within the soil-plant-animal system for the GHG inventory, litter is considered to recirculate within the agricultural system as it is returned to the field mixed with the manure (Adolfsson, 2005; Swedish EPA, 2006). Hence, the litter, which constituted about two thirds of total removed crop residues in Sweden (Statistics Sweden, 1999), is therefore not included in the estimations of the removed part in the inventory. This corresponds with the estimations of nitrogen contribution from manure, since the excretion factors used in the calculations characterise freshly excreted manure and hence, stable litter is not accounted for on the input side. Hence, whether the part used for litter shall be treated as left on or removed from the field in the calculations depends on what the coefficient for applied live-stock manure describes, i.e. if it includes straw or not.

Until the reporting of 2014 year's emissions of GHG for Sweden (Swedish EPA, 2016) and until 2011 year's official Swedish nutrient balances (Statistics Sweden, 2013a) and OECD/Eurostat balances (OECD, 2012), input data on share of crop residue removal from fields originate from a survey from 1997 (Statistics Sweden, 1999). In that survey, three categories were used to describe existing management practices of crop residues on arable land at the crop level (hectares): "burnt on field", "incorporated into the soil" and "removed from the field". For the category "removed from the field", the area was further divided into four subcategories representing different uses (% of area): "fodder", "litter", "energy production" and "other uses". In 2012, a new sample survey on the utilisation of crop residues was carried out among farmers in Sweden (Andrist Rangel et al., 2013a; b; Statistics Sweden, 2013b). The results were presented and published as shares of crop areas.

2. 2 Crops harvested green

In the 2012 survey on crop residues, the category "burnt on field" was excluded since this type of land management is insignificant Sweden (Statistics Sweden, 1999). Instead, the category "harvested green" was added, which enabled new and more precise estimations of the areas from which straw and tops had been removed from the field as residues (=dead biomass) or as part of crop products harvested green (=live biomass), respectively. According to 2006 IPCC Guidelines, no above ground crop residues are generated from crop areas harvested green, except stubble. Comparisons of the results from the 1997 and 2012 surveys showed that if the area harvested green is not considered specifically in the questionnaire, there is a risk that the respondent (farmer) reports that area in the category "removed from the field" instead, and then into the subcategory "fodder". This seems to have occurred in the 1997 survey, and is notable for crops that in Sweden typically have a high share of the crop area being harvested green, such as mixed grain (Table 1).

In the interpretation of the results from the 2012 survey, the area harvested green of crop(T) should be deducted from the total crop area of crop(T), before the partition of different uses/management practices of "real" crop residues. If the area harvested green is not accounted for in the GHG inventory, the fraction of crop residues left on the field and corresponding N2O-emissions will be overestimated.

Table 1 - Crop residues from mixed grain according the 1997 and 2012 surveys on the utilisation of crop residues in Sweden.

Year	Crop area (ha)	Share of crop area (%)					Usage of crop residues from the area where residues have been removed from the field (%)			
		Harvested green[1]	Burnt on field	Ploughed into the soil	Removed from the field	⇨	Fodder	Litter	Energy prod.	Other
1997	30 200	n.a.	0	41	59		28	70	1	1
2012	15 900	19	n.a.	35	39		37	63	0	-

1) Per definition according to 2006 IPCC Guidelines, no above ground crop residues are generated from this area, except stubble.

n.a. = not analysed

Based on the categories as defined in the 2012 survey and the assumption that litter is circulating internally, the ideal estimation of above ground cereal crop residues that are left on the soil, $Above\text{-}ground_{Left}\ N_{(T)}$, that is needed for the GHG calculation, is given in equation 1:

$$Above\text{-}ground_{Left}\ N_{(T)} = (Area\ with\ grain\ harvest_{(T)} \times Grain\ yield_{(T)} \times R_{AG(T)} \times N_{AG(T)} \times (1 - Frac_{Remove(T)})) + (Area\ harvested\ green_{(T)} \times N_{Stubble(T)}), \qquad \text{(eq. 1)}$$

where

$$Frac_{Remove(T)} = (Frac_{Removed\ from\ the\ field} / (Frac_{Ploughed\ into\ the\ soil} + Frac_{Removed\ from\ the\ field})) \times (1 - Frac_{Litter})$$

Rag(t) = Ratio of above ground crop residues (including stubble) to grain yield for crop T

Nag (t) = Nitrogen content in above ground crop residues for crop T

$N_{Stubble(T)}$ = Nitrogen in stubble per hectare of area harvested green for crop T

Grain $yield_{(T)}$ = Actual annual grain yield in dry matter for crop T

Equation 1 has not been implemented in the Swedish GHG calculations yet. Areas for annual crops harvested green have been published for Sweden since at least the year 2000 (Swedish Board of Agriculture and Statistics Sweden, 2016). The use of Equation 1 would be an improvement in accuracy in the GHG inventory.

2. 3 Ratios between crop residues and yield

To make use of updated statistics on crop residues from the 2012 survey in the GHG calculations and in the nutrient balances, areas need to be converted into quantities (Equation 1). For this, data on crop grain yields combined with coefficients for the ratio between crop residues and yield (i.e. RAG) are needed. For cereals and oil seed rape, coefficients for RAG constitute the weight ratio between straw and grain. For other crops such as potato and sugar beets it is the weight ratio between tops and harvested yield.

Another factor to consider for cereals and oil seed rape is the stubble, as this is left on the field after harvest and should be included in the above ground crop residues, Above-ground N(T), according to 2006 IPCC Guidelines. Note that stubble will also be left on the field on areas where the whole crop has been harvested green, Area harvested green(T), i.e. areas not included in Area with grain harvest(T).

For the Swedish GHG inventory, coefficients for ratios between crop residues and yield (RAG) where reviewed and changed for a range of crops before the 2006 submission (Adolfsson, 2005). Adolfsson based a lot of his conclusions on a comprehensive study conducted by Mattsson (2005), who scrutinised and compiled results from previous analyses of crop material collected at Swedish field experiments from the 1950's and onwards. The coefficients are based on a total of 5 221 observations, from 536 trials and 278 different experimental sites. The coefficients from Mattsson were subsequently turned into area weighted means in terms of level of N fertilisation in Sweden (Adolfsson, 2005) using statistics on fertiliser use (Statistics Sweden, 2004). Adolfsson also suggested adding 25 percent extra on the calculated ratios to account for stubble. This was also implemented in the 2006 NIR submission (Swedish EPA, 2006).

Concerning crop residue removals in the calculations of nutrient balances, the 2013 Handbook on Nutrient Budgets (Eurostat, 2013) implies that methodology for county specific data should be coordinated with the GHG inventory. However, until the 2011 nutrient balances, the county specific data had not been harmonised in the different reporting systems. The study by Mattson (2005) is a comprehensive source of information for

B13

the cereal crops of winter wheat, spring wheat, winter rye, spring barley and oats. In addition, the suggestion by Adolfsson (2006) to account for different levels of N fertilisation is sound. However, for other crops such as sugar beets, potato and maize, further investigation was needed to obtain country specific coefficients. Therefore, an additional review was carried out in 2015, which resulted in an updated table for all crops (Table 2), which was used in the Swedish national nutrient balance calculations for 2013 (Statistics Sweden, 2015a). These are yet to be implemented in the OECD/Eurostat balances as well as in the GHG calculations.

Table 2 - Ratios of above ground crop residue to yield, RAG, dry matter/dry matter (d.m.); nitrogen content in above ground crop residues, NAG, (% of d.m.); and removed crop residues, FracRemove, (% of crop area) for crops in Sweden.

Crop	Ratio of above ground crop residue to yield (d.m./d.m.) (R_{AG})[a]	Nitrogen content, crop residue (% of d.m.) (N_{AG}*100)	Phosphorus content, crop residue (% of d.m.) (N_{AG}*100)	Removed crop residues[v] (% of crop area) ($Frac_{Remove}$*100)
Winter barley	0.70[b]	0.77[o]	0.12[l]	22
Spring barley	0.66[c]	0.77[c]	0.12[l]	10
Oats	0.71[c]	0.73[c]	0.12[l]	10
Winter wheat	0.70[c]	0.51[c]	0.12[l]	12
Spring wheat	0.77[c]	0.44[c]	0.12[l]	10
Triticale	0.78[d]	0.76[p]	0.12[l]	12
Winter rye	0.86[c]	0.59[c]	0.12[l]	22
Grain maize	1.00[e]	0.94[q]	0.21[q]	19
Mixed grain (cereals)	0.69[f]	0.75[f]	0.12[f]	27
Mixed grain (cereals and legumes)	0.76[g]	0.95[g]	0.14[g]	27
Winter rape	1.50[h]	1.07[l]	0.14[l]	5.5
Spring rape	1.13[i]	1.07[l]	0.14[l]	5.5
Winter turnip rape	1.50[j]	1.07[l]	0.14[l]	5.5
Spring turnip rape	1.13[k]	1.07[l]	0.14[l]	5.5
Peas	0.80[l]	1.18[l]	0.15[l]	1.4
Peas for conservation	0.80[m]	1.18[m]	0.15[m]	0.0
Oil flax	n.a.	1.43[r]	0.10[r]	57
Table potato	n.a	3.25[l]	0.20[l]	1.3
Potato for starch production	n.a	3.25[l]	0.20[l]	1.3
Sugar beets	n.a	2.25[l]	0.25[l]	0.7
Field beans	0.80[l]	1.18[m]	0.15[m]	2.2
Green fodder	n.a	2.0[s]	0.3[s]	0.0
Temporary grass for seed	0.84[n]	1.09[t]	0.15[t]	35
Temporary grass	n.a	2.4[u]	0.26[u]	0.0
Pasture	n.a	2.4[u]	0.26[u]	0.0

a) Not including the 25 % extra for cereals to compensate for stubble (see section 2.3); b) same as winter wheat c) Mattsson 2005 (area weighted according to Adolfsson (2006)); d) mean of winter rye and winter wheat; e) Spõrndly; 2010 f) mean of spring barley and oats; g) mean of oats and peas; h) Gunnarsson 2009; i) 75% of winter rape according to Lindén in Gunnarsson (2009); j) same as winter rape; k) same as spring rape; l) Claesson and Steineck 1991; m) same as peas; n) source not identified; o) same as spring barley; p) mean of winter wheat and winter rye; q) estimated from conc. in grain and ensilage; r) S-E Andersson, pers com; s) wholecrop silage, Swedish Board of Agriculture 2015; t) assuming 80% straw from temporary grasses for seed. 20% straw from temporary leguminous crops for seed, Swedish Board of Agriculture 2015; u) Statistics Sweden 2005 and Andrist Rangel et al 2013a; v) derived from Statistics Sweden 2013b (see section 2.2)
n.a.= not analysed or not applicable

There was an overall trend with decreased ratios compared with the ones previously used in the nutrient balances, which resulted in lower amounts of crop residues compared with previous estimations (Statistics Sweden, 2015a). This can be explained by the increased use of short straw varieties. The coefficients in Table 2 were primarily compiled for use in nutrient balance calculations. Hence, they do not include the 25 percent extra for cereals to compensate for stubble, as the focus in these calculations is on the (net) removed part, and stubble is not included in the removed part in practice. Accordingly, the coefficients for cereals in Table 2 need to be adjusted when used for the GHG inventory, where the focus is on the (net) part that is left on the field, and hence, inclusion of stubble would be justified.

2. 4 Nitrogen contents in crop residues

In a previous study on P and N contents in grain and straw of winter wheat, spring barley and oats, (see Table 2 in Andrist Rangel et al (2013a; b)), it was concluded that there is a deviation between the coefficients used in the Swedish nutrient balance calculations and the GHG inventory. Hence, in connection with the review mentioned above on ratios between crop residues and yield, contents of nitrogen in straw and tops (NAG(T)) of all corresponding crops were also scrutinised to obtain a complete and updated table to use in the different statistical and policy reports (Table 2).

Nitrogen coefficients in the GHG inventory were updated for cereal straw for the 2006 submission. The new coefficients were suggested in the review by Adolfsson but originate from the compilation study by Mattsson (2005), which considers the effect of nitrogen fertilisation, and is based on more than five thousands observations (see section 3.2). During the scrutinisation it was concluded that Mattsson (2005) was the most comprehensive reference for Swedish conditions and the results were also in line with foreign studies (see for example Table VII in Appendix I in Andrist Rangel et al (2013a)). It was therefore decided that this reference could be used for the updating of N coefficients of cereal grain and straw in the national and the OECD/Eurostat balances. This increases the coherence between the nutrient balances and the GHG inventories. For other crops not included in Mattsson (2005), more investigation was carried out during 2015 and the resulting coefficients and references are listed in Table 2. The updated coefficients were used in the Swedish national nutrient balance calculations for 2013 (Statistics Sweden, 2015a) but are yet to be implemented in the OECD/Eurostat balances as well as in the GHG inventory.

3. Lime applied to arable land

Regarding the estimation of GHG from lime applied to arable land, annual sales statistics have been used until submission 2015 (Swedish EPA, 2015). However, indications of increased agricultural use of lime in the form of by-products from industry, not distributed through the ordinary market, imply that sales statistics may no longer fully reflect the amount of lime applied to arable land.

3. 1 Background

Annual statistics on sales of lime for agricultural and horticultural purposes have been produced and published since 1986 (Statistics Sweden, 2013c). Data have been collected from manufacturers, importers and retailers with the aim to cover the Swedish market. The time series published for sales of lime for agricultural purposes has been used in the GHG inventories until the reporting of the 2013 emissions (Swedish EPA, 2015). However, in the last 5 to 10 years substantial quantities of lime products have been detected that are not included in the ordinary sales records, and hence not included in the sales statistics. This is primarily lime in the form of by-products from the pulp- and paper industries. After discussions with the main users of the statistics, it was therefore decided to try changing from statistics on sales to statistics on actual use of lime in agriculture.

3. 2 Data collection from farmers on lime application

The existing sample surveys on fertiliser use and cultivation measures in agriculture were used as the frame for data collection and estimation of farmers' application of lime to arable land. Data were collected for the reference years 2010, 2012 and 2014. The sample sizes were 5 150, 3 650 and 3 000 agricultural holdings respectively for the three years. In the two first surveys, only telephone interviews were used, whereas in the survey 2014, "mixed mode" was used, using paper and web questionnaires with follow-up telephone interviews. The questions covered type and amount of lime product and size of land area where lime had been applied (Figure 1). Parallel to the new data collection, statistics on sales continued to be produced until the reference year 2012. This was to create a time period over which the two different sets of data could be compared, and also to keep the continuity in the sales statistics in case the new method did not turn out to be successful.

Figure 1 - Section on application of lime in the paper questionnaire from the sample survey "Cultivation measures in agriculture 2014" (translated from Swedish) (Statistics Sweden. 2015b).

D | Application of lime 2014

6a Have you applied or will you apply lime to your arable land during 2014?
OBS! *Shall include all application of lime, even lime for lime filter ditches.*

☐ Yes
☐ No ➔ ***Go to question 7***

6b Fill in name of lime product, total amount of product and area that has been or will be limed during 2014.

	Product name. Maximum three lime products.	Total amount		Area	
1		,	ton	,	hectares
2		,	ton	,	hectares
3		,	ton	,	hectares

3. 3 Results

One of the main outcomes of the new method of data collection, where the farmer could state and describe the type of lime, was that significant amounts of lime in the form of by-products were detected to be applied to agricultural land. Further research into the origin of these products showed that they were not always sold and/or distributed through the ordinary lime market, but could be free of charge for farmers and could for example be delivered by companies dealing with waste management. Hence, these products were not possible to detect through the sales statistics. Another obvious difference between the sales and the use statistics was that the former was a complete enumeration, whereas the latter a sample survey, and thus different in terms of estimation method. However, by using well-defined products available on the ordinary lime market such as lime produced as a co-product of the sugar manufacturing process, the two methods of estimations could be cross-checked. The outcome of the comparison was that data from the sample survey and from the sales statistics were comparable for these products.

The results from the sample surveys of 2010, 2012 and 2014 showed similar results in terms of limed area, with about 3 percent of the of arable land being limed (Statistics Sweden, 2015b). On the regional level, the corresponding value varied between 0.7 and 5.8 percent. The average application rate was also similar between the years, around 2 tonnes of CaO per hectare. However, the results showed a significant increase in the use of soil structure lime between the years 2010 and 2014. This was partly due to the introduction of subsidies for this specific type of soil management practice. The collected data were also used to estimate the amount of cadmium applied to soil via liming and the results were published in the statistical series for the first time. For 2014 it amounted to a total of ca 110 kg of cadmium, which can be compared with the amount applied via phosphorus fertilisers in Sweden, which was 82 kg in 2014/2015 (Statistics Sweden, 2016).

When data from 2010 and 2012 were compared with the sales statistics from corresponding years, the sample survey showed larger use than the sales. The difference could be explained by the quantities of by-products from e.g. the paper and concrete industries that were not accounted for in the sales statistics. This confirmed the assumption that the sales statistics no longer fully reflected the application of lime to agricultural land in Sweden. Another advantage with the sample survey was the possibility to estimate the uncertainty of the point estimate. With this as a basis, it was decided to change from sales statistics to statistics on actual use of lime. In the GHG inventory, the new estimates on lime usage available for the emission year 2010 and forward were implemented in the 2016 submission (Swedish EPA, 2016). Regarding time series consistency in the inventory, sales statistics were still used for the period 1990 - 2009, but there is no major effect as these by-products have only recently been introduced as lime products and were negligible before the turn of the century.

4. Conclusion

A review of the method of estimating the amount of crop residues has resulted in a recommendation of a more precise way to calculate amounts of straw and tops left on the field in the GHG inventory. The main suggestion for change is to include considerations of areas where crops have been harvested green. The review and updating of coefficients for ratios between crop residues and yield as well as for nitrogen contents in straw and tops is a step forward in the harmonisation process between the OECD/Eurostat nutrient budget compilation and the GHG inventory in Sweden. Using the existing sample survey on fertiliser use and cultivation measures for data collection and estimation of the application rate of lime to arable land has confirmed the hypothesis that significant quantities of lime in the form of by-products were not captured by the sales statistics. The new method has increased the quality in the statistical output compared to the sales statistics. For environmental monitoring such as the GHG inventory, statistics on farmers' application rates of lime to arable land constitute a better basis for estimation of CO2-emissions, as it reflects the actual amount that is applied to soil and hence affects the natural environment.

5. Acknowledgement

The work on crop residues reported in this paper has been conducted within the frame of an action, supported by Eurostat via an EU grant.

ABSTRACT

Pesticides (plant protection products and biocides) are among the best regulated chemicals in Europe. An in-depth risk assessment is carried out before the placing on the market, also the final stage of the life cycle is regulated, with the definition of non-hazardous residues in food and environment. Recently it has also been regulated intermediate the life cycle stage, the use, with a series of measures to improve agricultural practices minimizing the use of chemicals, to protect water bodies and sensitive areas, to properly train the operators. Nevertheless, the monitoring shows a widespread pesticide contamination in surface and groundwater (GW). It seems, therefore, that the regulatory framework or at least its implementation is not fully adequate to protect the environment and human health.

The report presents a study of the contamination of the Po basin, the most important in Italy, both for its size and for the intense human activity, with particularly intensive agriculture with high input of pesticides. The considerable amount of data arising from an extensive monitoring network, allows to study pesticide contamination and its evolution since 2003.

Chemical pollution is one of the main factors considered in the approach "planetary boundaries", recently proposed. The "planetary boundaries" is identified as the boundaries that define the safe operating space for humanity with respect to the Earth system and are associated with the planet's biophysical subsystems or processes, (Rockström, J. et al. 2009). Unlike other anthropogenic pressures acting on a global scale, the complexity of chemical pollution has not yet possible to identify a sustainability limit.

Taking into account the fact that it is simplistic to analyze the problem on a regional scale, as large and important it may be, because you cannot ignore the long range transport of contamination, the study aims to contribute to understanding the capacity of' environment to respond to human disturbance, returning to the previous conditions (the phenomenon of resilience). For this purpose, the study focused on residual contamination of a banned pesticide in Italy and in Europe for several years (atrazine). A first analysis of the results suggests that the environmental response to a chemical stress is extremely slow and the return to the initial undisturbed conditions is not at all obvious. This requires a reflection on the actual environmental sustainability, which should not rely only on the comparison with the acceptable concentration limits.

Keywords: pesticides, planetary boundaries, water pollution

PAPER

1. Introduction

Pesticides are chemicals used to control weeds, insects and other pests in agricultural areas and as biocides in many other activities. Despite the acknowledged benefits, their use raises concerns in terms of possible adverse effects on human health and environment. Most of them are synthetic molecules conceived to kill harmful organisms and therefore they are generally hazardous to all living organisms exposed.

European regulatory framework addresses the risk raising in all life cycle stages of pesticides: production, use, residues in food and environment, nevertheless monitoring data show a diffuse pollution of surface water (SW) and groundwater (GW). Despite the well defined Regulatory framework, the national monitoring results, show a widespread contamination in water. In particular in 2014 pesticides were found in 63.9% of 1284 monitoring points, in surface waters and in 31.7% of 2463 points in groundwater as reported in the National report on pesticides in water (ISPRA, 2016).

The chemical pollution is one of the major anthropogenic factors used as reference in the recent years to develop the "planetary boundaries" approach, to identify a safe operating space for humanity with respect to the Earth system (J. Rockström et al. 2009) in which humans can continue to develop and thrive. Respecting these boundaries would greatly reduce the risk that anthropogenic activities could inadvertently drive the Earth System to a much less hospitable state. Since its introduction, the proposed approach has attracted interest and discussions within the policy, governance, and business sectors. A scientific debate is on-going on the criteria to identify the kinds of chemical substances that are likely to have influence at the global scale (Scheringer M. Et al. 2012; Strempel S. et al, 2012).

The paper aims to provide a contribute analysing the sustainability of pesticide pollution at regional scale. Bearing in mind that it is not possible to ignore the global impact, as e.g. the long range transport, the study analyses the contamination of the Po River basin, the most important in Italy, where intense industrial and agricultural activity are present. Data collected since 2003 through an extensive monitoring network allow to analyze the evolution of pesticide pollution. The study focused on residual contamination of atrazine, an herbicide banned from several years. This can be useful to understand the environment ability to respond to anthropogenic disturbance in restoring the previous conditions (resilience phenomenum).

2. Regulatory framework

The European regulatory framework covers the risk raising in all life cycle phases of pesticides. According to the Regulation (EC) No 1107/2009, substances are evaluated to prove the safety for humans and the environment before the placing on the market. Directive 2009/128/EC, on sustainable use of pesticides, aims to reduce risks in the use-phase with a series of measures to improve agricultural practices, minimizing the use of chemicals, protecting water bodies and sensitive areas, properly training the operators. Regulation (EC) No 396/2005 deals with the end of the life cycle of pesticides, establishing the maximum residue levels (MRLs) in foodstuffs, with the aim of limiting the exposure of consumers.

Moreover a number of other legislative acts regard pesticides. In particular, the Water Framework Directive (WFD) (Dir . 2000/60/EC) and daughter directives aim to ensure the water quality, identifying, among other things, a list of " priority substances " and setting limit values for environmental protection.

Despite the well-defined regulatory framework, monitoring data show a widespread pollution of surface and ground water. This highlights an inadequacy of the regulations or their implementation. In particular, a critical issue is the environmental exposure estimation. The forecasting models used in risk assessment do not always seem adequate to predict the environmental fate and exposure of substances. They lack of realism, as recognized by the scientific committees of the European Commission "to face the new challenges for risk assessment"(SCHER, SCENIHR, SCCS, 2013). Another critical aspect is the risk assessment of substances , such as persistent , bioaccumulative and toxic , or as endocrine disruptors,, which do not seem to have a threshold effect. In this case it is very difficult to recognize a safe level in the environment, and even very low concentrations could pose a risk. Furthermore, the regulatory risk assessment does not take into account the effects of mixtures.

Therefore, monitoring is a useful tool to check the real impact of pesticides on the environment and identify, through a retrospective analysis, the critical issues not properly addressed in the authorization process.

3. Case Study - Po river Basin

Po basin is the largest in Italy. The river (652 km length) flows through from west to east. The catchment area measures about 74,000 sq km of which approximately 71,000 are located in Italy, the rest in Switzerland.

Approximately 16,000,000 inhabitants live in the catchment area. Considering the density of the productive activities, the infrastructure and the water resources utilization, the Po Basin is the most important area in the Italian economy. Agriculture occupies over half of the basin area, with high chemical inputs (fertilizers, pesticides) in the lowland and in the hilly areas and part of the mountain "endovallive" areas.

The basin is divided essentially into three geomorphological areas: alpine area, in the north and north-west; the Apennines in the south; the plain area (Padana plain), which characterizes the entire course of the river, until the Adriatic Sea.

The average annual rainfall on the basin is 1,108 mm. The corresponding water volumes are therefore 77.7 x 109 m3/year. The average annual outflow corresponds at 664 mm, equivalent to about 46.5 x 109 m3/year, which represents 60% of inflow and is equivalent to 1,470 m3/s.

The river has 141main tributaries, coming from the Alps and the Apennines. The basin includes many lakes, the most important of which (Garda, Como and Maggiore) are located in the Lombardy region and are fed by alpine mountain streams.

The aquifers are fed mainly in the high plain near the mountain, whose geology consists mostly of coarse materials. In the pre-Alpine plains and in the Apennines the aquifer, in correspondence with impermeable barriers, emerges as springs ("risorgive"). The central part of the plain, both north and south, consists of fluvial deposits that gradually become finer and less permeable and host confined aquifer. The groundwater speed in the water table high plains may reach tens of meters per day, instead in the deep under pressure aquifers speeds are very low until the "stagnation " for certain very deep aquifers.

Monitoring network of pesticides in the Po basin includes 1,035 sites in groundwater and 570 in the surface water. Samples were collected every month in surface water and at least twice a year on the groundwater.

4. Atrazine

Before the ban, atrazine was one on the most widespread herbicide used in Italy, applied on corn and sorghum, but also for urban and industrial areas. A reasonable estimate of the quantities used in the Po valley is about 1,000 tons /year, for about 25 years. The substance is an herbicide of the triazine class; it has a selective, systemic action with residual and foliar activity and inhibits photosynthesis.

Atrazine was detected in the atmosphere, also far away from the use areas. In the atmosphere it tends to exist more in the particulate and precipitation is the primary mechanism for removal. Volatilization from water surfaces is not expected to be an important fate process based on a Henry's Law constant value.

It is expected to have high to slight mobility in soil, based upon a log Koc range of 1.96 to 3.38. Soil pH may affect the transport of atrazine (sorption to soils increases with pH decreasing). Atrazine is not expected to volatilize from dry soil, if released into water may adsorb to suspended solids and sediment based on the Koc value range.

According to Mackay I model (Finizio A., 1997), atrazine mainly distributes in water (about 90% of the amount released to the environment), fractions of the order of 4% are distributed both in soil and in sediment, little significant percentages in air and in biomass.

According to Regulation (EC) No 1272/2008, atrazine is very toxic to aquatic life, both acute and chronic effects (Aquatic Acute 1 – H400, Aquatic chronic 1 – H410), may cause damage to organs through prolonged or repeated exposure (STOT RE 2 - H373) and may cause an allergic skin reaction (Skin Sens. 1 - H317).

Atrazine is in the priority list within the EU-Strategy (EC, 1999; EC, 2000) for Endocrine Disruptors (ED); it is considered ED Category 1 (evidence in organism). In particular, the substance (Norwegian Pollution Control Authority, 2005) may induce hermaphroditism and demasculinize the larynges of frogs (Hayes TB et al. 2002).

The substance is persistent and toxic, but it is not considerd bioaccumulative. According to WFD, il has been identified as "priority hazardous substance" on the basis of ED concern.

Atrazine was banned in Europe since 2004, because of widespread groundwater contamination at concentrations exceeding the drinking water limit of 0.1 µg/L. For the same reason, in Italy it had been banned since the early 90s.

Metabolites

Desethylatrazine is formed in the environment through the N-dealkylation of atrazine.

Desethylatrazine is expected to have very high to slight mobility in soil, based upon Koc values of 24 to 3000. In water, some adsorption to suspended solids and sediment is expected. Desethylatrazine has been shown to biodegrade in soils under aerobic conditions, but it is generally stable in groundwater microcosms under anaerobic conditions. According to the classification provided by companies to ECHA the substance is harmful if swallowed, causes serious eye irritation and is harmful if inhaled.

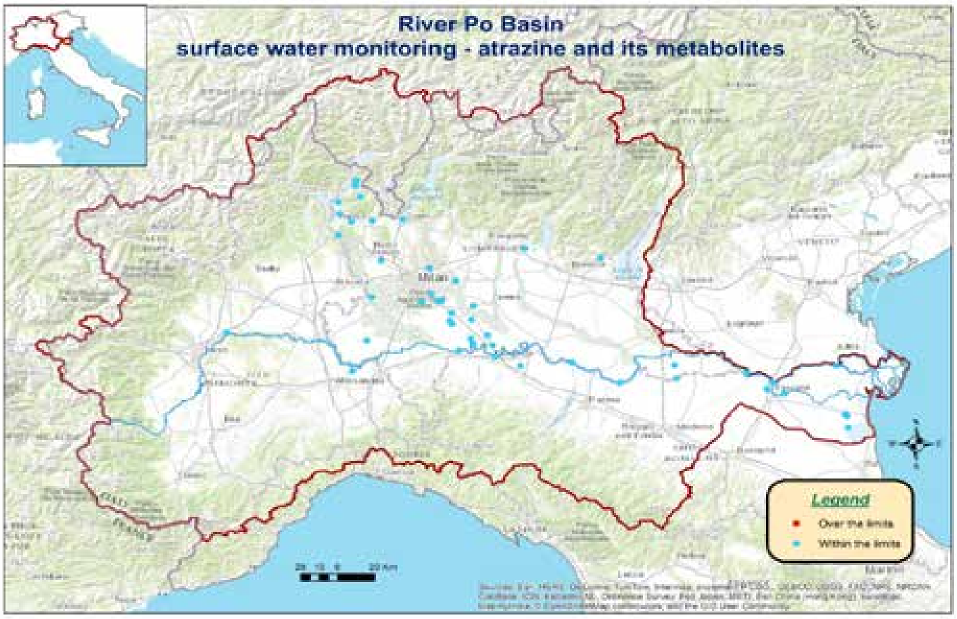
Deisopropylatrazine is formed in the environment through the N-dealkylation of atrazine. Deisopropylatrazine is more soluble than parental compound and less than deethylatrazine. The substance is not persistent to persistent in soil (half-life ranges from 32 to 172 days)and it is expected to have very high to moderate mobility based upon Koc values ranging from 28 to 130. Field studies show that it does not accumulate in the soil (Crobe A., et al, 2002). According to the classification provided by companies to ECHA the substance is harmful if swallowed, causes serious eye irritation and is harmful if inhaled.

4. Monitoring Results

Monitoring results show a widespread pesticide contamination of the Po valley, pesticides have been found in more than 70% of surface water sites and in more than 40% of groundwater sites. The triazine herbicides (atrazine, simazine, terbuthylazine and atrazine – desethyl, atrazina desisopropil, metabolites and desethyl - terbuthylazine) are among the substances most frequently detected in surface water and groundwater, often above the legal limits. With the exception of terbuthylazine, all other substances are no longer permitted in Europe.

The maps (Figure 1) shows the contamination level of atrazine and its main metabolites (atrazinedesethil, atrazine desisopropil) in the study area.

Figure 1 - surface water and groundwater contamination level of atrazine and its metabolites in Po basin (2014).



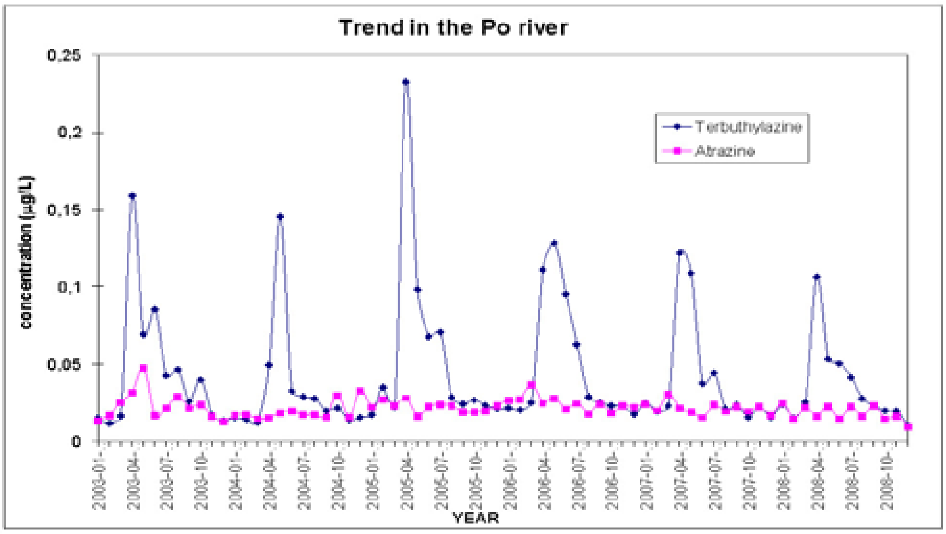
The contamination levels are referred to the limit value for the drinking water (0.1 g/L).

In 2014, atrazine has been detected in 46 sites of the surface waters (10.2% out of 453) and in 104 sites of the groundwater (10.8% out of 968). The concentration is never over the limit in the surface water and it is over the limit in the 0.7% of groundwater sites.

Taking into account that the substance has being banned for many years, the monitoring highlights a residue of a historical contamination, due to the widespread use in the past and to the environmental persistence. The detection of the its metabolites at levels generally greater than the parental substance supports the conclusion of a long-standing pollution.

Figure 2 compares the concentration trend in the Po river of atrazine and terbuthylazine, that replaced the use of atrazine after the ban. Terbuthylazine concentrations highlights a seasonal use related to an application in the spring (March–May) repeated year by year. Differently, the occurrence of atrazine shows a stable trend clearly indicating a residual contamination.

Figure 2 - Trend in the Po river of terbuthylazine and atrazine



Analysis of the Contamination Trend

The graph in Figure 3 shows that atrazine concentration (90%-ile of the medium values) in the river is significantly lower than the basin groundwater. Moreover it is highlighted that the concentration in the river decreases regularly with an asymptotic trend, while the concentration in the groundwater does not indicate any trend but ranges around a roughly constant value.

The purpose of the trend analysis is to follow how the pesticide and its main metabolites occurrence in surface and groundwater is changed over the last decade. From figure 3, it is possible to identify with a good correlation a well defined trend curve in the River and it allows to derive an half-time of about 8 years for disappearance of the parental substance. This value would trigger to a re-calculed average concentration referred to the period of the ban (early 90s) equal to ca. 1.0 g/L. This value seems to be consistent to the current average concentration of terbuthylazine in the river.

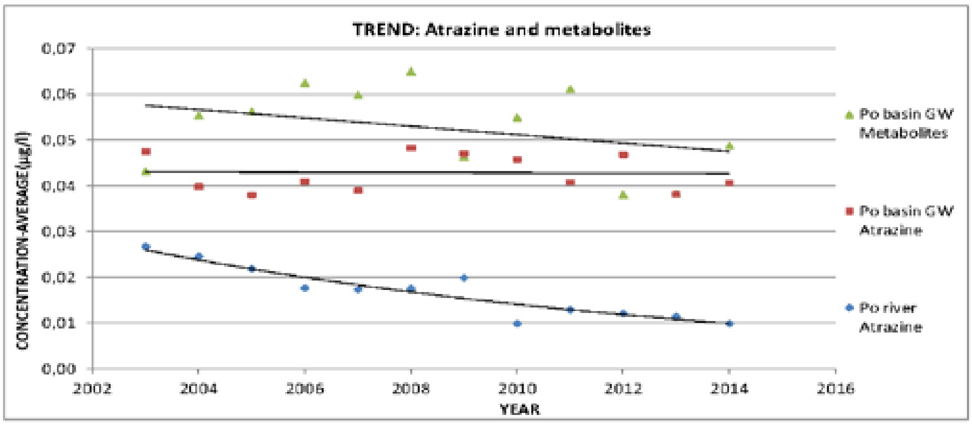
The possible explanations of the gradual decrease of the concentration in the river and the stable occurrence in the ground water are the following: the degradation of the parental substance in the groundwater is slow because lacks the degradating agents abiotic and biotic. Another possibility is that surface contamination is mainly due to the exchange with groundwater, which mainly concerns the shallow aquifer than the deep ones , well separated from the river, where the concentration is almost constant.

The stable trend of atrazine in groundwater, reasonably indicates that same situation is foreseeable for the future due to the very slow movement of the groundwaters, particularly, in the deep aquifers. The metabolites trend confirm the contribute of the overall stable contamination of the substance, once reached groundwaters.

In the surface water the contamination levels are lower than the regulatory thresholds and the Environmental Quality Standard (EQS). Nevertheless the hazourdous properties, in particular the ED property, (no-treshold) makes significant also the low measured concentrations.

The importance of very low concentration is also related to the concern for the mixture detected in the samples, for which it is still not well known the relevance for the Human Health and the environment. Infact in some samples there are mixtures up to tens of substances.

Figure 3 - Trend of atrazine and its metabolites (desethylatrazine, deisopropylatrazine)



5. Conclusion

The environmental sustainability of chemicals should be based on the capability of the environment to respond to anthropogenic stressors in restoring the previous conditions.

The present study allows to conclude that the regulatory framework does not comply the above general principle, as following summarised.

The regulatory framework seems not completely adequate to prevent a diffuse contamination of pesticides. In particular one of the critical issue is related to the exposure estimation in the authorization process. The estimations derived by models are not always representative of the real environmental behaviour of chemicals, at least on a large scale. A particular attention should be given to the substance persistence assessment. Standard information utilised seems not representative of the real persistence in the environment. Once the substances reach groundwaters, the degradation processes are very slow due to the lack of the biotic and abiotic degradation mechanisms.

The trend analyses of the occurrence in the Po basin of no more used herbicide, demonstrates that substances can persist in the environment longer than how estimated Evaluation of substances under authorization process may underestimate their ability to contaminate the environment, in particular the water compartment. It is necessary to take due account of the available measured information, considering the available monitoring data also on similar chemically substances.

Probably it is not enough cautelative to base the authorization process on the regulatory acceptable limits: e.g. concentrations in drinking water and EQS. This because some substances are considered "non-treshold" and it is not possible to define a safe concentration. Moreover the mixture concern is up to now an unsolved issue.

The reported results related to a herbicide banned since several years as atrazine can be useful to foresee the future critical issues of similar triazine substances still in use.

How to evaluate the impact of agrienvironmental policies on biodiversity in rural areas. The case of High Nature Value Farming systems

A. Povellato | Council for Agricultural Research and Economics, CREA | Legnaro (PD) | ITALY

DOI: 10.1481/icasVII.2016.b13d

ABSTRACT

Amongst all environmental public goods provided by farming, biodiversity is probably the most difficult to describe due to its multidimensional character that encompasses agronomic, environmental, social, cultural and economic dimensions. In spite of the efforts to guarantee a reasonable level of analysis in the different countries, to date methodologies applied for the evaluation have had limited success in detecting impacts. There are many reasons from lack of monitoring data to difficulties of establishing robust causal linkages between the action/measure/programme and impacts on biodiversity.

An attempt to assess the impacts of RDP measures on farm-related public good, such as high nature value farmland, has been carried out in a case study area dealing with different data availability and approaches for comparison groups. The aim of the study is to show how different methodologies can be used with fine- and coarse-scale variables, to disentangle the influence of site-specific circumstances and other intervening factors. In the context of rural policy spatial and temporal dimensions are interlinked with social dynamics while biodiversity responds to agricultural practices at different spatial and temporal scales. It is a methodological challenge to create consistent linkages between micro level, usually represented by beneficiary farms, and macro level that gives a comprehensive assessment of the RDP impacts.

Keywords: Biodiversity, Agrienvironment Policy, High Nature Value Farmland [9] Capturing the environmental impact of agricultural activities

PAPER

1. Introduction

The High Nature Value concept (HNV) was introduced in the research fields and policy arena in the beginning of the 1990s, aiming to demonstrate the role of certain farming systems in maintaining the biodiversity of the European countryside. This concept is grounded on the assumption that low intensity agriculturalmanagement often corresponds to an overall biological and landscape diversity in farmland (Baldock at al. 1993; Beaufoyet al. 1994; Bignal and McCracken, 2000; Cooper et al. 2007). A significant proportion of the European HNV farmland is located in Southern Europe mainly because agriculture in the Mediterranean region did not undergo the same levels of specialization and intensification as in the rest of Europe. As a consequence, it partially maintains its traditional farming systems (Beaufoy et al. 1994; Paracchini et al. 2008), especially those dependent on livestock grazing (Cooper et al. 2007).

The inclusion of the HNV concept into European policy, in the more general context of the integration of environmental objectivesin sectoral policies such as the Common Agricultural Policy (CAP), dated at the beginning of the first programming period 2000-2006 of the rural development policy under regulation (EC) 1957/1999. Only more recently the issue of farm-related biodiversity has been integrated among the measures of the first pillar of the CAP mainly focused on direct payments aimed to support farm income, through the greening practices established by regulation (EU) 1307/2013. Unfortunately, it does not produce reliable effects on the evolution of biodiversity, still under pressure with continuing loss of habitats associated with agriculture support threatened and declining species (Henle et al. 2008; Polákováet al., 2011; Pe'er et al., 2014).Agricultural intensification and land abandonment are important global drivers of biodiversity loss and ecosystem degradation.Market pressures and distortedfarm support policiesare increasingly making the farms in HNV areas economically unviable with the result of increasing processes of intensificationand land abandonmentthat adversely impact the HNVfarmland (Henle et al. 2008; Kleijn et al. 2009). The impact of policies on the evolution HNV areas was monitored and evaluated since the implementation of 2007-2014 Rural Development Programmes (RDP). In particular the Common Monitoring and Evaluation Framework (CMEF) foresaw a specific HNV indicator, mainly based on studies conducted at European level by European Environment Agency (Andersen et al. 2003) and the Joint research Centre (Paracchini et al. 2008; EEA, 2012). These first estimates were not considered exhaustive of the monitoring work to be done for targeting policy instruments at national or regional level. More context-based work needed within each Member States to estimate its extent and location. Among a range of efforts to develop HNV indicators atthe EU and Member States level (Keenleyside et al. 2014), it can be summarised three different types of approach to identify HNV farmland (HNVf): a) land cover characteristics; b) farming characteristics and practices; c) habitats or species of conservation concern. To some extent the farming system approach, based on investigations on the use of inputs, livestock density and other specific practices by farmers, presents more relationships with the implementation of agricultural policies where the beneficiaries are already directly monitored through surveys.

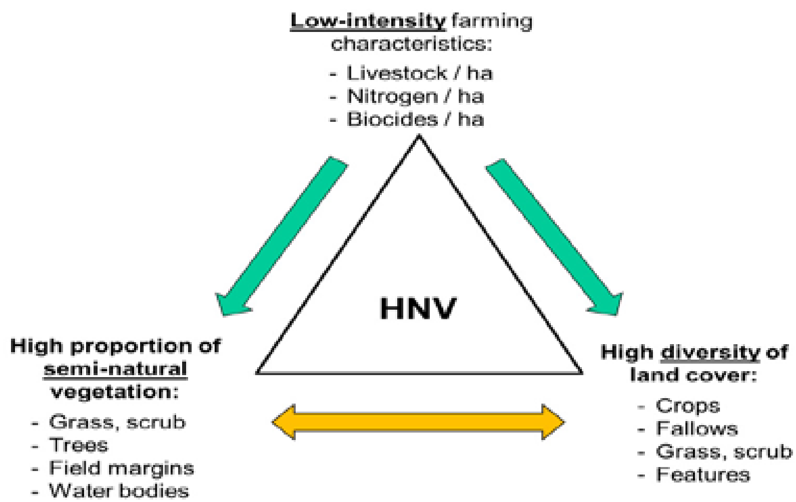
The identification of HNV farming systems (HNVfs) at farm level allows to show the links between nature values, agricultural practices and socio-economic characteristics where the farmer has seen as the main decision maker on (farm)land use and the key actor for adopting environmentally sensitive forms of farming also through the opportunity to obtain support under CAP policies. There were only few attempts to use farm level data to categorise HNVfs(Andersen et al. 2003; Pointereau et al. 2007) and even less to analyse the interrelationships among conservation efforts, production systems and policy implementation (Trisorio et al. 2008). In this paper, we discuss difficulties related to the development of HNV farming systems indicators, provide a short overview over current indicators, describe a specific approach to elaborate HNVfs indicators that are currently developed and give a short overview over the effects of policy instruments relevant to supporting HNV farming.

2. The concept of HNV farming systems

The European Environment Agency proposes three categories of HNVfarmland: 1) farmland with a high proportion of semi-natural vegetation; 2) farmland dominated by low-intensity agriculture or amosaic of semi-natural and cultivated land and small-scale features; and 3) farmland supporting rare species or a high proportionof European or world populations of conservation concern (Andersen et al. 2003). Although the third HNV farmland category may include intensively managed farming systemsthe vast majority of habitats for rare or significant species rely onextensive farming practices. On the contrary extensively or organically managed areas do not necessarily hold rare or endangered species but they have been recognized as potential HNV farmland areas.

Generally, the indicators able to assess the extent and location of HNV farmland are composed by sub-indicators considering all the three types of categories (Paracchini et. al. 2009). However,the physical extension of HNV farmland is mainly linked to both agricultural practices and farming systemsthat are essential for its maintenance. Some of the most critical nature conservation issues in Europe relate to changes to traditional farming practices on these habitats (Bignal and McCracken, 2000). To a certain extent the objective to produce maps of HNV farmland, excluding or including farms for the purpose of HNV support payments, is less important than using farm level indicators, adapted to local contexts, to assess the characteristics of HNV farming systems to increase the environmental effectiveness of the policy measures (Beaufoy and Cooper 2009; Poux and Pointereau2014; Keenleyside et al. 2014). According to the main studies on HNV (Andersen et al. 2003; Cooper et al. 2007) the key core characteristics of HNV farming systemsaround which a set of impact indicators can be set are: a) low intensity use of inputs and other technical means (fertiliser and pesticides, livestock, machinery); b) presence of semi-natural vegetation, such as unimproved grazing land and traditional hay meadows; and c) diversity of land cover with a mosaic of land cover and land use including unfarmed features (Figure 1).Generally farming systems,whose nature value results primarily from a high proportion of semi-natural vegetation or the presence of a diversity of land cover combined with semi-natural elements,are related to low input systems, corresponding to Type 1 and Type 2 of the HNV farmland categories. The difference between these farming and land use types is not perfectly dichotomous and many HNV farmland areas are a mix of different combinations at farm level.

Figure 1 - The Three Key Characteristics of HNV farming



Source: Cooper et al. 2007.

The way chosen at farm level to combine productive factors and land uses determines a continuum along which different varieties of interactions between farming systems and biodiversity can be found. Within this framework at farm level, the socioeconomic factors assume an important role because: This continuum can representsa sequence of changes over time towards both agricultural intensification orland abandoned, depending on local conditions,with loss of biodiversity value at parcel or landscape scale due to different levels of habitat fragmentation (Polákováet al. 2011; Keenleyside et al. 2014). a) the farm is the crucial level at which decisions are taken on land use and management; and b) the economic viability is the first condition for farm being at work (Trisorio et al. 2008). Indeed, one of the main threats to HNV farmland, that is abandonment or intensification of farming, strictly derives from the vulnerable economy of the farming systems associated. Moreover, the level of economic viability might affect the farm responsiveness to policy measures or, conversely, the policy measures in order to be effective should be differentiated according to the economic viability of farms.

The assessment of the socioeconomic characteristics of farms in connection to their environmental performance provides useful insights to policy design, allowing to better target instruments or to differentiate farming policies (O'Rourke and Kramm 2012; Keenleyside et al. 2014). Policy responses, indeed, are aimed at affecting farm behaviour that is mainly driven by economic and social factors. Therefore, also environmental performance of farms can be modified through economic measures.

Taking into consideration the above mentioned key characteristics of the conservation value of production systems and the nature of the land use decision making, HNV farming systems and the resulting farmland can be considered as socio-ecological systems, where human activities such as farming practices or crop and livestock breed selection have been influenced by local and regional socioeconomic, cultural and environmental conditions, and at the same time, ecosystems have been shaped by agricultural activities (Strohbachet al. 2015). HNV farming systems have in common that they are often, though not exclusively, based on traditional and extensive farming practices (Bignal and McCracken, 2000).

The variety of relationships among the different types of farming and land use creates a continuum of combinations that makesany classification quite difficult to assess. Andersen et al. (2003) used a categorical classification only based on few parameters (input cost; livestock; grassland; irrigation; set-aside) with clear-cut thresholds that do not allow to take into account all the different combinations showed by each farming systems. An alternative approach may be provided by the calculation of composite indicator that summarises the environmental characteristics of the farm and allows to rankthrough scores the level of nature value at farm level.

The use of composite indicators in order to analyse agricultural sustainability, or any other multi-dimensional concept such as HNV, is useful as a means of summarising the information provided by several specific indicators in an overall judgement or assessment of farm (environmental) performance. The development of transparent composite indicators allows to identify which aspects of agricultural sustainability (HNV) are relevant in practice, considering the high variety of combinations of farming practices and land uses.Several studies applied different techniques to build sustainability indices, although the main guidance remained almost the same (Bockstaller et al. 2008; Gómez-Limón and Sanchez-Fernandez 2010; Purvis et al. 2009; Reig-Martínez 2011; Westbury et al. 2011). The construction of composite indicators starts with a) the selection of relevant indicator based on data availability and a solid theoretical framework on the informative characteristics of each single indicator; b) the normalization of indicators that transform base indicators intoadimensional variables; c) the aggregation of indicators into one final index allowed by the normalization that makes indicators mathematically operational; d) the weighting of indicators if a different importance to each dimension/indicator has been assigned in the aggregation process,taking into account society's preferences if possible. The use of indices should be done with carefulness in all cases considering their pros and cons (OECD, EU and JRC 2008).

3. Materials and methods

The case study area is represented by Veneto region (NUTS 2 level) located in North East of Italy. The territory is 56% low-lying, 15% hilly and 29% mountainous and the regional Utilised Agricultural Area (UAA) amounts to 811,440 hectaresaccording to the 2010 agricultural census data. There are around 120,000 regional farms, with approximately 75,000 employed units. Veneto is located within the Po Valley, one of the most intensive agricultural areas of Italy. The sample used for the analysis is based on the Farm Accountancy Data Network (FADN), established in all the EU member States since 1965. Data on individual holdings are available for the period 2008 to 2013 which covers most of the years of the 2007-2013 RDP programming period. For each year a number of observations variable from 691 to 879 farms was collected and processed.

One of the advantages of using the FADN dataset is that it includes information on the intensity of farming that cannot be found in other EU wide datasets and, due to the common framework across the Member States and the yearly update, enables its use for monitoring purposes and comparative analysis at EU level. On the other hand there are also disadvantages due to the exclusion of economically small farms and "non-professional" farms that may in fact represent an interesting share of potentially HNV farms and in some areas they represent an important social pattern characterized by the presence of semi-natural elements (hedgerows, stonewalls, trees, etc.). However they generally have an extremely reduced significance in terms of farmland and income. Moreover, a considerable part of theirfarmed areas is run by contractor services or by other neighbouring farms and they may not show any particular difference from the large-size intensive farms.

The multi-criteria approach aims to assess a naturalness score which determine the level of HNVfor each farm. The method is based on different farming dimensions: management, cropping and livestock; and two relevant domains of definition HNV, namely: land use and farm biodiversity. In this case study nine measurable indicators are identified and calculated by FADN for each year. This allowed to define a score for each farm between 0 and 1 (0 min, 1 max), depending on the level of impact on biodiversity coming from the different farming practices taken into consideration in each farm. The values obtained were inferred to the regional population through a weighing operation of the sample FADN. The list of the base indicators with the weight associated and theiraverage values (with specific metric) with standard deviations are presented in Table 1.

After the identification of indicators, the normalization of indicator scales allowed to sum up different indicators. Indicator values were converted into scores according to the relationships between indicators values and level of sustainability. Relationships can be linear, non linear, and scaling can be categorical or binary. For each indicator scores are on a 0-to-1 scale. Before to aggregate the normalised indicators, a weight was assigned to each base indicators (table 1). The high variability of the parameters depends on the wide spectrum of typologies included in the FADN sample, representative of all the different type of farming and economic dimension of the regional farms.

Table 1 - List of base indicators used in the analysis

Indicators	Weight	Mean	Stand. Dev.
Permanent grassland (% of UAA)	0,24	9,6	26,0
Livestock Units per forage area	0,13	1,5	25,7
Irrigated UAA (% of UAA)	0,10	35,0	42,4
Fertilizer expenses per hectar (euros)	0,07	409	1.462
Pesticide expenses per hectar (euros)	0,08	296	707
Feed expenses per hectar (euros)	0,10	433	4.410
Organic farm (dummy Y = 1, N=0)	0,08	0,02	0,1
Number of crops	0,14	2,4	1,3
Set aside (% of UAA)	0,06	2,0	9,1

The FADN dataset covers all the aspects related to farming intensity, although in some cases only with measurementin monetary terms (input costs), and also gives some information on farm biodiversity (number of crops, type of grassland). The only aspect not covered by this survey concerns the presence of semi-natural vegetation and unfarmed features that require extra-time for surveying without any advantaged from the point of view of economic situation of the farms. The use of some proxies (e.g. presence of unproductive land or small patches of forest areas) did not prove very effective to identify other variables useful to assess some of the topics of Type 1 or Type 2 criteria for the classification of HNV farming systems.

4. Results and discussion

In general the average value of HNV-score remains more or less constant for all comparative periods, reaching around to 0.29 in 2008-10 and 0.28 per 2011-13. For the socio-economic analysis we create three different classes of HNV-score: i) No-HNV (HNV score ↓0.27); ii) Low-Medium HNV (HNV-score of between 0.27- 0:35); iii) Medium-High HNV (HNV-score↑ 0.35). The definition of classes took into account the frequency and distribution of the median HNV-score values of each year. In order to imply the naive approach before-and-after the average score values for the period 2008-2010 vs. 2011-2013were considered.

In terms of relative distribution of HNV farms (Table 2), there is a slight decrease of the number of farms from the first to the second period (from 44% in 2008-10 to 41% in 2011-13). In particular this reduction pertains to farms with medium-high HNV scores. The same trend occurs to Utilised Agricultural Area potentially classified as HNV switches from 33% (2008-10) to 26% (2011-13) for the medium-high HNV farms, while it is stable in the medium-low score. The most of UAA relates the permanent grassland in medium-high HNV farms, while arable crops are dominant for score low-medium farms, following the permanent crops. These dynamics are reasonable considering the farm reduction during the reporting period due to the economic situation. In fact, if in 2008-10 the economic situation has lowered the input costs, and it has increased the permanent grassland systems and extensive systems, in the latter period the worsening of the economic crisis has pushed out of the agricultural sector the marginal farms less intensive and uncompetitive. Similarly, the percentage of livestock farms is greater for holding with medium-high HNV score and in average fewer than 31 Livestock units (LU). Considering the LU on forage area, the ratio for HNV farms is very low compared to no-HNV farms (Table 3).

Table 2 - Percentage distribution of main economic indicators

	No-HNV	Low-Medium HNV	Medium-High HNV	Total
		Average 2008-2010		
No. farms	56,1	21,5	22,4	100,0
Utilised Agricultural Area	42,6	24,1	33,3	100,0
Annual Work Units	59,7	17,0	23,3	100,0
Farm Net Value Added	60,6	18,0	21,4	100,0
Subsidies	50,7	23,8	25,5	100,0
		Average 2011-2013		
No. farms	58,9	21,7	19,4	100,0
Utilised Agricultural Area	50,0	24,4	25,7	100,0
Annual Work Units	60,9	18,4	20,7	100,0
Farm Net Value Added	65,9	17,0	17,1	100,0
Subsidies	52,5	23,5	24,1	100,0

As for other features farms, there are not significant differences as to the farmers' age (values around 60 years for all classes considered). Taking into consideration a parameter measuring the percentage share of family annual worker units below 40 years old on the total worker units, any difference emerges. In fact, there is a tendency of youngFWU in the case of medium-high HNV score. However, the differences are very small and considered the socio-demographic factors - synthesised by the age proxies - do not seem to have such an effect on the farmers' choices as to generate differences between HNV scores of farms, probably due to the influence of other factors not currently taken into account. The size of HNV holdings is larger than non-HNV ones only in terms of farming area for both periods (17 ha vs. 11 ha), whereas the economic size as well as the number of worker units are basically larger in non-HNV farms (Table 3).

Table 3 - Structural profile of HNV and non-HNV farms

	No-HNV	Low-Medium HNV	Medium-High HNV	Total
		Average 2008-2010		
No. farms (sample)	481,7	150,3	171,0	803,0
Utilised Agricultural Area (UAA)	10,1	14,9	19,7	13,3
UAA distribution (%)				
- Arable crops	70,9	81,4	33,5	60,6
- Permanent crops	19,6	8,4	6,2	12,4
- Permanent grassland	0,7	1,5	45,1	15,8
Livestock farms (in % of total farms)	14,3	14,1	37,3	19,5
Livestock units (LU)	85,0	54,2	31,9	53,2
Livestock units / Forage area	12,2	5,9	1,6	3,7
		Average 2011-2013		
No. farms (sample)	434,0	128,0	140,0	702,0
Utilised Agricultural Area (UAA)	11,2	15,5	17,9	13,2
UAA distribution (%)				
- Arable crops	72,4	76,4	34,4	63,6
- Permanent crops	17,5	12,1	9,3	14,1
- Permanent grassland	0,5	1,9	41,1	11,2
Livestock farms (in % of total farms)	13,1	12,8	42,5	18,8
Livestock units (LU)	85,8	39,9	30,9	53,2
Livestock units / Forage area	10,2	3,0	1,4	3,6

Considering the comparison between the two periods, there has been a trend decline in the farm net value added for all classes of HNV farms, although more impressive for the high HNV score. The choice of adopting low intensive farming practices seems to depend mostly on soil-climatic factors. Nevertheless, the lack of good opportunities for the economic development seems to limit the ability of holdings to produce an adequate income. In terms of the subsidies, in general it detects a more or less equal distribution for all the years considered. The larger economic size and the possibility of allocating the production factors in a more effective way determine a remarkable difference in terms of labour productivity (Net Value Added per AWU), that is higher in non-HNV farms than in the HNV ones. In particular the analysis shows the increasing of the labour productivity for the no-HNV farms by +26% between 2008-10 and 2011-13,while increasing the values onHNV farms, only respectively of + 6% for low-score and + 7% for medium-high score. However the gap of labour productivity between HNV and non-HNV farms increases from 10% to 23% in both periods (Table 4). The differences described above can be explained by the hypothesis that more favourable soil-climatic conditions (generally in lowland farms) allow the farmer to choose among a larger number of productive combinations, thus favouring the specialised and intensive holdings. The greater difference between HNV and no HNV farms, located generally in mountain areas, where structural and social factors very likely determine a higher difference, is less intuitive.

Table 4 - Economic profile of HNV and non-HNV farms

	No-HNV	Low-Medium HNV	Medium-High HNV	Total
		Average 2008-2010		
Farm Net Value Added (NVA, euro)	40.229	30.856	34.825	36.979
NVA / UAA (euro)	3.948	2.063	1.799	2.776
NVA / AWU (euro)	31.225	32.430	28.104	30.739
Farm Net Income (FNI, euro)	31.293	21.490	31.033	29.148
Subsidies (euro)	6.307	7.503	7.638	6.854
Subsidies / UAA	612	502	394	513
Subsidies / AWU	4.869	7.889	6.190	5.696
Subsidies / NVA (%)	15,4	24,3	21,9	18,4
Distribution of subsides (%):				
- Direct payments	94,7	93,3	81,3	90,8
- Agri-environment payments	0,2	0,0	2,4	0,7
- LFA payments	0,0	0,0	4,8	1,3
- Other RDP subsides	4,9	5,0	10,4	6,5
- Other subsides	0,2	1,6	1,1	0,7
		Average 2011-2013		
Farm Net Value Added (NVA, euro)	48.477	35.413	39.567	43.314
NVA / UAA (euro)	4.314	2.292	2.164	3.273
NVA / AWU (euro)	39.190	34.347	30.066	36.274
Farm Net Income (FNI, euro)	34.808	24.877	27.833	30.923
Subsidies (euro)	7.986	10.06 5	11.20 4	8.950
Subsidies / UAA	710	652	637	677
Subsidies / AWU	6.462	9.747	8.708	7.496
Subsidies / NVA (%)	16,5	28,6	30,2	20,7
Distribution of subsides (%):				
- Direct payments	85,9	82,5	68,7	80,8
- Agri-environment payments	2,6	2,9	9,8	4,5
- LFA payments	0,0	0,0	6,5	1,6
- Other RDP subsides	9,3	13,3	13,5	11,3
- Other subsides	2,2	1,3	1,5	1,8

This analysis confirms the essential contribution of the subsidies to the economic viability of the HNV farms. The subsidies per Annual Worker Unit are greater in HNV farms compared to non-HNV farms, where the amount of subsidies reaches higher levels in terms of area units. More precisely in the periods

2008-10 and 2011-13 the subsidies per AWU generally increase: + 41% for the farm HNV at high score; of + 24% for medium-low score; + 33% for no-HNV farms. Also the gap between no-HNV and HNV farms increases, from 27% to 35%. At least, comparing the net-of-subsidies labour productivity (net value added minus subsidies per AWU) the difference between the two periods for the all HNV farm types comes out very clearly: the "net" labour productivity of the medium-high HNV score farms (coming from the market) is about two-thirds than the productivity of non-HNV farms in 2011-13, whereas many more share in the previous period (83%) (Table 4).

The FADN dataset allows the analysis of the RDP impact on HNV farming systems. In the assessment of the RDP effects, we considered Measures 211, 214 and other RDP subsides. The sub-measures are not considered because FADN does not allow this differentiation. In general between 2008-10 and 2011-13 the beneficiaries farms located in HNV areas arise. In terms of distribution of all subsidies, those related to the RDP doubled from about 8% to 17% of the total. In particular, the share of subsidies related to agrienvironment payments increases from 2% to 10% of the total for HNV-farms at high score, as well as the payments for Less Favoured Area (LFA) which increased from 5% to 6.5% for HNV farms at high score. In general the same growth trend occurs for no-HNV farms and low-score (Table 4). The source of the subsidies is slightly different between HNV (low-medium and medium-high score) and non-HNV farms: the latter rely more on direct payments, whereas HNV farms received a more significant part of the payments through the agrienvironment payments and the LFA allowance. The higher share of HNV farms in mountain and other marginal areas can explain this difference. The choice to adopt a less intensive farming system should be favoured by the AES payments. In particular these results show that public expenditures play an important role in HNV farms. In fact, this subsides represent on average 30% of the net value added for medium-low and medium-high HNV score farms, against 16% registered in non-HNV farms in the 2011-13 period (while in the previous period the share of subsides on value added was respectively of 23% and 15%).

3. Conclusions

The availability of a farm sample yearly updated such as FADN gives the chance to monitor over time the evolution of HNV farmland at micro level. Structural characteristics and information on crop and livestock management already present in the current database allow to create good indicators that can lead to the final composite indicator measuring the nature value of the farming system. The FADN sample has the same structure all over European countries, so a relatively good comparison is possible among Member States.The integration with other statistical surveys such as the Farm Structure Survey(FSS) and administrative dataset such as the Integrated Administration and Control System (IACS) potentially could increase the whole information system at farm level.

FADN data allow for the distinction in comparison groups (participant/non participant) where the HNV characteristics can be assessed. A score at farm level - based on the aggregation of appropriate indicators previously standardised and weighted - has been set in order to calculate the HNV degree of farmed areas treated or not treated by RDP or other CAP measures. The efficiency analysis of HNV farms vs non-HNV farms would provide useful insights into the role of subsidies supporting biodiversity friendly practices. At the same time without an adequate knowledge of the economic and social mechanisms which regulate the farmers´ behaviour it is not possible to understand the cause-effect relation between farming and the preservation of biodiversity. The investigation of farming systems is therefore essential to provide a complete picture in order to design appropriate measures for HNV farming systems conservation. Well targeted measures design to reward for positive externalities generated by farming activities can motivate farmers to modify their behaviour.

The FADN sample is more suitable than the one created by the Farm Structure Survey, since the survey of economic and financial aspects allows a more appropriate description of farm-holders´ behaviour. In order to exploit to the best the economic and financial information contained in FADN it is necessary to integrate data gathering with information about farming practices, agricultural land use and the management of the unfarmed features within the holdings. A major data limitation, observed in the case study and cited in other references of this paper, concerns the lack of information on the extent of semi-natural features in the farms and more generally in terms of land cover. Semi-natural vegetation plays a major role in the provision of green infrastructures that increase significantly the biodiversity values of a farmland area. Until now other indicators have proved not to be sufficiently informed to create good proxy indicators. On the other hand the increasing availability of data concerning large and small patches of perennial vegetation detected in fine-resolution satellite images should increase the reliability of land cover in agro-ecosystems at reasonable monitoring costs (García-Feced et al. 2015).

An important challenge for the future regards georeferencing FADN data which might permit an upscaling to regional level. The complexity of the georeferencing process – in spite of the progresses achieved in recent years in terms of information technologies – further widens the difficulties related to the availability of resources for this kind of surveys. It is necessary a better statistical representativeness for more robust extrapolation from the FADN sample to regional estimations. Of course this could increase the number of observations needed to have a sufficient statistical significance of the estimated parameters and, consequently, the cost of the analysis. An alternative option could come from a link between FADN and FSS samples and IACS databases that could guaranteed a more appropriated georeference for the farm samples. In this case special attention has to be given to data access that at the moment represent one of the major obstacles for a better use of already existing databases both from statistics institutes, monitoring agencies and administrative bodies.

ABSTRACT

The food production chains are subject to increasing attention to food quality and safety aspects and to the environmental impacts that they produce. The livestock sector has significant impacts on different environmental matrices including soil, air and water.

Related to the atmosphere, the Carbon Footprint is one of the major indicators; it describes the emissions of greenhouse gases generated by a set of agricultural and industrial processes. Irrespective of the rules of calculation and from the selected indicators, it is clear how the meat is the principal food with the highest environmental impact per unit mass (the kg, for example). In particular livestock cause significant methane production resulting from the digestive processes (enteric emissions). In this paper will be presented some evaluations of these environmental impacts through the use of several indicators in order to evaluate the polluting effect of cattle and buffaloes, sheep, goats and pigs emissions at the local level. This will be estimated integrating administrative.

The environmental effects of meat from livestock to slaughter in Italy: integration between data and GIS data and data from statistical surveys. Livestock farms surveyed from the Ministry of Health Registry, data derived from Istat survey on the slaughter of red meat will be taken into account. Through the use of geographic coordinates related to livestock farms, it will be possible geo-referencing the proposed indicators and representing cartographic products.

Keywords: GIS, Environmental, Livestock

PAPER

1. Introduction

The evaluation of the environmental impacts of a product can be performed using different methods that, based on the specific characteristics of the object, focus particularly on some characteristic indicators. The livestock sector has significant impacts on environmental aspects including air, water and soil (Williams et al., 2006). The most common indicators in the calculation of the environmental impacts are related to the use of water resources (water footprint) and to the greenhouse gas emissions (carbon footprint). Regarding water plays a very important role is played by nitrate pollution, caused by the release of nitrogenous substances in the surface aquifer. In the atmosphere, the major impacts are on the emissions of ammonia (NH3), methane (CH4) and nitrous oxide (N2O) (Campbell et al., 2008). Ammonia emissions from the agricultural sector are primarily produced by intensive farming and animals.

An emission inventory is an accounting of the amount of pollutants discharged into the atmosphere. It usually contains the total emissions for one or more specific greenhouse gases or air pollutants, originating from all source categories in a certain geographical area and within a specified time span, usually a specific year.

An emission inventory is generally characterized by the following aspects: types of activities that cause emissions, chemical or physical identity of the pollutants included, geographic area covered, time period over which emissions are estimated, methodology to use. Emission inventories are compiled for both scientific applications and for use in policy processes.

In this work it was decided to investigate the environmental impact in terms of carbon footprint being the most widely used indicator, and interpretation easier. The project is expected to consider livestock farms surveyed from the Registry from the Ministry of Health, data derived from Population Census for Emilia Romagna region and at the provincial level. The data refers to 8,822 farms on a total of 10,000 in Emilia Romagna who hold cattle, buffalo and pigs in the year 2015.

Livestock farms within the territory of Emilia Romagna are of a primary importance as the value of dairy cows in the production of "Parmigiano Reggiano" and of pigs for "Prosciutto".

In this area data related to various features have been gathered: data on livestock, on the type of animal bred and geo-referencing data (geographic coordinates that identify the farms). In the next table it is presented the distribution within the province of the animal types considered: dairy cows, bovine, buffaloes, pigs.

2. Emission factors

In order to calculate the emissions of livestock pollutions it has been considerate three elements:

- Ammonia (NH3): ammonia emissions in the agricultural sector contribute to the increase of the greenhouse gases for the production of gases. These emissions also contribute to the formation of fine particles. The formation of ammonia from animal manure depends upon the enzyme urease, whose activity is affected by the pH and temperature.
- Methane (CH4): methane livestock formation depends on the digestive processes (enteric emissions).

The environmental effects of meat from livestock to slaughter in Italy: integration between data and GIS

- Nitrous oxide (N2O): in the livestock farming, the nitrous oxide emission depends on the storage and the spreading of manure on the land.

So, these three factors have been taken into account (ARPA, 2013), as well as the number of heads for animal typology (just for dairy cows, bovine, buffalo and pork) in three phases of livestock process:

- Livestock housing;
- Storage of manure;
- Spreading manure.

In the following table we show values of the emission factors (kilo for head) for the three pollutants and for the three process steps involved. The factors of emissions are calculated considering several studies (IPCC, 2006), using specific weights depending on different animal species.

Table 1 - Emissions factors, kilo for head and animal typology

	NH3			CH4		N2O
Animal typology	**Livestock housing**	**Storage of manure**	**Spreading manure**	**Livestock housing**	**Storage of manure**	**Livestock housing and Storage of manure**
Dairy cows	15.46	20.36	12.65	113.24	15.04	2.1497
Bovine	6.66	8.96	5.46	44.72	7.65	0.6683
Buffalo	12.61	16.61	11.95	69.74	11.96	1.89
Pork	2.39	2.00	1.39	1.5	7.94	0.0202

Final results of emissions per provinces are shown in the following table:

Table 2 - Total emissions per province, year 2015

Provinces	NH3 (Kg)	CH4 (Kg)	N2O (Kg)
Rimini	117,007.80	417,347.22	51,421.26
Piacenza	4,975,971.03	7,178,382.13	88,349.12
Parma	7,424,407.50	10,774,264.21	142,990.23
Reggio nell'Emilia	7,171,421.04	10,309,793.92	134,397.42
Modena	6,458,882.35	9,621,531.77	128,905.33
Bologna	5,501,862.58	7,985,779.79	110,200.00
Ferrara	1,102,631.27	1,663,968.47	21,765.89
Ravenna	1,364,916.02	1,997,112.97	26,730.18
Forli-Cesena	3,771,979.30	5,475,044.37	71,996.43
Total	**37,889,078.89**	**55,423,224.85**	**776,755.86**

The assessment of health effects from environmental hazards involves people who lives close to the livestock. To compute the risk it was built an indicator that put in relationship the emissions and population under potential health risk.

We have created multiple buffers at specified distances around the urban areas and we have selected farms inside them.

The distances considered are: 100 mt, 200 mt, 300 mt and 500 mt.

In other words let Ai be the area of the i-th urban area, i=1,2…m for each province and *Ai the buffer area corresponding to i-th urban area for a distance D. Then the risk is defined as:

$$r_i = \frac{P_i}{e_i}$$

where P_i is the population in $^*A_i$ and e_i is the total emission from the n_i farms in $^*A_i$

$$e_i = \sum_{j=1}^{n_i} e_{i,j},\ n_i \geq 1$$

for $i \in I$ where I is the subset of urban areas $^*A_i$ that contains at least one farm.

The locations building for the Population Census are been considered: urban areas, inhabited areas and production areas (Istat, 1992).

If the indicator is high it means that the proportion of the population exposed at health risk is higher.

The results are reported in table 3 for provinces. The column "total" expresses the values for provinces total population. Considering the total values, every indicator is high for Rimini, Parma, Piacenza and Reggio nell'Emilia provinces. It's important to underline the different results based on the distances by the livestock houses. Obviously the population size nearest to the farms is small but the pollution risk is higher. So it's important to highlight also the high results of the indices for Modena and Bologna for the indices relative to N2O and Ferrara provinces for all the indices (N20, NH3 e CH4). Note that it was possible to achieve this because the data refer to a geographic scale more accurate than the provincial one.

Table 3 - Potential population espoused at health risks for distance

Provinces	Meters (N2O)				Total	Meters (NH3)				Total	Meters (CH4)				Total
	100	200	300	500		100	200	300	500		100	200	300	500	
Rimini	3,9	7,2	13,6	19,2	335,5	39,0	63,7	112,4	144,9	1.748,9	33,9	60,2	108,2	148,2	2492,1
Parma	139,9	195,7	231,4	321,6	498,0	619,3	863,9	1.031,6	1.441,1	2.262,0	966,3	1.337,4	1.590,1	2.214,7	3.482,7
Reggio nell'Emilia	171,9	187,5	219,0	283,8	384,9	801,3	877,7	1.043,1	1.341,2	1.888,4	1.246,3	1.356,0	1.619,6	2.082,3	2.873,4
Piacenza	174,2	192,8	200,0	265,9	458,8	830,5	920,3	965,8	1.280,2	2.402,2	1.200,3	1.318,8	1.379,2	1.853,2	3.590,4

Modena	58,3	65,8	87,1	127,8	18,0	269,2	321,7	426,4	652,5	197,9	411,4	480,1	645,2	974,0	213,0
Ferrara	34,5	33,3	37,3	46,6	18,2	272,1	263,3	308,7	354,0	138,7	255,7	247,4	280,8	342,0	147,3
Region	**63,2**	**75,8**	**90,3**	**122,9**	**168,5**	**306,2**	**367,3**	**447,0**	**608,1**	**880,6**	**452,8**	**540,8**	**656,7**	**896,5**	**1.278,1**

3. Maps data analysis

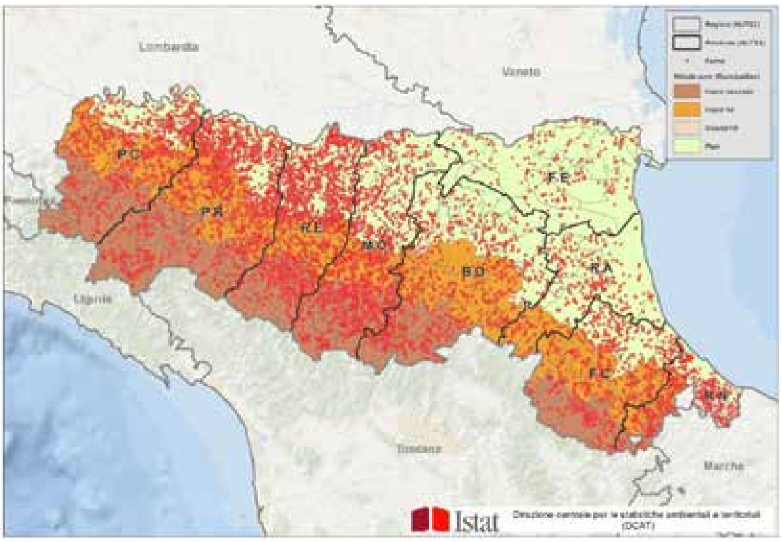
In Emilia-Romagna 8,822 farms have been georeferenced of a total of about 10,000[1]. The difference depends on the inexistence of a validated coordinates for few livestock houses. The farms without geo-referred data are little in terms of heads and uniform distributed on the territory. The emissions calculated and the relative indicators are represented on the following maps.

The farms with livestock are concentrated in the provinces Forlì-Cesena, Modena, Reggio nell'Emila, Parma (figure 1), Parmiggiano Reggiano e Prosciutto production areas. On the coast the number is lower, probably because this is an area with a great sea tourism vocation (Bologna, Ferrara, Ravenna and Rimini provinces).

In the figure the farms are represented by altimetric area (each farm is a geo-referenced point). It's clear the independence between this matter and the presence of animals. Very interesting could be the evaluation of environmental and health risks for people who lives close to the livestock.

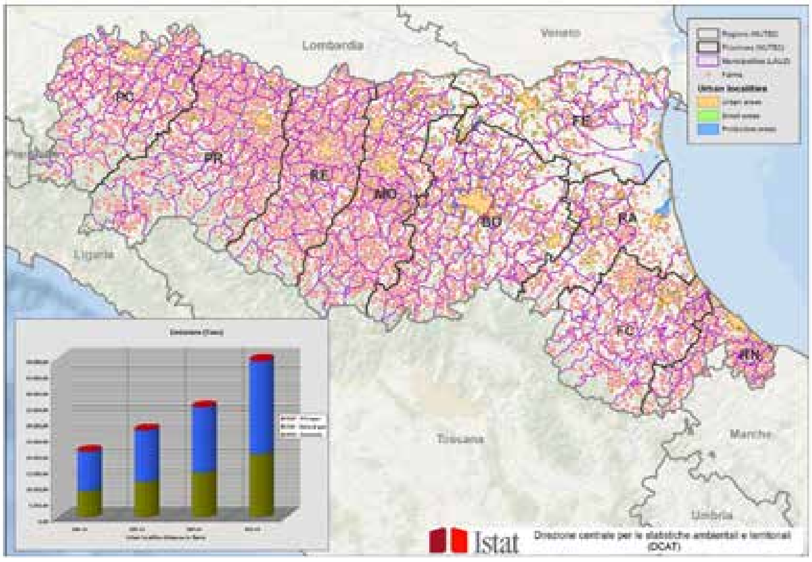
[1] Source Registry from the Ministry of Health

Figure 1 - Farms by municipality and altimetric area.



In the urban localities, delimited by a geographic information system (GIS) and available on the Istat site web[2], are detected and localized people and local units of the general censuses of population, enterprises and agriculture. The integration between the thematic maps of territorial bases (Lipizzi, 2013) and geo-referred farms, estimates the potential health risks on humans.

Figure 2 - Farms and emissions for distances from built-up, inhabited and production.



The environmental effects of meat from livestock to slaughter in Italy: integration between data and GIS

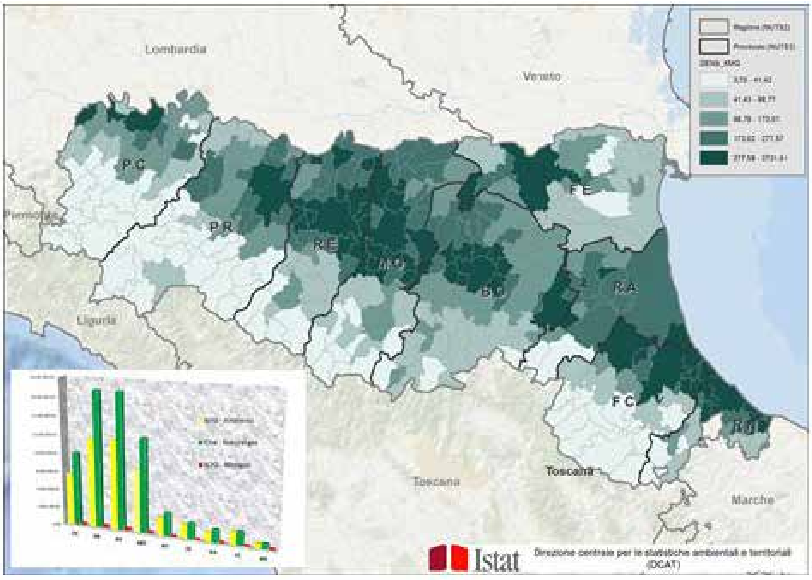
In the figure 2 are geo-referred the livestock houses and the urban localities, urban area (high density population) in yellow color, small area (inhabited areas) in green, production areas in blue. Each municipality is categorized according to quintiles of regional distribution. In figure it is also shown a graph, which indicate the sum of pollutant emissions by distance to the livestock houses. Methane and ammonia are the elements more consistent in the region Emilia-Romagna.

The figure 3 show the density population. The soft green indicate a low density and the deep green an high density. The population is concentrated in the north of motorway, into the Po valley.

The graph shows the total pollution per province. Methane and ammonia production caused by livestock are concentrated in Piacenza, Parma, Reggio Emilia and Modena provinces, how reported in table 2.

[2] http://www.istat.it/it/archivio/104317

Figure 3 - Density municipal population and total pollutants per province.



The last three figures are the overlapping of figure 1 and 2: they show for municipality the three components of carbon footprint (ammonia, azote and methane) normalized based on the population density. The theming is done by classifying quantile. In other words, they represent the table 2 calculate at municipal level.

Considering the single factors the situation is quite different respect to the total pollutant. It's clear the high concentration of polluting factors in interior area of the Region (particularly in Piacenza, Parma and Reggio nell'Emilia provinces), where is more incisive the presence of nitrous oxide (figure 5).

The areas near the cost are deeper because of the presence of Valli di Comacchio, a vast uninhabited wetland located in Emilia-Romagna, in the provinces of Ravenna and Ferrara. So even if the density population is lower, people lives nearest the farms and the health risk is higher.

Figure 4 - Ratio between ammonia produced in the municipality and density population

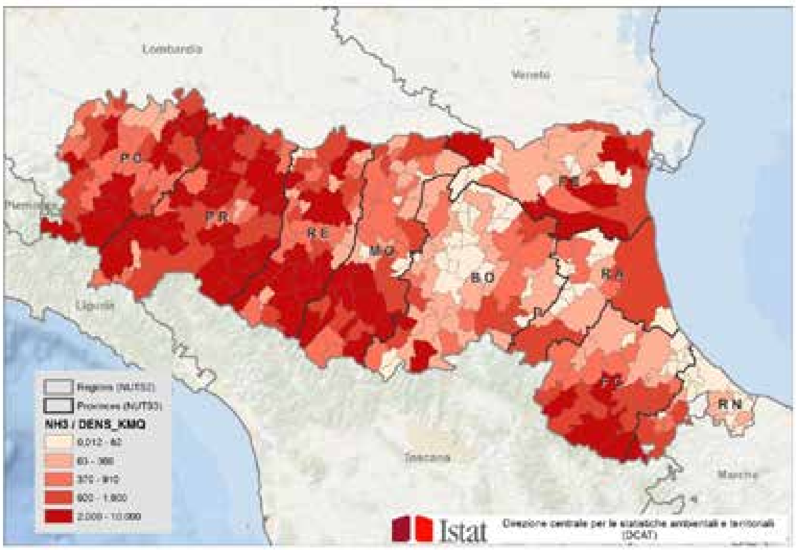


Figure 5 - Ratio between nitrous oxide produced in the municipality and density population

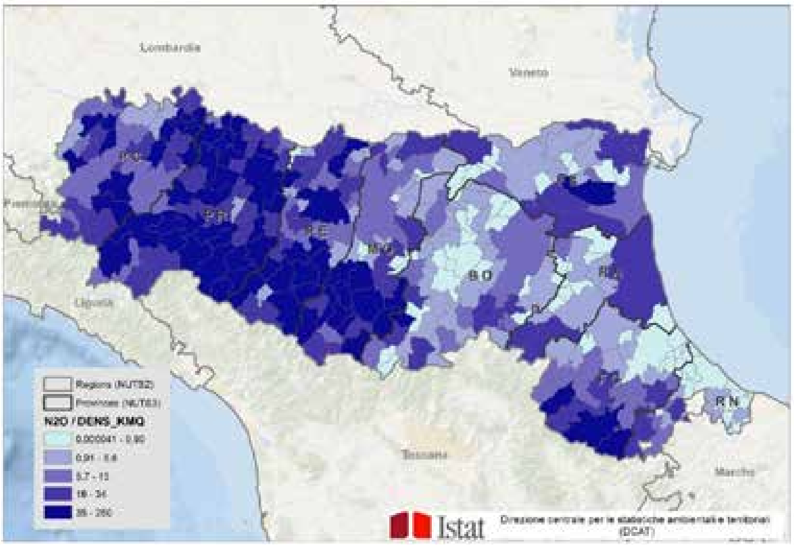

Figure 6 - Ratio between methane produced in the municipality and density population

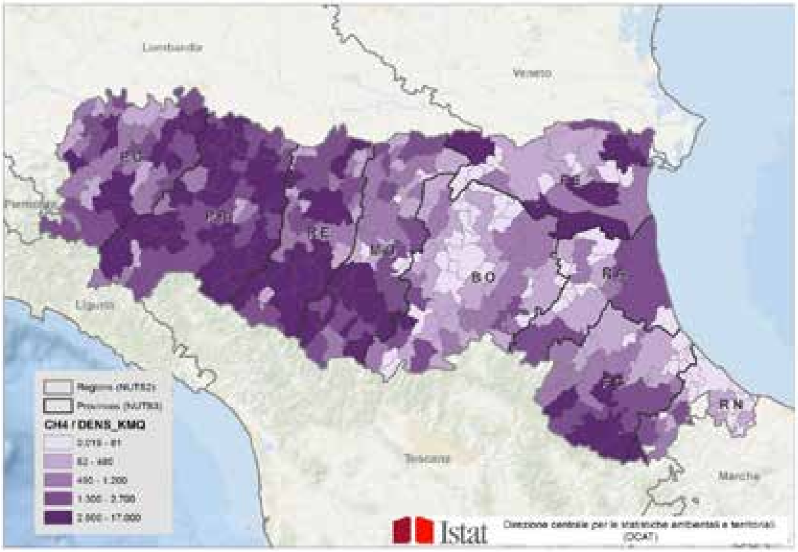

Conclusion

The exercise carried out shows the increasingly important need to overlap geo-referenced data coming from multiple sources in order to obtain a broader and more detailed information linked with the territory . Data previously heterogeneous now take the chance to a new interpretation . It should be stressed that the potential of georeferenced information depends on the easy availability of them.

This study highlighted the strong connection between data related to bovine and data relate to the atmosphere. The results of this paper allow a more accurate definition of emissions from livestock activities and the evaluations obtained may also be useful to develop abatement strategies of pollutants in order to reduce emissions from the livestock sector.

Furthermore the analysis on a sub-municipal level, is a discriminating factor in assessing more accurately the health risk to the population. It would be interesting to extend the analysis to all regions and in other critical areas.

B14

COMMUNICATING YHE COMPLEXITY OF SUSTAINABLE FOOD AND AGRICULTURE

Session Co-Organizer
P. Conforti | FAO | Rome | Italy
M. Dominguez Torreiro | FAO | Rome | Italy

ABSTRACT

Composite indicators (or performance indices) are recognized as a useful analytical and communication tool. Their attractiveness lies in their potential to synthesize multidimensional phenomena such as human development or food security into a single score, rank entities (such as countries) when appropriate, and facilitate advocacy. Furthermore, rankings force institutions and governments to question their standards; rankings are drivers of behaviour and of change. Hence, it comes as no surprise that there has been a turbulent growth of performance indices over the past two decades.

On the other hand, there is a more sceptical audience warning that composite indices may be misleading and difficult to interpret since much information may be lost or concealed. Others question how a single index may inform decision-making since more detailed disaggregation is needed for this. Further, the methods to make up such an index are not universal and are under constant revision. Much revolves around the problem of assigning appropriate weightings to the different components in the calculation of a single index.

For this type of audience, scorecards, dashboards and key indicators might be the preferred option. One cannot disagree that there are many low quality composite indicators out there but this should not imply that composite indicators are altogether useless in informing debates. What is most important is that one systematically assesses the quality of existing composite indicators. There are already well-established principles of good practice which would allow the users of these new statistical artefacts to gauge their quality:

(a) a handbook, published jointly by the OECD and the European Commission's Joint Research Centre, offering guidelines on constructing composite indicators;

(b) sensitivity analysis offers tools to assess the extent to which a composite indicator is volatile to the specificities of its underlying assumptions;

(c) sensitivity auditing assesses whether and to what extent models (including composite indicators) conform to the scientific standards of accessibility, transparency, and reproducibility.

Taken together, these tools at least facilitate a public debate based on explicit reasoning in which composite indicators play a role. This session will engage presenters and participants in discussions of methods and applications of composite indicators in agriculture and social sciences. Are performance indices considered more as a means to an end or an end in itself? What are the latest developments for identifying suitable and general criteria for judging their quality and ability to summarize the underlying phenomena? Are scorecards, dashboards and key indicators to be preferred over composite indicators or are they complementary tools?

Developing the Indicator System of Sustainable Agriculture – Application of Composite Indicators

G. Valkó | Hungarian Central Statistical Office, Rural Development, Agricultural and Environmental Statistics Department | Budapest | Hungary

DOI: 10.1481/icasVII.2016.b14

ABSTRACT

The sustainability of agriculture has become one of the most important areas of agricultural research in the last decade. The focus of research has changed from efficiency of production, quality and quantity of product to the impact of agriculture on environment and rural population. An important area of research is the development of indicator systems measuring the sustainability of agricultural systems on micro or macro level.

The aim of this paper is to present the results of the author's research focusing on the development of an indicator system measuring the sustainability of agriculture. The indicator system is built on macro level statistical data and its structure is based on a theoretical framework that was developed using the definition of sustainable agriculture. Data were gathered for the EU Member Countries for the time period of 2000 to 2012. Composite indices of the overall sustainability of agriculture and separately for the four domains (food supply, environment, economy, society) were calculated. The weight system was established based on the results of a primary expert survey.

The indicators and composite indices are suitable for carrying out temporal and spatial comparisons and can also be used for analysing the causes of trends in the European agriculture in terms of sustainability.

Keywords: sustainability, agriculture, indicators

PAPER

1. Introduction

Agricultural production is a nature-related activity, and has a significant impact on the state of the environment, but also is an integral part of rural life. On the one hand it has a remarkable influence on rural areas and on the other hand it is dependent on them in many aspects. Agricultural production is multi-purpose: there are economic, environmental and social roles of agriculture (OECD, 2001; Boody et al., 2005; Rossing et al., 2007; Huang et al., 2015). The Earth's growing population will require a huge amount of surplus production of food; so the increase of utilised agricultural area and / or the increase of production efficiency are inevitable if consumption patterns remain unchanged. Therefore, the efficiency and the economic dimension of sustainability for agriculture – similarly to the energy sector – are more emphasised within the topic of sustainability compared to other economic sectors.

A reliable indicator system describing sustainability has become a more and more pronounced requirement of decision-makers. Besides, there is also an intensified expectation among the population to gain information on the social and economic processes in terms of sustainability. Many organizations and scientific institutions have developed indicators and indicator systems that attempt to measure the performance of agriculture in terms of sustainability. However, they are not fully adapted to the Hungarian and European Union agriculture, and most of them do not allow temporal or spatial comparisons.

2. Material and method

The theoretical framework of the indicators of sustainable agriculture is based on the definition of sustainable agriculture, which was created by synthesizing the literature sources including the following: EU, 2012; Kirchmann and Thorvaldsson, 2000; National Research Council, 2010; OECD, 2001; RISE, 2016; SARE, 1997; Smith and McDonald, 1998; USDA, 1999; Valkó and Farkasné Fekete, 2014; Van Cauwenbergh et al., 2007. Four points of the definition identified the domains of the indicators system, which are as follows:

• production of good quality, safe and healthy foods, satisfaction of needs – food supply,

• conservation of natural resources, protection of the environment, creation of animal welfare – environment,

• efficiency, competitiveness, economic viability, ensuring profitability – economy,

• improving the quality of life in rural areas, social justice, and development of attractive rural landscape – society.

According to the theoretical framework, 44 indicators were chosen and grouped in 4 domains (food supply, environment, economy and society). The themes covered by the indicators are listed in Table 1. Only those indicators were selected, for which data were available for the EU Member Countries for the years 2000-2012. The most important data source was the Eurostat database, but to a lesser extent, other data sources were also used (FAO, WHO, etc.). 15 thousand data items were gathered, which phase was followed by their check and editing, as well as the imputation of missing data. Through the phases of selection of indicators and collection of basic data, quality requirements developed by Eurostat and the OECD were followed. An examination of the relationship between indicators using correlation matrices was carried out prior to the finalization of the indicator system. The revealed relationships between the individual indicators in several cases exist and can be explained. However, the number and strength of these relationships is not such that would reduce the reliability of the indicator system. Based on the correlation analysis, the inclusion of each indicators in the indicator system is reasonable. The weights required for the calculation of the composite indices were determined by expert opinion. In the literature (OECD, 2008), this procedure is referred as the Budget Allocation Process (BAP).

Table 1 - Themes covered by the indicators in the indicator system for sustainable agriculture

Food supply	Environment	Economy	Society
Organic farming	Resource use	Resource use	Production of value
Production of genetically modified crops	Energy use	Efficiency of land use	Employment
Food security	Land use	Labour productivity	Rural development subsidies
Food processing capacity	Livestock density	Competitiveness in foreign trade	Change of population
Food price	Emission of greenhouse gases	Yields	Poverty
Consumption of healthy food	Emission of ammonia	Utilization of agricultural land area	Housing conditions
Safe food	Nutrient balance of soil	Replacement of means of production	Age composition of population
	Manure use	Diversification of production	Internet access
	Pesticide use	Research and development	Environmental harm
	State of flora and fauna	Age composition of farmers	
	Environmental commitment	Agricultural income	
	Organic farming	Subsidy dependency	
	Own produced inputs		
	Land use		
	Training of farm managers		
	Agricultural education		

Source: own research

In order to develop the Sustainable Agricultural Index, first the normalization of data of the indicator system was carried out using min-max method with the application of the following formula (OECD, 2008):

$$I_{qc}^{t} = \frac{x_{qc}^{t} - \min_{t \in T} \min_{c}(x_{q}^{t})}{\max_{t \in T} \max_{c}(x_{q}^{t}) - \min_{t \in T} \min_{c}(x_{q}^{t})}$$

where

x_{qc}^{t} = value of indicator q for country c and year t,

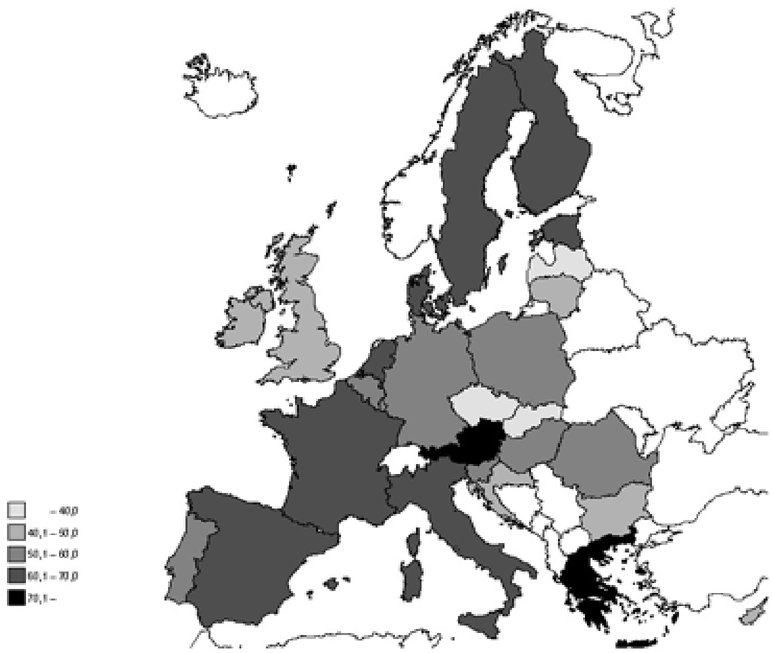
I_{qc}^{t} = normalised value of indicator q for country c and year t.

During this process, the experts distribute 100 points for the indicators according to their importance in terms of the target determined by the theoretical framework of the indicator system. Determination of the weights is complex, and it is very difficult to make an informed decision because of too many circumstances to be considered and the limited information. For this reason, an opportunity was offered for the experts who had difficulties in the distribution of 100 points to determine the rank of indicators in terms of their importance. The aggregation of indicators was performed using the method of linear aggregation by adding the normalised and weighted values of the indicators. The weight system of the composite indicators was developed by using the results of an expert survey. Sub domains were created for two domains of the indicator system in order to facilitate the work of experts in valuing the different indicators in terms or their contribution to sustainability of agriculture. These sub domains are: Resource use; Environmental pressures, state of the environment and Proper farm management in the domain Environment while Efficiency, competitiveness and Economic viability, profitability in the domain Economy. The survey was carried out between 28 October 2014 and 6 January 2015. A total of 102 experts (including international experts), who have the expertise in sustainability of agriculture, received the questionnaire. During the research, 60 experts returned the questionnaire, representing a return rate of 59% (Table 21). 65% of the respondent experts held at least a PhD degree. The expert survey resulted in the weights for the indicators and the domains of the indicator system. The weights for the four domains are as follows: 30.9 for Environment, 28.3 for Food supply, 20.5 for Society and 20.3 for the domain Economy. When compiling a composite indicator system, a number of subjective decisions are to be made, which may even substantially influence the composite indicator values. Therefore, the robustness and the reliability of the composite indicators were measured using sensitivity analyses, which were carried out for the following areas: compilation of indicator system, type of weighting system and selection of experts. The values of the Sustainable Agricultural Index (key composite indicator for the sustainability of agriculture) calculated with modified conditions were compared with the results from the original method. Based on the results, only the selection of the type of weighting system influenced significantly the values of the composite indicators.

3. Results

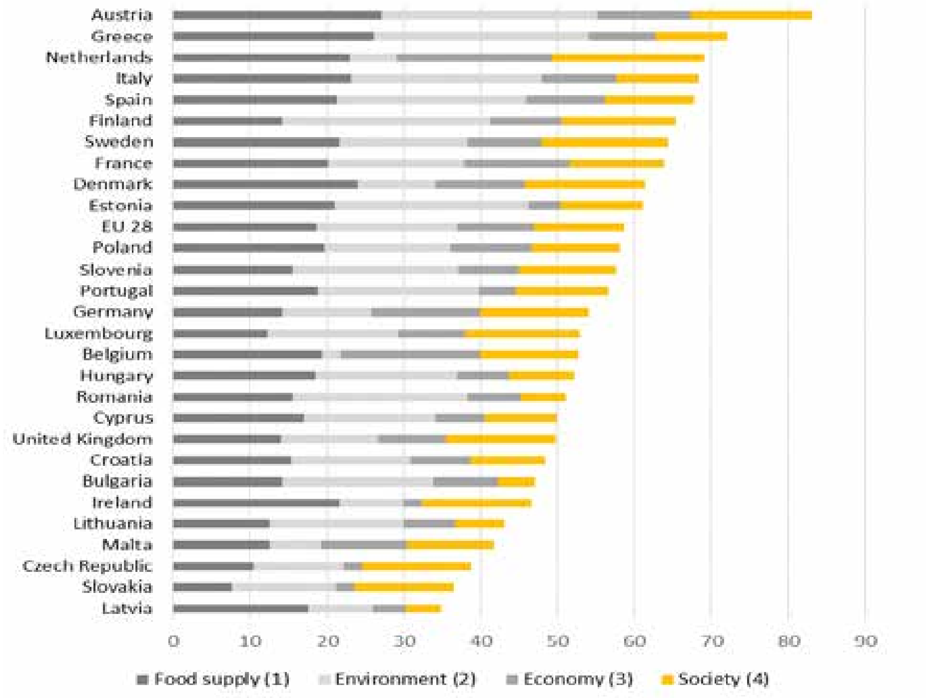
Sustainable Agricultural Index (values for 2010 are shown in the map of Figure 1) had the highest value in Austria in 2010 in the EU, followed by Greece and the Netherlands, while Latvia, Slovakia and the Czech Republic had the lowest values The contributions of components of the Sustainable Agricultural Index to the index values for 2010 are presented in Figure 2. The agriculture of Austria performed well in all major areas. The Austrian value of "Food supply" indicator is the highest in the EU, while second for that of the "Environment", and third for the indicator for the "Society". Greece showed an outstanding performance in the domains for environment and food supply, and the Netherlands achieved high values for the composite indicators of economy and society. At the other end of the country order, Latvia reached the lowest level in the EU in the domain "Society", while Slovakia had the lowest value in the domain "Food supply". 2010 values of the Sustainable Agricultural Index and the rate of change compared to the 2000 figures are presented in Figure 3. The Sustainable Agricultural Index of the Polish (94%), the Estonian (71%) and the Czech (63%) agriculture reached the strongest improvements between 2000 and 2010, while decrease in Ireland (24%), Denmark (8%) and Croatia (6%) can be detected.

Figure 1 - Values of the Sustainable Agricultural Index in the EU Member Countries, 2010



Source: own research

Figure 2 - Values of the components of Sustainable Agricultural Index in the EU Member Countries, 2010



Source: own research

Figures 4 and 5 compare the values of Sustainable Agricultural Index in the region of Central and Eastern Europe. In the whole period, Austria had the highest index value, while Poland achieved a significant increase, and reached a higher value than that of Hungary and Romania in 2010. If we examine changes in the values of individual countries, we can conclude that Poland reached the most significant growth during the decade studied, while changes in the values of other countries were not significant apart from the minor growth in Slovakia.

The indicator system and the composite indices give an opportunity for detailed country analysis where the performance of a country can be analysed by components, against competitors and also temporal changes can be investigated. As an example for country analysis, the values of Sustainable Agricultural Index and its components in Hungary are shown in Figure 6. Sustainable Agricultural Index of Hungary was 11% lower than the EU average in 2010. The index for the environmental dimension showed a slightly higher value than the average, while the index for the "Food supply" domain was slightly lower than the average. The values of indices for the "Economy" and "Society" domains were significantly lower than the EU average.

Source: own research

4. Conclusion

Numerous institutions and research teams have developed indicator systems for measuring the sustainability of agricultural production; however, none of these gave a summary assessment of the sustainability of the EU Member Countries' agriculture.

The average value of Sustainable Agriculture Index rose in the EU in the period between 2000 and 2010, according to which the EU agriculture moved towards sustainability. The index values showed the most significant increase in the domain "Economy" during the period under review, while the lowest growth rate was measured in the domain "Environment". There are significant differences between the sustainability performances of the Member Countries.

The compilation of the indicator system was difficult because of the lack of basic data or the inadequate quality of them in some areas. The quality of the composite indices is basically influenced by coverage of the specific areas in the theoretical framework by relevant indicators supported by basic data with adequate quality. For this reason, it is essential to improve the accessibility and quality of basic data. An additional problem in many areas is the long production time of data; timeliness needs to be improved. The production of indicators at a lower territorial level is currently not possible in many areas because raw data are not available, which deficiency could be eliminated by applying data collection methodologies or estimation procedures that could enable the dissemination of data at a lower territorial level.

A major difficulty related to the composite indicators is the lack of their widespread acceptance. The value of the indicators can be significantly affected by the theoretical framework, the scope of indicators in the indicator system and the methodology of the weight system that is needed for the calculation of the indicators. In many cases, subjective decisions are needed for the development. However, the communication value and the role of composite indicators in decision support are indisputable. It is necessary that the development methodology of a composite index should have the appropriate political support to become widely accepted. The system of indicators and the related composite indicators produced as a result of this research are capable of supporting the European and national agricultural policy decisions, as well as of the shaping of Common Agricultural Policy and its components. A distinct advantage of the indicator system is that it is suitable for the systemic tracking of changes in the main aspects of agricultural production both at national and at EU level.
