ABSTRACT

The reduction of Food Losses and Waste (FLW) is a central topic in the current policy agenda. An FAO study of 2011[1] suggests that roughly one-third of food produced for human consumption is lost or wasted globally, which amounts to about 1.3 billion tons per year. Of this, potentially more than 40% is lost during post-harvest handling and processing in developing countries, while more than 40% is lost at retail and consumer levels in industrialized countries. Additional losses occur in non-food agricultural value chains such as animal feed or seeds. Taken together, these losses undermine economic, food security, nutrition, and other welfare outcomes; and they impact on the environment. Yet regional and national knowledge about FLW remains incomplete and unreliable. There is a poor understanding of, and limited accurate or comparable data on, the scale, nature, location, sources, and consequences of FLW across food systems. Without reliable information, countries and the global community are unable to assess the scale, causes and consequences of PHL; they hesitate to invest significant resources; and they are unable to design and target effective policies and investments. The challenge of measuring FLW is significant. There is methodological gap on a cost-effective and statistically sound approach to effectively assess FLW in support of measures for their reduction. FLW are a multi-dimensional phenomenon that affects the whole value chain from producer to consumer. Furthermore, problems and characteristics can be product-specific and require product-specific methods. Ultimately, measuring FLW in their entirety requires developing a conceptual framework to differentiate losses and waste, as well as the types of losses (quantitative, qualitative, and nutritional) and different actors or units of observation (farms, households, traders, food processors, distributors, warehouse owners, etc.), as food moves from food to fork. Compiling FLW statistics therefore implies establishing a multi-layered system consisting of different surveys each with its associated sampling and measurement challenges. The aim of this session is to discuss: statistical methods that can address the methodological challenges of measurement; options for designing integrated FLW measurement systems; and cost-reduction strategies such as use of small-scale case studies to identify main losses/waste points and focus sample surveys on those. Possible topics for papers include: integration of post-harvest losses into existing agricultural statistical surveys and systems;; survey design (two-phase sampling, indirect sampling for traders and distributors); estimates based on experimental design; commodity-specific methods (milk, horticultural products, fish); measurement issues; pre-harvest losses waste; modeling approaches.

ABSTRACT

In order to improve food security in Cameroon, a diagnostic study for the reduction of Post-Harvest Losses (PHL) in tomato supply chain was carried out in 2013, by a team of two FAO consultants, for the Ministry of Agriculture and Rural Development (MINADER). The study was conducted in the West (main production area), and Littoral (urban markets) regions of the country. The methodology was based on four main stages: (i) preliminary diagnosis of the situation of PHL throughout the supply chain, (ii) field work with various actors of the sub-sector, (iii) synthesis of the results obtained, and finally (iv) the development a strategy and the relevant work plan and for a significant reduction of these losses over a period of 10 years.

With an average consumption of 30.05 kg/person/year and 35% of all vegetables consumed in the country, fresh tomato occupies a prominent place in the country's food security. About 329 033 small farmers are involved in the sub-sector with a potential of 1 645 165 jobs.Tomato produced locally is mainly marketed fresh, without any significant processing after harvest. For reasons related to logistics and time constraints, the western production area and urban market of Douala were selected for further analysis in the field. Moreover, we also considered financial resources available for the study and the following criteria, defined by the FAO guide: (i) be part of an organization of small farmers producers of tomato, (ii) final products are intended for human consumption, (iii) have their end markets in villages, urban areas or abroad, (iv) create value added by small and medium sized farms in the supply chain; (5i) to be integrated into a support program underway in the tomato subsector. Preliminary investigations revealed that Pre-harvest, Transport and Marketing were the highest Food Losses stages. Even though the production of fresh tomato was about 932 530 tons in 2012, and the consumption estimated at 605 054 tons, the country still faced huge deficit which were partly filled by concentrated tomato imports; This is due to high losses along the supply chain. Interviews with different actors of the supply chain, and a study conducted in markets, allowed us to compare the preliminary information obtained during the screening phase, with the results of measurements of losses at critical points. Hence, losses in tomato supply chain are both quantitative (reduction of mass) and qualitative (reduction of market and nutritional value). Causes of these losses depend on several factors: technological, managerial, infrastructural, etc. Origin of these losses is diverse and include among others: climate, soil, variety, physiology, mechanical damage, diseases, pests, and agricultural processing practices. Field analysis revealed the steps where tomato losses (quantitative and qualitative) were most significant: Pre-harvest/harvesting (28.30%; # %), Transport (7.70%; 5.15%), and Retail sale (#%; 25.85%) of production. The synthesis of results helped us to identify the following solutions: (i) improve access to agricultural inputs (quantity, cost, regulation, certification, etc.) and adequate knowledge of the usage; (ii) drive an inclusive research-development action to improve traditional containers used for tomato transportation; (iii) develop farmer's capacities in farm management practices, and market access; (iv) improve market infrastructure, (v) Facilitate access to innovative packaging and handling techniques. Finally, a strategy for the reduction of losses in the tomato sub-sector over a period of 10 years was proposed to Cameroonian Government.

Keywords: supply chain,critical stages, quantitative losses, qualitative losses

PAPER

1. Introduction

According to FAO statistics, the current energy consumption which is about 2300 kcal/ person/day in Cameroon remains below the average of developing countries (2600 Kcal/day/ person). The State of Cameroon in its strategy for growth and jobs (agriculture and rural development component) had set a goal to reach a level of 3100 Kcal/day/person in 2015. To achieve this objective, it was necessary to combine the growth of agricultural production initiatives, with the reduction PHL. These losses account for about 20 to 50% of production or more for some crops in Cameroon, including fruits and vegetables. Indeed, a significant reduction in losses is not only beneficial to all stakeholders of the various agricultural and food sectors but is also conducive to food security in its different dimensions (availability, accessibility, stability of market supplies, sanitary quality and nutritional food) and preservation of the environment. No previous study had been conducted for the assessment of post-harvest losses on the tomato supply chain in Cameroon.

Although these estimates come from the Ministry of Agriculture in Cameroon, they are not confirmed by reliable field analysis.

From the Ministry of Agriculture data in Cameroon (not confirmed by reliable field analysis), although estimates are available on the level of food losses, there is always the need to identify the most critical determinants at different points of the food supply chain in order to achieve profitable and sustainable socio-economic and environmental solutions. Studies are needed as a prerequisite for setting priorities for the implementation of specific interventions for reducing losses and obtaining a maximum desired effect. It is in this context that MINADER requested a diagnostic study for reducing PHL of three crops (cassava, potato and tomato) with FAO support. This was evidenced by project MINADER/FAO-TCP/CMR/3402: "Diagnostic study of post-harvest losses in cassava tomato and potato value chains in Cameroon". This report covers only the work done in the context of tomato in Cameroon. For FAO, the study is part of a series of case studies from the global initiative to reduce food losses and waste (Save Food).

The main objective of this study is to make an inventory of PHL and critical stages in the tomato supply chain in order to propose a strategy for better control of losses. The fieldwork was conducted in 2013 and was subject to a detailed report and validated during a national workshop held in Yaoundé in April 2014.

2. Intermediate sections

2.1 Methodological approach

The methodological approach used is that developed by FAO for the case studies as part of the Save Food initiative. It consists of the implementation of the main steps and actions summarized below:
- Preliminary diagnosis of the sub-sector. It brought out general situation of losses on the tomato sector in Cameroon, identify key critical steps and reveals the levels of qualitative and quantitative losses as perceived by experts and other resource-persons in the sector;
- Field surveys for evaluation of losses. In the production area (western region), they were made via field measurements in farms, and semi-structured interviews with groups of stakeholders (producers, processors), completed by field observations. In consumption areas(Douala markets), specific questionnaires were administrated to transporters, wholesalers and retailers.
- Monitoring of tomato shipments from the fields through the rural markets (or assembly markets), to urban consumer markets (wholesale and retail);
- Analysis of data collected in the production areas and markets in order to establish a detailed statement of the causes of food losses, estimate their size and the possibilities of their reduction to the different critical stages of the supply chain;
- Preparation of the study report and validation via a national workshop Based on the findings, interventions are proposed, aiming for a significant reduction in losses over a period of ten years in the tomato supply chain.

The fieldwork was made in 2013 in the following areas: (i) Production area and rural markets (West)and (ii) urban-consumption markets: Douala (Littoral). The choice of supply chains for the field work was done at the end of the preliminary phase, in regard of the following criteria: creation of added value, contribution to income generation, ability to generate non-family labor, importance of the export market (generation currency), and contribution to food security. It is also based on the following criteria: (i) size of the food chain operations; (ii) creating added value for small and medium farms in the supply chain; (iii) nature of the products obtained in the supply chain; (iv)existence of markets in villages, urban areas and opportunities to sell abroad; (5i) sector/ study is included in an ongoing program of support for the sector.
A team including two national experts (an economist and a food technologist) conducted the field study under the supervision of FAO.

2.2 Status and importance of the tomato subsector in Cameroon

With an estimated production of 889,800 tons and annual growth rate of 9.4% in 2012, tomato sector occupy about 329,000 producers in Cameroon. Based on FAO estimates, 150 000 hectares were planted in 2012, with an average yield of 11.3 tons/ha, still well below the value of 20 tons/ha referred. The production is still artisanal, largely carried out by small producers operating in a context of family farming, and organized into cooperatives. Moreover, tomato is grown mostly by men who typically exploit an area of 0.25 hectare each where they practice monoculture. An estimate conducted by MINADER between 2007 and 2008 shows that current consumption of tomato in Cameroon is about 30 kg per capita. Tomato is firstly produced for marketing and it contains a potential of 1,645,200 jobs. The tomato processing is almost non-existent in Cameroon yet. There is a significant demand for derivatives products such as concentrate and sauces, covered by imports. Moreover, this sector also has enormous export potential in the CEMAC sub-region unfortunately; this opportunity is not used because of the high volume of PHL recorded throughout the supply chain, aggravated by poor organization of the sector, the isolation of production areas and the instability of marketing channels.

Table 1 summarizes the essential information on the national tomato production. It shows that this production is greater than consumption of the country that would amount to 605 054 tons, valued at 148.5 billion CFA francs. However, it is only an apparent surplus because if one takes into account all the losses suffered by the product after its harvest, the supply of fresh tomato in Cameroon would be negative. This significant gap is filled in part by imports of tomato paste which constitutes an offer of 6,000 tons for a demandabout 60 390 tons.

Table1 - Information on production and by-products of the tomato sector

Item	Data	Observations
Annual volume of production (tons / year)	889 800	Data for 2012 (FAOSTAT, 2015)
Area (ha)	150 000	Data for 2012 (FAOSTAT, 2015)
Average yield (tons/ ha)	5,9	Production volume/area
Average rate of increase over the last 10 years (%)	9,4	Data for 2012 (FAOSTAT 2015)
Average production cost (FCFA /ton)	221 240 (434 USD/ ton)	Average production costs of tomato growers organizations in the targeted regions.
% Of production consumed	2	Almost all family farmers which cultivate tomato consume a small amount (less than 1 Kg/day), the rest going to the market
% Of production marketed	98	Interview with Experts
Estimate% sold wholesale / retail sold by producers	90 10	Interview with experts; Field confirmation
Output value (FCFA / year)	166 billion (325.5 million USD)	Turnover for 2012 (FAOSTAT 2015)
Number of producers	600 000	The majority of farms in the studied production areas have an area of 0.25 hectares. Number of producers/ 0.25 = area.
Market size of fresh tomatoes (request) (tons / year)	867 000	In 2007, the consumption of fresh tomatoes in Cameroon was 27.5 kg per capita (MINADER, 2009). It is assumed that it evolves with the same trend as production (average annual growth rate: 9.4%); so, it is of 43 kg per capita in 2012.
Market value of fresh tomatoes (FCFA / year)	213 billion (417 million USD)	Average price/kg = 245.5 FCFA ($ 0.48), value calculated from measurements of the market.
Size concentrated tomato market (tons/ year)	60 400	Tomato paste consumption is about 3 kg/person/year in some African countries, including Benin, Nigeria and Niger (LARES and IRAM 2002). The consumption of 3 kg/person/year is extrapolated to that of Cameroon's population has almost the same diet as that of Nigeria.
Market value of concentrated tomato (FCFA/ year)	69 billion (135 million USD)	minimum average price/kg = 1142 FCFA ($ 2.24) calculated from the imported brands on the market

Source: *Results of the study; 1 USD = 510 FCFA*

2.3 Description of studied areas, actors involved and stages along the supply chain

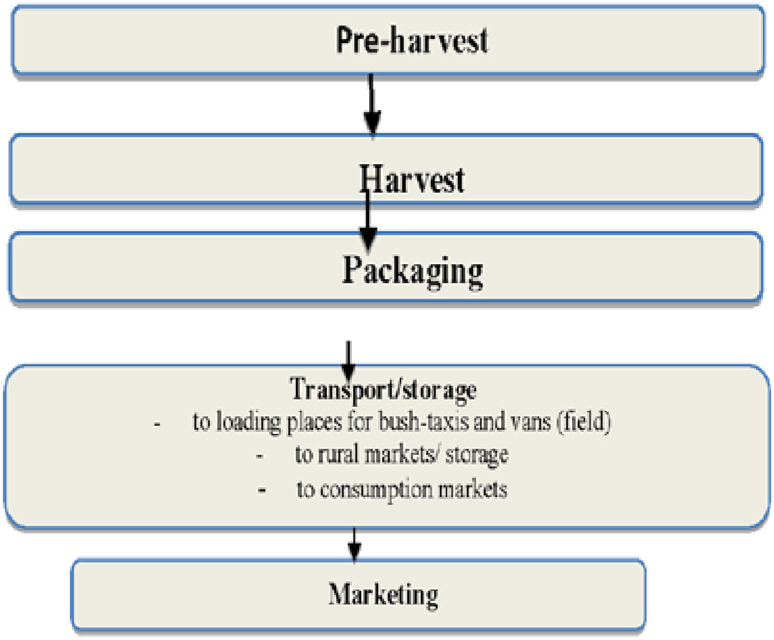
Two fresh tomato supply chains were selected for detailed study on PHL: Mbouda-Bafoussam-Douala and Foumbot-Bafoussam-Douala, with exports opportunities in neighboring countries namely Gabon and Equatorial Guinea. The following criteria were taken into consideration: (i) value added, (ii) contribution to revenue generation of each operator, (iii) ability to generate non-family jobs and ease to organize and track shipments and, (4i) ability to sell in the CEMAC zone.

The selected communities are located within a radius of about 70 km around the towns of Mbouda and Foumbot. The production of fresh tomato is done in two seasons: (i) dry (February-April) and (ii) rainy (August-October), where it reaches its peak. Women are almost absent in this sub-sector. There are carriers, wholesalers and retailers. Rio variety is the most cultivated in Cameroon and is characterized by its resistance to disease, its pear-shaped size of fruit, deep red, with a diameter of 4.9 ± 2 cm and an average weight of about 150g. The production cycle takes around 80 days. Several harvests take place on the same field of tomato (4-6) with one week interval between two successive harvests. The production facilities consist of rudimentary tools. Fresh tomatoes could be left non-cropped days after the maturity of fruit to meet the uncertainties of the market demand and lack of markets information.

Basic constraints such as (i) lack of electricity in rural areas, (ii) poor organization, (iii) limited volume of tomato per farmer, (iv) lack of maintenance, etc., cooling facilities seems not to be appropriate for the moment.

After harvest, the ripe or half-ripe fruit are packed in baskets (crates), made by local craftsmen from raffia bamboo. The full crate is covered by a bunch of grass or banana leaf. With a volume that varies between 20 to 25 liters, the average empty crate weighs 400 g and sold between 250 and 300 FCFA per unit is the most requested format. In the case of fresh tomatoes packed for export the conditioning is done in plastic boxes brought by the customer. Once packed in the field, crates are then transported on the heads, in wheelbarrows or on motorcycles to the nearest rural track where they can be stored by the roadside in full air (for maximum a day), until the arrival of the conveyance. A second storage takes place in the rural markets, in preparation of loading for high consumption areas. The transporters usually travel at night, with an average temperature of 20 to 25°C. Night trip reduces the perishability of the product that keeps certain level of freshness, while facilitating early arrival to consumption markets. Storage or exposure of the product to the sale is to put tomato in the open. Wholesalers and retailers do not have the means to create the ideal conditions for the conservation of fresh tomato for three days or more, in Douala where average temperature varies between 25 and 30 °c.

Figure1 - Flow Diagram of fresh tomato supply chain



2.4 Alleged losses in selected supply chains

With its high water content (about 90%), tomato is a particularly fragile vegetable. Should harvesting, transportation and marketing standards not achieved, they can cause huge PHL. Preliminary analysis revealed that pre-harvesting, transport and retail sales are the critical points where food losses (quantitative and qualitative) are the most significant. Qualitative losses appear at harvest and increase with process steps (transport, marketing). Quantitative loss is mainly expressed during the pre-harvest phase (because of the fruit growing or ripe rotting up especially when they are placed on the floor or fall), or during transport (as a result of mechanical factors such as shocks that cause the crushing of fruit and water loss). Thus in the first stream (Mbouda - Douala market), the level of fresh tomatoes loss was estimated at 27% during the pre-harvest phase, 5.3% at harvest, 8.8% in transport and 1.4% in marketing. The second stream (Foumbot - Douala market), gives an estimate of 31.7% during pre-harvest/harvest stage, 5.9% in transport and 0.65% for marketing.These low values of quantitative losses in marketing could be justified by poor practices observed on retail markets. Indeed, injured, crushed or sometimes even rotten tomatoes, are rarely disgarded; rather they are collected, crushed and re-sold to pig breeder or small restaurants. Hence, qualitative losses (25,85%) are important losses during marketing; and low quality tomatoes are even sold half price.

2.5 Post-Harvest Losses along the supply chain: Results of study

At each stage of the supply chain, detailed description considered the following aspects: location, time of the year, number of players involved, intermediates, quantities produced, location, facilities used, duration/distance, required inputs and services, cost of production and the cost of products at sale. Results of analysis show that losses of fresh tomatoes which are both quantitative (mass or volume reduction), and qualitative (reduced market value, nutritional value and food safety) have various origins: physiological, mechanical, microbiological and pests action. Furthermore, the identified critical points are pre-harvesting, transportation and marketing.

Table 2 - Critical points and levels of PHLalong fresh tomatosupply chains (average)

Supplychainsteps	Qualitative losses (%)	Quantitative losses (%)	
		Losses at critical point (% ingoing quantity)	Losses (% total harvested)
Pre-harvest		28.3	28.3
Transport	5.15	10.85	7.7
Marketing	25.85	-	-
Total	-	-	**36.0%**

Source: *Results of the study*

Qualitative losses are primarily valued as depreciation in the market value of the product at retail. Product quality decreases, it loses its economic value and is sold at a lower price. It will still be consumed. Monitoring of tomato shipments shows that most losses are obtained during transport.

A synthesis matrix of the results of semi-structured interviews, shipments tracking and market research on food has been developed. The main aspects taken into consideration were: (i) cause of losses, (ii) % of loss relative to the initial amount, (3i) affected people, (4i) impact of losses, (5i) loss of market value in FCFA (6i) trends, (7i) time / season (8i) perception of actors and, (9i) solutions suggested by stakeholders. All actors in the tomato supply chain are affected by PHL: producers, distributors, consumers and their families. Causes of losses appearing at all stages, potential solutions should therefore involve all actors in the supply chain. Summary tables allowed us to have an overview of interventions that can be performed at critical points to sustainably reduce the loss of fresh tomato. The economic feasibility, social acceptability, environmental impact and management of the practical implementation of these interventions should be carefully studied beforehand. Their formulation and implementation should be inclusive and involve stakeholders from the public and private sectors.

At each critical stage identified, the following aspects were considered: (i) extent of losses (qualitative and quantitative), (ii) economic loss, (iii) causes of losses, (iv) intervention proposed to reduce these losses, (5i) impact of reducing losses, (6i) intervention costs over 10 years and (7i) risks.

A rapid calculation of economic feasibility (cost-benefit analysis) of loss reduction interventions shows that the total cost of implementation is estimated at USD 10.4 million over 10 years. PHL can thus be reduced gradually to 50% over 10 years (5% per year) with a mid-term review. Quantitative losses in the supply chains amounted to 35%. After ten years, they are expected to be about 17.5%. If we assume that the losses are reduced by 5% a year, therefore the level of economic loss estimated at USD 110 809 000 per year will also be reduced by 5% per year (or USD 5 540 500 per year); yet the annual cost of interventions is only estimated about USD 1 million.

To achieve the objectives of reducing PHL it would be appropriate to develop an intervention program, which will be implemented at the national level through one or more institutional actors. During the implementation and monitoring/evaluation activities, other relevant partners such as Unions of Cooperatives, research organizations, NGOs and actors in the public and private sector should be involved. Hence, in order to reduce PHL in the tomato sector, three main axes should guide the implementation of an operational strategy:
a) Core axe effect: (i) organization of the supply of agricultural inputs through improvement of availability, accessibility and quality; (ii) capacity development in management and marketing, especially for producer organizations, to better manage marketssupply; (iii) facilitating access to rural financing (acquisition of transport and packaging equipment);(iv) implement a national network for tomato actor's chain;
b) Relay axe effect: inclusive Research and Development on packaging practices of fresh products for the improvement and/or substitution of traditional containers;
c) Result axe effect: strengthening of technical capacities of actors (producer organizations and other) on management (including logistics), marketing, hygiene and food safety.

A national strategy for the reduction of post-production losses was adopted in December 2015 by the Cameroonian government with FAO support, but the implementation of activities is still to be launch.

3. Conclusion

The quantitative and qualitative losses are present at all stages of the tomato supply chain with consequences on the income of actors and lower product availability in markets.

The critical stages where losses are most significant are: the pre-harvest, harvest, transport and marketing. The production stage, with at least 2/3 of losses identified on the entire supply chain, is the main critical point that should be a priority in loss reduction strategies. The losses represent approximately 39.5% in quantitative terms including: 28.3% for the pre-harvest stage and 10.9% during transport from the main production areas (Mbouda, Foumbot) to the marketing town (Douala); Qualitative losses are estimated at 31%, of which 5.2% for transport and 25.6% in marketing.

The poor chain organization impacts on transport (low professionalization), fragile packaging, lack of information on the product label, low mastery of conditioning techniques necessary for good conservation, etc. In addition, the poor state of roads prevents the product to arrive on time in the market, with a live effect on transport costs, increasing market prices. The level of losses for delayed shipments is reflected in its low price in the consumption market. Despite these constraints, there is a significant potential for the extension of production in different areas for the cultivation and development of marketing both at national and sub-regional level.

Reducing losses in the harvesting and processing greatly benefit from targeted actions such as: improving access to quality inputs, strengthening of technical and organizational capacities of stakeholders, the use of suitable agricultural and processing facilities, etc. To sustainably reduce product losses at the marketing stage, actions to be taken should have a direct effect on the transport, storage and display on retail. While the use of more robust and suitable packaging would greatly reduce mechanical losses, storage in the appropriate conditions would drastically drop the level of losses caused by the physiological deterioration of the product as a result of its conservation outdoors, under the sun or rain.

Control and reduction of losses throughout the tomato supply chain, and mainly at critical points will increase the income of the actors involved, increase the availability of goods and improve the level of professionalism in the sector. The results of this study recommend the development and implementation of an intervention program for reducing PHL, which would be implemented by the Government, in partnership with the Unions of Cooperatives, local councils, and other key stakeholders in the public and private sectors. At the level of the proposed measures, it will ensure that any implemented action benefits women, in particular actions facilitating access to finance and micro-finance structures will be relevant in this area.

Finally, the establishment of a sustainable system of monitoring/evaluation of PHL, especially in collaboration with relevant technical and financial partners, is important because it will measure, manage and know different performance of targeted value chains, through the levels of PHL performance indicators. It will also contribute to the evaluation of the implementation of PHL reduction solutions by 50% by 2025, target set in the Declaration of Heads of State and Governments of Africa in Malabo in June 2014.

Post harvest food losses: a framework for horticulture sub sector analysis in sub-saharan Africa

M. R. Baha | The University of Dodoma | Dodoma | United Republic of Tanzania
M. Msafiri | The University of Dodoma | Dodoma | United Republic of Tanzania
DOI: 10.1481/icasVII.2016.b15b

ABSTRACT

This paper contributes a framework for analyzing post-harvest food losses in horticultural crops in developing countries settings specifically Sub Saharan Africa. The review is based on estimation horticultural products at various critical stages of post-harvest supply chain. This was driven by the deficiency noted at both quantitative and qualitative studies which based on our understanding have failed to account for estimation of post-harvest losses specifically on horticultural crops.

Thus, this paper suggests a framework that generalize the understanding of horticultural sub – sector post-harvest losses. It also identifies some intervention points along the supply chain which if employed will be vital for reducing losses, improve nutritional aspects and enhancing food availability for domestic as well as for export. Yet, this is important given the recent macro

and sectoral – policies for most developing countries that emphasize on building a strong agriculture sector that is competitive at both domestically and at international level. It is also a means for more researches in the area given very few studies done and documented especially in developing countries so far.

Keywords: Post harvest losses, Horticultural crops, Sub Saharan Africa

PAPER

1. Introduction

Quantitative and qualitative losses of agricultural products are the main concerns in all stages of the post-harvest chain including; harvesting, handling, storage, processing, packaging, transportation and marketing until the crops are delivered to the final consumers all over the world. However, in developed countries losses in post harvest chain are generally small during processing, handling and storage because of availability and affordability of advanced technology, strictness in management of variables that may lead into losses and the high- quality standards set by retailers. (Hodges et al., 2010; Pedreschi et al., 2013). In developing countries post-harvest, losses are higher since most of the countries are characterized by lack or the use of old or poor equipment and lack of skilled managers for assisting in losses reduction in the food sector properly (FAO, 2005; Hodges et al., 2010).

Generally, fruit and vegetable production globally has recently experienced a remarkable increase. Evidence from the literature indicates production to increase at the the rate of 3% output during the previous decade. During 2011, nearly 640 million and more than one (1) billion tons' fruits and vegetables respectively got produced globally (FAOa, 2013). The growth rate noted globally is not unique given that food-in secured and developing countries of sub-Saharan Africa and Southern Asia have also witnessed a substantial increase in growth rate. Evidence from the literature indicates that, fruits and vegetables of developing countries are one of the fastest growing agricultural markets, with production increasing by 3.6% a year for fruits and 5.5% for vegetables over 1980 - 2004 (World Bank, 2008).

Horticulture crops (fruits and vegetables) have a number of economic importance such as creation of employment. On average it is pointed out that, they provide twice the amount of employment per hectare of production compared to cereal crop production (Ali and Abedullah, 2002). Thus, the move from cereal production towards horticulture crops is one of the important contributor to employment opportunities in developing countries (Joshi et al., 2003). They are also vital in improvement of diets by providing micro-nutrients rich diet, thereby impact the health status of the people. Low horticultural food intake as pointed by World Health Organization and cited by FAO (2014), accounts for about sixteen (16) million disability adjusted life and about 1.7 million of death globally.

Despite high production figures and the notable significances of these crops, horticulture post-harvest losses have continued to be a major challenge in developing countries agriculture. Further, the assessment of post – harvest losses of horticultural crops for these countries remain questionable. While some such as Asian Vegetable Research and Development Center (2012) have used the interview to establish their statistics on post-harvest losses, others have even used the historical statistics from other authors to generalize their results (Kasso & Bekele, 2016). Other emerging concern we found interesting was on whether the assessment should be cumulative along the whole horticultural crop value chain or for every stage along the chain. The other challenge rests on whether the assessment of the value chain should group all horticultural crops in an area or deal with a specific crop. These are important concerns that require prompt answers. Lack of quality and necessary data for post-harvest losses assessment in developing countries should also not be underestimated (Bureau of Economics and Business Affairs, US Department of state, 2013).

Thus, this paper contributes a framework for post harvest losses assessment from different literatures, explain the constraints faced by developing countries in developing a consistent methodology and then suggesting a consistent method of assessment of horticulture crops pertaining to our context.

2 Review of Assessment Procedures for Horticulture PHL

Currently, data on postharvest losses have been collected either via experiments, surveys/interviews or via sampling/direct measurements, and entomological storage studies essentially reporting physical and/or economic loss. Occasionally there are evidences provide on qualitative losses (due to damage, disease, pests, appearance changes, etc.).

The results from the studies that we are aware of were not comprehensive as they failed to provide the readers with sufficient information on the methods employed to enable a decision to be made about the reliability of the estimate. Also most studies were limited in scope considering the supply chain of the crops. However, some of the studies have proposed statistical estimations methodology for post harvest losses. Aulakh, and Regmi, (2013) proposed a method (by developing scales of damages in maize cob) in which a complete post harvest loss within a postharvest supply chain is computed by summing up all the food losses for established scales at all stages in the chain using controlled experiment surveys. They identified critical stages of food

supply chain (FSC) i.e. harvesting, storage, processing, packaging and sales and different measurable factors which contribute to these losses such as agro-climatic factors, farm and farmer related factors, credit availability and quality of management related factors. Then to estimate parameters, controlled experimental surveys are done to calculate post harvest losses at each node within a supply chain from harvesting to sales. Finally, a regressions are used establish drivers of losses within the supply chain that will have an impact on loss minimization, different indicators of loss are then often regressed. However, the experience and the literature shows that the method used is limited given that in most cases is confined only in the area under experiment hence difficult to generalize the results.

In 2010, a comprehensive study was done by Indian council of agricultural research "Harvest and Post harvest losses of major crops and livestock produce in India". The study used stratified multistage random sampling procedure to select 25 states in India, 100 districts within selected states and 1500 household farmers in the selected districts for estimating losses in different farm operations and storage. Data were collected through enquiry only. Data collected pertaining to losses during on farm operations (harvesting and other operations prior to storage) included method of operation, equipment's used, quantity handled and quantity lost. Each district selected data were then analyzed separately and the results pooled by assigning appropriate weights at higher levels. For estimating the losses at agro-climatic zone level, weightage was assigned based on the selection of specific crop/ commodity in all the sample districts. Similarly, PHL at the national level were estimated by assigning weightage on the basis of the production of a specific commodity in the agro-climatic zones. The challenge noted in the analysis is that the method used in the analysis is generalized to all crops regardless of the difference in rates of perishability between crops eg. grains versus fruits.

3 Challenges for Developing Countries Post Harvest Losses Assessment for Horticulture Crops

The stream of literature on Post harvest losses assessment studies in developing countries (Humble & Reneby, 2014; Léo et al, 2011) of which Sub – Saharan Africa is inclusive, shows that most of the studies are experimental oriented and therefore do not provide a macro level picture of the problem. Further most of the studies are crop specific and location specific which also limits their generalization. It has also been a problem for the specific nodes within a supply chain that are highly affected. Finally, for producers that are champions of horticultural crop production mostly do not consider changes in texture, color or tests as a loss therefore making them radical to postharvest management.

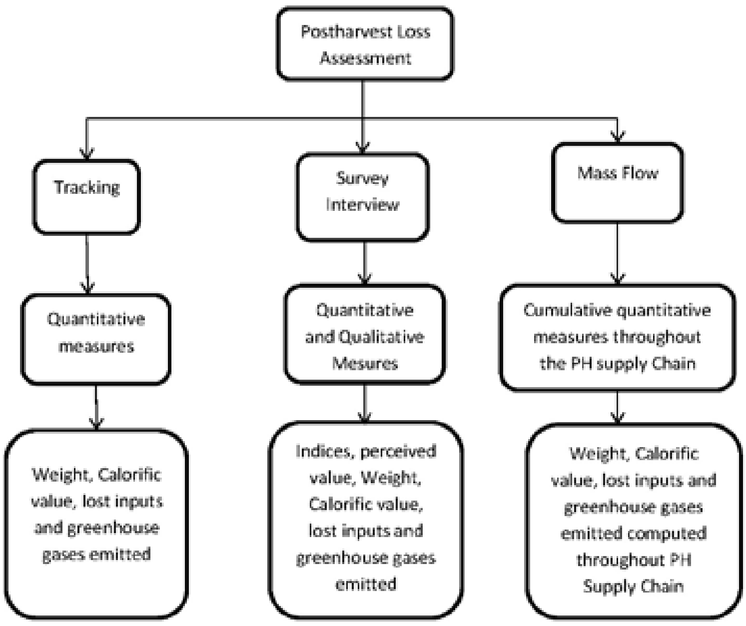
According to FAO (2014), post harvest losses in developing countries are highly pronounced during harvesting, transporting and and storing of horticultural crops creating a challenge throughout the whole supply chain. However, according to Kader, (2003), losses pronounced during processing, packaging, and marketing should not be undermined. Other losses are even a result changes in weather, pests and diseases at production level and physical environment and such as harvesting before time (Aulakh and Regmi, 2013). Losses in developing countries are pointed at texture, color and tastes of the product and it ranges from 15% to 50% (FAO, 2014).

4 Theoretical Approach to post harvest losses assessment

Trienekens (2011) provided a theoretical foundation based on value chain for developing countries such as those of Sub Saharan Africa on postharvest analysis in horticultural crops. The scope of the theoretical foundation provided by Trienekens touches different aspects in the agricultural value chain such as global value chain, supply chain management, new institutional economics and social network theory. In a mean time, this study will not consider all aspects rather it will consider the supply chain management and neglect the aspects. A working supply chain needs to have the value maximized within the chain, costs managed at different stages within the supply chain (Chopra & Meindl, 2010). If this is managed properly the losses will be avoided and output and nutritional aspects improved (Trienekens, 2011). It will also be easy to assess postharvest losses within different nodes within a supply chain which is essentially a major issue in food supply chain.

5 Post harvest Loss Assessment/ Analysis for horticulture crops

Complications in Measuring postharvest losses has been a common phenomenon in both developing and developed countries overtime (Hodges, et al, 2011). Evidences driven from previous studies indicates that commonly used approaches are firstly taking actual measurement for post harvest losses through tracking, secondly the use of questionnaire interview and thirdly the use of flow methods (Aulakh, and Regmi, 2013; Morris and Kamarulzaman, 2014). The developed nations apply approach one and two while developing countries use mostly the second. The third approach is commonly used by Food and Agricultural Organization of United nations based on regional data. The use of all the three approaches has the shortcomings given that it is difficult to practice them under different circumstance. Tracking method is tedious when the study is to be conducted in large area (Kader, 2005). Survey interview is also difficult as it might underestimate or overestimate the results if it is not conducted timely and the flow method is limited especially in developing countries due to data problems throughout the postharvest supply chain (Aulakh, and Regmi, 2013; Morris and Kamarulzaman, 2014). Further, evidence from the literature indicates that most of the studies are confined in a single area therefore generalizing the result is not plausible. The summary of commonly methods for postharvest losses assessment is summarized in the following diagram.



Source: Modified from Morris and Kamarulzaman, (2014).

According to Kader (2005), the context of post harvest losses assessment in fruits and vegetables between developing and developed countries also differs. While the former consider highly the quantitative loss due to food insecurity and nutritional problems noted in these countries the later focuses on qualitative losses due to high income prevailing to majority in these countries (Aulakh, and Regmi, 2013). It then recommends that developing countries assessment should invest on analyzing the quantitative loss. However, due to difference in income between people and between countries in developing countries this argument also remains controversial. Given that there are groups of people with preference on quality horticultural products and the other on quantitative products also resulting from income differences.

The analysis of post harvest losses regardless of the nature of the crops so far have involved post harvest chain level and production level analysis (Kader 2005, Buzby & Hyman 2012). Analyzed losses includes food waste, quantity loss (the amount produced minus the sum of sold and consumed products) and weighted measures, and qualitative losses (money). Commonly statistical methods used in post harvest losses assessment of horticulture crops includes descriptive statistics such means, variance and standard deviations and percentages and some econometric methods such as regressions which are commonly used to determine the drivers of postharvest losses at different nodes depending on the length of integration (Buzby & Hyman 2012; Gao, et al., 2008: Kader, 2005). However, it is important to group crops based on similarities eg. All citrus being grouped together and PHL assessed. For comparisons reasons before other analysis are conducted it vital to compare areas or countries with a common perception of post harvest losses.

6 Results of the Review

After conducting a review to the literature in developing and developed nation on postharvest losses, some few cases are shown that will guide the framework to be proposed by this study.

Table 1 - below provide some few reviewed studies as follows

Sn	Title of the study	Unit of Analysis	Data	Sampling design	Instruments for data collection	Method of analysis	Results
1	PHL and quality deterioration of horticultural crops in Dire Dawa Region, Ethiopia(Kasso & Bekele, 2016)	Farmers Associations, wholesalers, retailers and consumers	Primary	Two stage sampling design	Questionnaire , Key informants and FGDs &Checklist	Purchased/produced and quantity sold in relation to total quantity purchased /produced (Percentage)	PHL ranged from 20% to 50% in between market-ing and consumption
2	An Economic Analysis of Post-Harvest Losses in Vegetables (Onion and Potato) in Karnataka, India(Kumar et al, 2006)	Farmers, wholesalers and retailers)	Primary and Secondary	Multi-stage sampling design has been adopted for the selection of vegetable growing farmers	Time series Data and Questionnaire	Mean averages and percentages	PHL varies at different stages of supply chain in both crops, Onion (2.21 - 59.6) and Potato (1.16 - 56.59)
3	Post Harvest Economic Losses in Peach Production in District Swat, Pakistan (Khan et al, 2008)	Farmers	Primary data	Multi-stage sampling design. Strata of Peach farmers and random	Interview	Frequencies and means	PHL varies based on categories of varieties however the other stages of

7 Application of Postharvest Harvest Losses Framework

From the literature reviewed, it has been noted that postharvest losses differ between horticultural crops (Morris and Kamarulzaman, 2014). There are variations of losses between technology accessing regions and regions with little or lack of technologies such as cold rooms (Beretta et al, 2013). There are also horizontal integration and vertical integration variations of losses within a supply chain of a crop and finally post harvest losses may vary also vary based on market development for example in a situation where low quality goods are restricted from high income people (Trienekens, 2011). Post harvest losses may also vary based on the season of production especially in developing countries which in most cases depends on rain for production activities.

Given that postharvest losses in developing countries are mostly pronounced from the field to the market stages of the supply chain any study that aims at analyzing the losses should consider the following;

...a) Whether the assessment should analyze losses by grouping all horticultural crops in an area in a single basket or deal with a specific crop, we suggest analysis should be independent due to the existing differences in losses and crops agronomic characteristics, however it is rational in the end to have cumulative results obtained by combining similar crop studies results within a country to avoid statistical biases.

...b) In case of limited resources, it is vital to group crops of similar characteristics e.g. citrus and establish the level of losses in group.

...c) There is also a need to include economic losses specifically at the farm level during the analysis of postharvest losses, given that it has the implication on farmers' decision of whether to grow a particular crop next season or not. Economic losses will also assist in qualitative postharvest losses assessment.

...d) In order to determine the drivers of post harvest losses one should consider demographic, agro ecological difference between areas in a country and between regions, market environment, technologies available and the level of income.

8 Conclusion

Regarding the objective set by this paper, we have attempted to re visit body of knowledge on post harvest loss assessment and establish the gap within the aspects of supply chain of horticultural crops in developing countries set up. The review of literature indicates some deficit on the context, quantitative, qualitative, mass flow and economic assessment of post harvest not only in horticultural crops but also to other crops. It is therefore important that, for any study that aims at assessment of postharvest losses in horticultural crops to analyze crop specific loss and where resources are limited to categorize crops with similar characteristics such as fruits or spices and assess the losses in group throughout the chain from the field to the market. In case of countries' comparison, we recommend a comparison that use a similar definition of postharvest losses. Include number of harvest within a season in the analysis given most horticultural crops are not harvested once and involvement of Economic Assessment - Value. For generalizing the results in large geographical area a focus should be in compiling the results from different locations and generalize the results.

Measurement Issues and Lessons Learned from Estimating Food Loss at the Retail and Consumer Levels in the USA

J. C. Buzby | Economic Research Service, U.S. Department of Agriculture | Washington, DC | USA
J. T. Bentley | Economic Research Service, U.S. Department of Agriculture | Washington, DC | USA
DOI: 10.1481/icasVII.2016.b15c

ABSTRACT

In the United States, 31%—or 133 billion pounds—of the 430 billion pounds of the available food supply at the retail and consumer levels in 2010 went uneaten according to the Loss-Adjusted Food Availability (LAFA) data series from the U.S. Department of Agriculture's Economic Research Service (USDA/ERS). The estimated retail value of this food loss was $161.6 billion.ERS has undertaken a series of initiatives to improve the technical and measurement assumptions underlying the LAFA loss estimates, including sponsoring a workshop to inform its data and research planning on food availability and food loss. This paper shares lessons learned from these efforts and provides valuable information for researchers interested in measuring food loss. Key lessons learned include the difficulty of obtaining food loss data from the private sector and measuring the loss of raw commodities embedded in multi-ingredient foods.

Keywords: Food availability, Food Availability Data System (FADS), food waste, Loss-Adjusted Food Availability (LAFA) data series.

PAPER

1 Intoduction

The Economic Research Service (ERS) of the U.S. Department of Agriculture (USDA) maintains the Loss-Adjusted Food Availability (LAFA) data series. The primary purpose of this series is to estimate the per capita daily calories and food pattern equivalents (i.e., "servings") for five major food groups (fruit, vegetables, grains, meat, and dairy) plus added sugars and sweeteners and added fats and oils. These estimates represent the food available for consumption as a proxy for actual intake.

ERS also uses the underlying loss assumptions in the LAFA data series to estimate the amount, value, and calories of food loss at the retail and consumer levels in the United States for around 215 commodities(e.g., beef, eggs, fresh apples, canned corn). Here, food loss represents the amount of food, post-farm-gate that is available for human consumption (i.e., does not include animal feed) but is not eaten for any reason. It includes cooking loss and natural shrinkage (e.g., moisture loss); loss from mold, pests, or inadequate climate control; and food waste. Consumer level loss estimates do not include inedible portions. The denominator for retail level food loss is the amount of food availability at the retail level and the denominator for consumer level food loss is the amount of food availability at the consumer level.

ERS estimates that in the United States, 31%—or 133 billion pounds—of the 430 billion pounds of the available food supply at the retail and consumer levels in 2010 went uneaten (Table 1)(Buzby et al., 2014). The food loss had an estimated retail value of $161.6 billion and equaled 141 trillion calories annually, or 1,249 calories per capita per day. One-third of these losses, or 43 billion pounds, were in grocery stores and other retailers, and two-thirds, or almost 90 billion pounds, occurred in homes, restaurants, and other away-from home eating places. Had losses on-farm and between the farm gate and retail level been included, total food loss nationally would have been greater.

Measuring food loss in the United States has recently gained new importance following the September 16, 2015 announcement of a new Food Waste Reduction Goal by USDA and the U.S. Environmental Protection Agency (EPA), which aims to reduce total food waste in the U.S. by 50% by 2030(USDA, 2015). This paper advances knowledge and understanding of the measurement and technical challenges of estimating food loss with a focus on loss at the retail and consumer levels. In recent years, ERS has undertaken a series of initiatives to improve the technical and measurement assumptions underlying the LAFA loss estimates, and in 2014 sponsored a workshop to inform its data and research planning on food availability and food loss (NRC and IOM, 2015). This paper shares lessons learned from these efforts and provides valuable information for researchers interested in measuring food loss and its food waste subcomponent. The LAFA data series is considered preliminary because ERS has initiatives underway to further refine the data series.

Table 1 - Estimated Food Loss in the United States, 2010

Commodity	Food Supply[a]	Retail Level Losses	Losses	Consumer Level Loss		Total	
	Billion Pounds	*Billion Pounds*	*Percent*	*Billion Pounds*	*Percent*	*Billion Pounds*	*Percent*
Grain products	60.4	7.2	12	11.3	19	18.5	31
Fruit	64.3	6.0	9	12.5	19	18.4	29
Vegetables	83.9	7.0	8	18.2	22	25.2	30
Dairy products	83.0	9.3	11	16.2	20	25.4	31
Meat, poultry, and fish	58.4	2.7	5	12.7	22	15.3	26
Eggs	9.8	0.7	7	2.1	21	2.8	28
Tree nuts and peanuts	3.5	0.2	6	0.3	9	0.5	15
Added sugar and sweeteners	40.8	4.5	11	12.3	30	16.7	41
Added fats and oils	26.0	5.4	21	4.5	17	9.9	38
Total	430.0	43.0	10	89.9	21	132.9	31

2. FOOD AVAILABILITYDATA SYSTEM

The ERS' Food Availability Data System (FADS)is an important and useful resource for assessing the country's ability to provide healthy diets, and for evaluating policy changes and interventions aimed at improving diets (Krebs-Smith in NRC and IOM(2015), p. 61).The core series in the system, the Food Availability (FA) data series is based on supply and use balance sheets, which provide estimates of the supply of around 215 commodities or foods available for consumption in the United States. For a given year and commodity, the supply of that commodity is the sum of production, imports, and beginning stocks (i.e., inventories). From this amount, ERS subtracts out exports, farm and industrial uses, and ending stocks to estimate the amount available for consumption. Per capita estimates for a commodity are calculated by dividing the total annual availability by the U.S. population for that year. The data system relies on annual measures of U.S. agricultural production and stocks at the farm level from the USDA's National Agricultural Statistics Service (NASS) and on estimates of U.S. imports and exports from the U.S. Census Bureau' trade data. The data to estimate farm and industrial (non-food) use, if available, come from a variety of sources depending on the commodity, and include products used on the farm for feed, seed, or industrial uses, such as ethanol or biofuels.

Because the FA data series overstates the amount of food actually eaten by capturing substantial quantities of food lost to human consumption(e.g., spoilage, plate waste) beyond the farm gate in the marketing system, in foodservice outlets and restaurants, and in the home, ERS created the LAFA series, which adjusts the FA data for loss at three levels:

- 1) Primary: Farm gate to retail (e.g., during transport, processing, and wholesaling);
- 2) Retail: Supermarket losses (e.g., dented cans, unpurchased holiday foods, spoilage, and the culling of blemished or misshaped foods);
- 3) Consumer: Losses of food consumed at home and away from home (e.g., in restaurants, fast-food outlets, schools and other institutions). This loss includes cooking loss and uneaten food, such as plate waste from the edible share.[For selected commodities (e.g., produce), the series also removes the non edible share of a food (e.g., apple cores, asparagus stalks) at this stage. Other commodities have inedible portions removed at the primary level (e.g., boneless meat, poultry, and seafood)].

For each LAFA commodity, retail and consumer level food losses are measured by multiplying the per capita quantity of that commodity available for consumption by a loss factor. Per capita loss estimates are multiplied by the U.S. population and summed by food group.

3. LESSONS LEARNED FROM INITIATIVES TO UPDATE ERS'S FOOD LOSS ASSUMPTIONS

ERS's long-run goal is to provide the best estimates of food availability (as a proxy for actual consumption) possible given available resources. A key component of that goal has been to increase the rigor and reliability of the LAFA data series through a series of initiatives to improve the technical and measurement assumptions underlying the LAFA loss estimates. This has been challenging due to resource limitations, the diverse nature of the three types of food loss assumptions in LAFA, and the complexity of the U.S. food system. To date, ERS has completed several initiatives to update the three types of loss assumptions for many of the 200 plus commodities in the LAFA data series. Data from two of the initiatives, which measured losses at the retail and consumer levels, are now used directly in the LAFA data series. Select data from a third initiative, which measured farm-gate to retail losses, are used by ERS commodity analysts in the FADS supply and use balance sheets.

3.1 Losses at the primary level (farm gate to retail)

In 2003, ERS and the University of Minnesota's Food Industry Center (TFIC) compiled revised agricultural conversion factors from the farm gate to the retail level, which described how a farm commodity (e.g., fresh chicken) is transformed into a consumer-ready product (e.g., boneless fresh chicken). Using information from a series of industry interviews, TFIC updated conversion factors for major meats and poultry commodities, and for several fruits and vegetables.In 2007, researchers from Pennsylvania State University and the International Life Sciences Institute (ILSI) built on the TFIC work under a new cooperative agreement with ERS. They reviewed the TFIC estimates, collected data on the remaining commodities not covered by TFIC (e.g., grains, fats, and dairy products), and explored additional areas of concern.

Lessons learned:

- One identified area of concern is how well the FA supply and balance sheets account for the increased amount of some commodities (e.g., chicken) going to pet food use.
- It is very difficult to produce reliable national farm to retail conversion factors or food loss estimates for individual commodities given the size and diversity of the U.S. farm and food processing sector, the wide range of commodities, and diverse growing regions, as well as year-to-year variation in weather (e.g., drought, floods), pest infestation, and farm animal and plant diseases. Some of these may affect the quality of the commodities and hence, ultimately, the post-farm gate shelf life of individual products.
- Even if farmers, processors, and others collected this information, concerns about losing competitive advantage may preclude them from publically releasing the data;
- For some commodities, like baby carrots, production is too concentrated in a small number of firms to report data without disclosing information on individual firms.

3.2 Losses at the retail level

In September 2007, ERS obtained 2005-06 food loss estimate sat the retail level (e.g., from supermarkets) for fresh fruits, vegetables, meat, poultry, and seafood through a competitive grant with the Perishables Group, Inc. (PG). For individual fresh fruits and vegetables, PG compared supplier shipment data with corresponding point-of-sale data (with both types of data aggregated across all stores and retailers in the sample) from stores in supermarket retail chains to identify shrink, which was later used as a proxy for food loss in LAFA. The sample provided estimates for over 600 retail stores from 6 national or regional chains in all 4 U.S. regions (East, South, Central, and West). Supermarket shrink for fresh meat, poultry, and seafood was estimated via interviews with a small sample of retail executives due to a lack of reliable supplier shipment data for these foods. The updated loss estimates were incorporated into LAFA in February 2009 and are documented in Buzby et al.(2009).PG did not have appropriate data to update the retail-level loss assumptions for other LAFA commodities, including added fats and oils, added sugars and sweeteners, dairy products, grain products, and processed fruits and vegetables (e.g., canned, frozen, dried/dehydrated, and juice).

More recently, ERS repeated the study for the same commodities with PG, now known as the Nielsen Perishables Group (NPG), and obtained 2011 and 2012 shrink estimates for the same individual fresh foods(Buzby et al., 2015, Buzby et al., Forthcoming). This study had greater coverage: roughly 2,900 stores from 5 retail chains (one large national and four regional supermarket retailers). These stores were located in 45 states plus the District of Columbia (DC). The same method was used for individual fresh fruits and vegetables (i.e., supplier shipment data was compared with point-of-sale data to estimate shrink). Unlike the previous study, shrink was estimated directly for fresh meat, poultry, and seafood, but only for case-ready, Universal Product Code (UPC)-coded items. Data were not available for random-weight items.For perspective, a National Meat Case Study found that the estimated share of case ready, UPC-coded fresh meat and poultry was 66% of the market in 2010 (SealedAir/BCP/NPB, 2010).

Lessons learned:

- Supermarket shrink for fresh meat, poultry, and seafood is difficult to estimate due to a lack of reliable supplier shipment data. In the United States, a significant share of fresh meat is delivered to grocery stores in carcass portions, which are later butchered in-store into retail-size cuts and sold as random weight;
- Using UPC-coded data alone to estimate shrink for fresh meat, poultry, and seafood is not appropriate due to a lack of data on random weight items, which account for a significant share of total product sales;
- Comparing shipment to point-of-sale data to estimate shrink is not appropriate for many FADS commodities (e.g. flour) that are primarily consumed as multi-ingredient foods (e.g. bread, cookies). As most foods that people eat are mixtures (Moshfegh in NRC and IOM(2015), p. 83), a method that starts with foods as eaten and works backwards (i.e., fork to farm) would require the use of recipes to break down these foods into commodity ingredients to estimate food loss;
- Further retail-level research is needed to:

- estimate shrink for the other commodities in LAFA;
- determine the extent to which shrink captures an unknown amount of theft, accounting errors, and other factors;
- determine if shrink is dependent on the assortment offered for sale, including the variety of products of a particular commodity at different value levels (e.g., lower-, average-, and higher-priced bagged spinach or salad greens) (Buzby et al., 2015)(p. 644); and
- determine if shrink varies by store type (e.g., megastores, convenience stores, supermarkets).

3.3 Losses at the consumer level

Under a grant with ERS, RTI International (henceforth RTI) generated new consumer-level loss factors for the majority of the LAFA commodities (Muth et al., 2011).First, RTI reviewed existing studies on consumer-level food loss and interviewed a small sample of restaurant managers(Muth et al., 2007). Next, they calculated household food loss by comparing household food purchase data (Nielsen Homescan data) with at home dietary intake data from the National Health and Nutrition Examination Survey (NHANES). ERS then analyzed the impact of the proposed RTI loss factors on the LAFA data series(Muth et al., 2011). In August 2012, ERS incorporated most of RTI's „best estimates" of consumer-level food loss (where available) in the LAFA data series.

Lessons Learned:

- Comparing food purchase with intake data is challenging for LAFA commodities typically consumed as multi-ingredient foods (e.g., wheat and rye flour consumed as breads, cookies, rolls, and pasta).
- Sample sizes were too small for some commodities (e.g., rye flour, corn starch, and select fruit juices) to calculate accurate loss factors.
- Methods are needed to estimate food loss for individual foods consumed away from home (i.e., in restaurants, fast-food outlets, and schools).Currently, the LAFA data do not distinguish food loss (or food availability) at home versus away from home. Some food loss is likely greater in away from home settings (e.g., plate waste in restaurants due to larger portion sizes)(Muth et al., 2011).
- Nationally representative data are not available to analyze consumer-level food loss patterns by demographic or regional groups (e.g., level of education; rural vs. urban; age).

4. OTHER MEASUREMENT ISSUES AND CHALLENGES

In 2013, ERS contracted with the National Research Council (NRC) and the Institute of Medicine (IOM) of the National Academies to organize a workshop to advance knowledge and understanding of the technical and measurement issues of the Food Availability data series, the LAFA data series, and the LAFA food loss factors so that the data can be maintained and improved (NRC and IOM, 2015). As a result, a day-and-a-half workshop was held April 8-9, 2014 in Washington DC. Some of the measurement issues and challenges discussed include:

- **FADS relies on continuous, high-quality national, annual data at different points of the farm gate to fork chain**. Most time-series data rely on a steady stream of high-quality, national, and annual data. However, researchers cannot always anticipate, or control, data shortfalls. For example, in 2011, the Census Bureau discontinued select Current Industrial Reports (CIR), which provided FADS data for added fats and oils (except butter), durum flour, and candy and other confectionery products. Therefore, 2010 is the last year that FADS data are available for these commodities. Subsequently, NASS developed the Current Agricultural Industrial Reports (CAIR) data series to collect data on specific manufactured products in key agricultural industries. ERS plans to incorporate the CAIR estimates in FADS.
- **Food loss factors are not refined enough to vary over time (in most cases)**. In LAFA, the food loss factors for individual foods and levels are the same for the entire data series range (i.e., 1970 to the most recent year), with few exceptions. For example, one exception is that beef conversion factors have changed over time to reflect greater trimming of fat when transforming meat from carcass to boneless weight.
- **Food donations are not directly measured**. FADS doesn"t adequately reflect food donations (e.g., at the retail level to food banks and other charitable organizations) or the transfers of unsold food in retail stores to thrift shops for sale at lower prices. Donated food ultimately eaten by people should not be counted as food loss.
- **FADS import and export data do not reflect the growth of multi-ingredient foods**. An increasing share of U.S. food trade is in the form of multi-ingredient or processed foods (e.g., vegetable beef soup). However, trade data in the FADS is mainly commodity-based (e.g., beef). This is an increasingly important issue to address. The Food and Agriculture Organization (FAO) is also confronted with this problem in

their food balance sheet system, which has data for around 185 countries or territories for more than 80 primary commodities plus 10 commodity groups, though not all commodities are produced or consumed in every country (Schmidhuber in NRC and IOM(2015), pgs. 68, 71). Methods need to be developed to account for the commodity portion of multi-ingredient foods in trade data.

- **Various definitions complicate comparisons of studies worldwide and the estimation of new loss factors**. Definitions of food loss and waste differ widely across studies worldwide, complicating the comparison of estimates and the identification of trends across the supply chain, U.S. localities, and internationally(Buzby & Hyman, 2012). Not only are there different definitions of the measured variable (e.g., shrink, food loss, and food waste) but studies may also use different points of reference and different areas of coverage in the analyses (Buzby et al., 2015).

5. CONCLUSION

To date, ERS has updated and explored food loss estimates with an ad hoc approach for various commodities and marketing levels (i.e., primary, retail, and consumer), rather than updating the data simultaneously. The underlying estimates are derived from several sources (e.g., NASS, Census, and the aforementioned food loss initiatives). Currently, probability distributions or other measures of variation are not reported. ERS plans to obtain such measures in future food loss research initiatives. For example, in April 2016, ERS contracted with RTI to update food loss factors for the consumer level.

Moving forward, ERS will have many decisions to make about whether and how to integrate any new loss factors into the LAFA data series (e.g., whether to adopt them for the entire time span of 1970 to the most recent year available). Currently, the FADS data are a valuable resource for assessing the country's ability to provide healthy diets to the population, and for evaluating policy changes and interventions meant to improve nutrition and health. Improved accuracy and precision of the food loss assumptions underlying the LAFA data will improve the data's usefulness to researchers and policymakers. Once further improvements are made, the LAFA data series can be used as an important foundation for analyzing the national „food loss foodprint," such as the amounts of CO_2, water, and energy equivalents embedded in the food lost to human consumption in the United States in a given year. To date, Venkat(2012) has used the LAFA data to analyze the climate change and economic impacts of food waste in the United States. However, other measures of the societal burden of food loss could help target private and public sector actions to address food loss.

Developing cost-effective statistical methods for measuring post-harvest losses in developing countries

M. Kebe | FAO, ESSD | New York | USA
DOI: 10.1481/icasVII.2016.b15d

ABSTRACT

In line with the current policy debate on agriculture and rural development, the improvement of methods for estimating post-harvest losses was identified by FAO member countries as a priority research topic to be included in the Research Programme of the FAO Global Strategy to Improve Agriculture and Rural Statistics (GS). The objective of this research is to develop cost-effective statistical methods for measuring post-harvest losses.

Keywords: post-harvest losses, statistical methods, cost-effective.

PAPER

1. Introduction and background

Historically, loss assessment studies have been associated with loss reduction/prevention programmes. The Seventh Session of the United Nations General Assembly, meeting in 1975, set the goal of 50% reduction of post-harvest losses by 1985.

In 1976, FAO formulated a Special Action Programme that identified three major constraints on post-harvest loss prevention in the developing countries. They were as follow:

1. lack of information about the amplitude of the losses, the nature of the losses, their causes and the most effective techniques for reducing or preventing them;
2. lack of infrastructure for implementing loss prevention measures;
3. lack of investment in food loss prevention.

These events highlighted the need to develop standard and suitable terminology and methodology for the measurement of losses.

The manual "Postharvest grain loss assessment methods. A manual of methods for the evaluation of postharvest losses" was then developed by Kenton L. Harris and Carl J. Lindblad published in 1978.

Some methods and techniques compiled by Harris and Lindblad (quite accurate and detailed) were first reviewed by R. A. Boxall in the period 1980-1986, in an attempt to simplify them.

During that same period, FAO also published a manual "assessment and collection of data on post-harvest food-grain losses", manual intended to serve as a guide to the statistical methodology for assessing and collecting data on post-harvest food-grain losses, using objective measurements coupled with statistical survey sampling techniques.

During the period 1990-2000 researchers improved on the previous methods and kept on more and more using the rapid methods (visual scales, standard chart for instance, described above). J.A.F. Compton and J. Sherington, for instance, devised rapid assessment methods for stored maize cobs where weight losses were due to insect pests. From 2000 onward, additional methodological improvements have been brought about by the APHLIS team project and other researchers by making the rapid methods work with more modern sampling-based field surveys to provide the data necessary for loss estimations.

Most of the time, loss prevention and reduction efforts are undertaken within only part of the post-harvest system. Basically this is done by identifying the most obvious and serious grain loss points in a country's post-harvest food system and concentrate the loss prevention and reduction efforts on those points. Methodologies for measuring post-harvest losses, aim at providing outcomes that allow the determination of priorities for loss prevention and reduction efforts.

Assessments may be made by surveys (traditional or improved), or by experimental design studies (field studies, trials), and more recently by using econometric modelling (special cases of machine learning algorithms).

Because of the need to obtain reliable estimates of loss, FAO and other organizations conducted literature reviews in the seventies to map the extent of available quantitative information on post-harvest losses in cereals. A number of examples of very high estimates of unsubstantiated losses were found, most of it due to the ambiguity of the terminology used by their authors. Quoted figures of the type "39% for grain losses in Sub-Saharan Africa, or 45% for pearl millet losses in Namibia" may not provide an objective view of the real situation. In certain situations, figures provided for certain stages of a stated post-harvest chain have simply been totalled, leading to over-estimates. Boxall, in 1986 gave an illustration along the following example:

Table 1 - How post-harvest losses may be over-estimated (Boxall, 1986)

Chain level	% loss	Weight loss (kg)	Balance (kg)
Start	----	----	1,000.00
Harvesting	15	150.00	850.00
Threshing	10	85.00	765.00
Drying	5	38.25	726.75
Transport	5	36.34	690.41
Storage	10	69.04	621.37
Processing	10	62.14	559.23
	-----	--------	
	55%	440.77	

If it is wrongly assumed that each loss figure is a percentage of the initial weight of product, over-estimation will ensure. In fact, here, each loss figure is a percentage of the amount remaining in the preceding level of the chain. Hence, the total loss 55%, a simple addition of the losses at different levels, is an obvious over-estimate. The proper loss is shown on the weights in the right-most two columns, namely 440.77 kg loss from the potential 1,000 kg or 44.077%.

Over-estimation can also happen during farm level storage loss studies, when grains are being withdrawn at certain intervals during the storage period. In that case it is not enough to record only one loss figure at one point in time during the season and use it as an indication of the overall loss for the year.

2. Types of loss assessment studies

General baseline surveys

These are for preliminary examination of specific problem points and are conducted first to expose the most serious grain loss points. They may or may not be randomized, and may include elements of purposive sampling. Properly conducted, they allow the post-harvest system to be better understood, and the causes of losses to be revealed. At the same time they are conducted, additional relevant available data from other sources like administrative records (rainfall, temperature, etc.) should be collected. These surveys always preceding the main loss assessment survey, should also try to provide initial rough expected values for losses.

Probability sample surveys

They are used for the main loss assessment exercise, with the aim is to obtain statistically reliable quantitative data at different administrative and agro-ecological units (village, regional, national, etc.). Procedures like random sampling (simple, stratified, clustered) with possibly sampling stages, are used. In cases where the primary sampling units differ widely in size, sampling with probability proportional to size can be used. These operations are of course quite expensive and require specially trained personnel. Probability sample surveys (both traditional and modern) are best suited for value chain processes like harvesting, threshing, drying, and processing. They tend to be less suitable for estimating losses during the storage stages of the value chain, where processes of biological degradation occur.

Experimental designs – Field trials

These are also used for loss assessment studies; moreover they can handle loss comparisons between traditional and improved practices. Storage simulation trials can be conducted at research stations with a high degree of control over the conditions of the experiment; alternative post-harvest production practices can be evaluated for their effect on the level of losses, and multivariate analysis is performed using regression models.

Appiah F, Guisse R, and Dartey P.K.A 2009/2010, have used this technique in a study of post-harvest losses of rice from harvesting to milling in Ghana (Ejisu Juabeng District) to provide basic important information regarding the losses.

Multivariate Linear Regression Fitting

Strictly speaking, this is more of an estimation technique than a type of study; data are collected from surveys and administrative records to create a database that is then used to estimate model parameters. At different stages of the food loss value chain, some of the factors causing quantitative and qualitative losses are inter-related. For example at the storage stage, variables like storage structure, moisture content, temperature, relative humidity, insects, mites, rodents, micro-organisms attacks, respiration, and other biological processes (independent variables), all act together at the same place to impact loss variables (dependent variables). Hence, regression equations can easily be fitted to quantify the relationships between dependent and independent variables. The big advantage of doing this is the ability to predict losses in advance so that planners and decision makers can take appropriate measures as early as possible in their decision cycles.

Some of these techniques have been used with some success in studying the factors affecting post-harvest losses in rice and wheat at farm level in India. See H. Basavaraja, S.B. Mahajanashetti and Naveen C. Udagatti. 2007. AbdollahTaherzadeh, Seyed Saeid Hojjat. 2013 also used a regression model in Iran for the study of Post-Harvest Losses of Wheat in North Western Iran, combining post-harvest loss survey data and administrative records data.

3. General Principles of loss assessment studies

In the literature, measurement techniques and methodologies are most often presented at each of the main stages of the food loss chain. For food grain losses to be assessed at any of those stages, statisticians have developed a number of techniques, based on the following principles:

1. definition of the population for which loss estimates are to be produced;
2. construction of a proper sampling frame;
3. design of proper sampling procedure and measurement technique;
4. design of the field work organization, data collection tools, data processing and analysis tools;
5. production and publication of standard errors of the estimated variables to evaluate the quality of the information thus obtained;
6. breakdown the loss estimation at various stages into at least three levels: (a) losses at farm level; (b) losses at the level of the intermediaries (grain merchants, etc.); (c) losses at the level of government agencies (warehouses, etc).

Once the sampling issues have been sorted, the data collection techniques as briefly described below are then implemented, and appropriate estimation procedures devised to obtain average loss figures for the desired level (region, national, etc.).

As a general observation, during harvesting, in-field drying, stacking, transport, threshing, drying and cleaning, all losses caused by biological agents, should be adjusted to a dry-weight basis. Other losses are usually expressed in terms of weight of material at 14-percent moisture content (Boxall R.A. 1986). It has been found (Boxall R.A. 1986), that it was more convenient to work on the basis of the dry weight of grain which can then be simply calculated from the formula:

$$Dry\ wt.of\ grain = wt.of\ grain * \frac{(100 - m.c.of\ grain)}{100}$$

$m.c.$ is moisture content

To also be able to compare with other-loss assessment figures, losses can be expressed as percentages (rather than adjusted weights) with a clear statement of the basis of the presentation (the denominator of the percentage). Losses in harvesting, in-field drying, and stacking operations, are expressed as percentage of yield, with yield defined as obtained yield (maximum quantity of clean grain less the losses being assessed. For threshing and cleaning, losses are expressed as a percentage of the grain input to the operation. It should also be noted that farmers' practices in time of harvesting (and rainfall), duration of in-field drying, and stacking, have a marked effect on the level of losses.

4. Data collection and measurement in loss assessment studies

Building a suitable sampling frame is normally the very first stage when planning a main loss assessment survey. First and ultimate sampling units will vary depending on the level/stage of the post harvest process where losses are being measured. Lists of all these units should be prepared to allow proper selection of sampling units.

At the *harvesting level* of the chain, villages (or their groupings) are commonly the primary sampling units (PSU); holders are the secondary sampling units (SSU), and fields the ultimate (tertiary) sampling units.

PSUs may be clustered prior to sampling. Simple or stratified random sampling may be used to select the holders; for each chosen holder, a simple random sample of subplots within fields can then be selected.

For *threshing, cleaning, drying, transportation, and processing*, villages are PSUs and holders the secondary units.

For these levels, additional sampling stages will be necessary; for instance selecting a random sample of produce (maize cobs, etc.) to be threshed and observed for lost or damaged grain.

For *storage*, villages are PSUs, holders are the SSUs, and the storage units (if there are more than one) within the holding are the ultimate sampling units.

The villages (PSUs) may be selected via simple random sampling, stratified random sampling, or may be sampled with probability proportional to size. FAO has produced a number of useful guidelines and manuals on these procedures, to be consulted by the interested readers.

Grain losses at farm level

Losses during harvesting

Strictly speaking, these are post-production rather than post-harvest losses. In fact, they were not considered by Harris and Lindblad in 1978.

Ideally, this stage of the value chain should benefit from a linkage with an annual production survey that has a crop-cutting component. The crop cutting plot is selected at random within the field before harvesting by the holder. The crop inside a crop-cutting plot (usually 10 meters x 5 meters, or 5 meters x meters depending on the type of crop) is harvested according to the usual farmer practices and the yield is weighted and recorded. After the harvested produce is removed from the plot, all grains shed or missed are then carefully picked up for estimating harvest loss.

If a stratified two-stage random sampling design has been used with village as PSU and holder as SSU, *estimates of production and loss* per hectare can be produced as follows (assessment and collection of data on post-harvest food grain losses, FAO Rome 1980):

p_{ij} is production per hectare for holder j in village i

a_{ij} is the area under the crop for holder j in village i

A_i is the area under the crop for village i

l_{ij} is loss per hectare for holder j in village i

m is the number of sampled holders

n is the number of sampled villages for the given stratum

$$\mathrm{P_i} = \frac{\sum_{j=1}^{j=m} a_{ij} p_{ij}}{\sum_{j=1}^{j=m} a_{ij}}$$ is the estimate of production for village i

$$\mathrm{P} = \frac{\sum_{i=1}^{i=n} A_i P_i}{\sum_{i=1}^{i=n} A_i}$$ is the estimate of production per hectare for the given stratum

$$\mathrm{L_i} = \frac{\sum_{j=1}^{j=m} a_{ij} l_{ij}}{\sum_{j=1}^{j=m} a_{ij}}$$ is the estimate of loss for village i

$$\mathrm{L} = \frac{\sum_{i=1}^{i=n} A_i L_i}{\sum_{i=1}^{i=n} A_i}$$ is the estimate of loss per hectare for the given stratum

Hence the percentage loss in this harvesting stage is given by

$$\mathrm{PCL} = \frac{\mathrm{L}}{\mathrm{P}}$$

Estimates of variances for P and L can easily be derived as well as for their ratio PCL.

Tremendous difficulties are associated with the usage of crop-cutting techniques to assess yields in normal annual agriculture production surveys as conducted in developing countries. Therefore the use of these techniques for loss assessment should be carefully evaluated for the situation at hand. In fact, there is still no best single ideal method for crop-cutting.

Losses during stacking/stooking

In the literature, it has been suggested to measure these losses when the operation is being carried out normally by ensuring the stacks or stooks are built on a plastic sheet or tarpaulin to collect all scattered grains when the bundles are later removed. This approach might be a problem if the labourers perceive the situation as a not 'normal' situation and hence try to handle the bundles (carefully or roughly) differently from the usual situation.

Sometimes, loss of quality may occur for newly harvested grain stacked for threshing during a wet season. Grain may become mould or discoloured, when exposed to humidity for relatively long period. In case of severe deterioration of grain leading to grain rejection as unfit for human consumption, then reduction of quality may be expressed on a quantitative basis. In case the grain is not rejected, some sort of estimate of the reduction in quality can be provided by contrasting the condition of a carefully processed sample of grain from a stack/stook at threshing time with that of a sample drawn at time of stacking/stooking.

If grain remains stacked or stooked for many months, this can be regarded as a means of storage during which losses to rodents, birds, insects and microorganisms may occur. Hence, the standard techniques for estimating losses due to insects during storage can still be applied, though it might be difficult to estimate losses due to birds and rodents. Using the standard technique, grain samples are collected at stacking time and also before threshing; they are then carefully threshed and analysed for insect loss. There was no substantial account in the literature of such technique being used.

Losses during threshing/shelling

Data on grain loss at this stage of the chain will be collected from a sample of produce from the sampled holders.

Losses during threshing may occur following (i) incomplete threshing (grain remains on the straw) or (ii) damage through the grain or (iii) spillage and scattering during the process.

In case of incomplete threshing, random samples of bundles of harvested crops are threshed by farmers' methods, and the grain obtained weighed and recorded. After that the remaining straw is carefully examined for grain which has escaped the threshing process. Hand-winnowing is done next to bring the two samples to the same quality level. Moisture content measurement is conducted for both samples and weights converted to standard moisture content.

Assessing grain damage during threshing is similar to with any other processing stage. Basically, all processing steps leading to the final products are standardized; then grains are threshed by the farmers' methods and by an optimal method which provides the optimal yield of the undamaged grain.

For losses due to scattering and spillage, there is little guidance in the literature on ways to assess these losses. Some researchers suggested using a large sheet to be spread on the threshing floor to capture all possible scattered grains. This however might be difficult to achieve in practice especially is the area to cover is quite big (grains can be scattered several meters from the point of threshing.

In the case of maize shelling, losses may be due to grains remaining on the cob or damage caused to the grain by the shelling method. The technique for assessing the loss of maize on the cob is similar to assessing threshing losses as shown above. Usually the loss is expressed as a percentage of the total weight of grain; some researchers however, have elected to express it as a percentage of the weight of shelled grain.

There might be an interest in examining grain damage caused by the shelling process, possibly to provide an indication of the efficiency of the shelling instead of an estimate of food loss. In that case shelled grain are grouped as a representative sample of a minimum of 200 grains and examined for damage in order to express the number of damaged grains as a percentage. Then a second sample of cobs is hand-striped and a sample of 200 grains observed as previously to constitute a check of shelling damage.

Estimates of average losses for the given stratum can be computed as follows (assessment and collection of data on post-harvest food grain losses, FAO Rome 1980):

P_i is the estimated grain production for village i

p_{ij} is grain production for holder j in village i

x_{ij} is the percentage loss of any kind for holder j in village i

m is the number of sampled holders

n is the number of sampled villages for the given stratum?

$$X_i = \frac{\sum_{j=1}^{j=m} p_{ij} x_{ij}}{\sum_{j=1}^{j=m} p_{ij}}$$ is the estimate of percentage loss of grain for village i

$$X = \frac{\sum_{i=1}^{i=n} P_i X_i}{\sum_{i=1}^{i=n} P_i}$$ is the estimate of percentage loss of grain for the given stratum

Variances and hence standard errors can also be worked for X.

Losses during cleaning/winnowing

Losses occur because part of the edible grain passes into the chaff. For the estimation, a sample of grain in a single batch is taken and the quantity of chaff and grain obtained in the operation are recorded.

Lost grain isolated from a sample of chaff has to be grossed up to give the total quantity. Percentage is calculated on the basis of grain obtained by normal cleaning. In the case where two or more samples were taken, they will be averaged to get the percentage loss in the winnowing process. Stratum and regional levels of percentages are then computed from holder percentage level using the same technique as in threshing/shelling stage

Losses during drying

To estimate losses at this stage, it is required to know the quantity of grain initially spread out for drying, along with its moisture content (reduction in weight resulting from loss of moisture is not counted as loss), and also the quantity of dried grain collected (with its moisture content) by the farmer after drying. Methods for determining moisture content are many and therefore care should be exercised to ensure methods are uniform in any given region.

For estimating losses at this stage, a stratified two-stage random sampling design is assumed. The difference between initial quantity of grain spread out for drying, and the quantity of grain collected after drying is divided by the initial quantity of grain spread out to obtain the percentage loss. For getting the obtained percentage at stratum and regional levels, the formulae used for the threshing/shelling stage apply.

Losses during storage

Storage losses are investigated at different levels of farmer, trade, and government distribution agency. Hence, the losses will be estimated differently. Again, in countries where crop-cutting surveys are being conducted annually, a sample of farmers can easily be obtained from the annual production survey; otherwise, multistage stratified sampling of farmers can be used, as already described. Loss data may be collected at different frequent intervals, depending on the prevailing period and mode of storage.

Loss in weight during storage (due to insects and moulds, rodents, and birds at farm and village level) must always be related to the quantity in store at the time of assessment. A number of methods have been devised for assessing losses during storage; most original methods are found in the manual of methods compiled by Kenton L. Harris and Carl J. Lindblad; these methods were then reviewed by Boxall et al. in the eighties and later on also by Compton A. J. and other researchers (in the nineties) to make them more "rapid"(hence also less reliable); for the purpose of illustration, the original methods (compiled by Kenton L. Harris and Carl J. Lindblad) are quickly reviewed here. The reference section of this report contains the essentials of the other methods; in addition, new methods are also being devised by researchers in other countries around the world.

As reported in the manual of Harris and Lindblad, J.M. Adams and G.G.M. Schulten (1978), suggested three methods of determining losses in grains due to insects, and microorganisms.

Losses due to insects

Determination of the weight of a measured volume of grain: in this **Standard Volume/Weight method (SVM)**, also known as **Volumetric/Bulk density**, dry weight of a standard volume of grain is measured by a standard method at the beginning of the storage period and is compared with the dry weight of the same volume of grain after a certain storage period (depending on farmers practices in the study region - 6 to 9 months – in some African countries). The dry weight of a standard volume of grain depends on moisture content and variety. This is probably the most reliable method of loss determination. A variation of the technique exists when baseline samples cannot be obtained (Boxall R.A.1986). The modified standard volume/weight method uses an artificial baseline prepared by selecting undamaged samples from the grain present in the store at the time of loss determination. The loss is then the difference in weight (expressed as a percentage) between the undamaged and the damaged sample. Moisture content being approximately the same, there is no need for conversion for moisture.

The Count and Weight or Gravimetric method: The count and weight method provides an estimate of loss where a baseline cannot be determined at the beginning of the storage period and requires only minimal equipment. The method, which is applied to a single sample, requires the computation of (a) the proportion by weight of grains damaged by insects, and

(b) the percentage of damaged grains. Damaged and undamaged grains in a sample of 100-1000 grains are counted and weighted. The weight of the sample is compared with the weight it would have registered in the absence of damage. The base equation (FAO. 1985 "Prevention of post-harvest food losses") reads as follows:

$$\% \; weight \; loss = \frac{[UaN - (U + D)] * 100}{UaN}$$

With U = weight of undamaged fraction in sample
N = total number of grains in sample
Ua = average weight of one undamaged kernel
D = weight of damaged fraction in sample

With this formula, the percentage weight loss has to be adjusted to 14-percent mcwb, or moisture content should be stated. Percentage weight loss can also be computed using a formula that does not require the value of the mean weight of undamaged grain. This method has some sources of error, which may give negative weight-loss figures at low infestation levels. Other variations of the formula have been reported as follows: (Harris & Lindblad)

$$\% \text{ weight loss} = \frac{(UNd) - (DNu)}{U(Nd + Nu)} * 100$$

Where U = weight of undamaged grain,
Nu = number of undamaged grains,
D = weight of damaged grains,
Nd = number of damaged grains.

This formula does not require knowing the value of the mean weight of undamaged grain.

There is a variation of this traditional count and weigh method, in case maize grain kernels are destroyed or lost, as opposed to damaged by pests. In those cases, the traditional count and weigh method, grossly underestimates the losses. The modified count and weigh method was proposed by J.A.F. Compton in 1998 for assessing losses due to insect pests in stored maize cobs. In essence, the method is applied by counting the destroyed grains in each cob and applying an adjusted calculation through an 8-step process. After performing the 8 steps, the formula as given by Compton is as follows:

$$\text{Percentage weight loss} = 100 \times \frac{TND(W_d + W_u)W_u + FW(N_d W_u - N_u W_d)}{TND(W_d + W_u)W_u + FW(N_d + N_u)W_u}$$

Where TND = total number of destroyed and missing grains,
FW = the final weight after the 8-step process,
Nd = number damaged grains in subsample,
Wd = weight damaged grains in subsample,
Wu = weight undamaged grains in subsample.

This method is an improvement on the traditional one when maize grain kernels are destroyed or lost during storage.

The Converted Percentage Damage Method relies on the determination of the percentage insect-damaged grain in a sample and its conversion to a weight loss using a predetermined factor; it is a method suitable only for insect damage that provides a useful estimate for quick appraisal of losses. Although the method is liable to the same sources of error as the modified standard volume/weight method and the count and weighs method, it has apparently given good results in practice. Hence, it is recommended to use it rather than guessing when these two earlier mentioned methods cannot be used. Boxall R.A. suggests that once the relationship between percentage damage has been established by laboratory experiment, a conversion factor could be calculated and subsequently used to determine the weight losses in other samples of the same type of grain. Adams and Schulten (1978) recommended that the percentage damage/weight loss relationship be established from the count and weight method. This obviously, is the reason why this method is subject to the same sources of errors as the count and weight method. The conversion factor is calculated from the formula by using the figures from the count and weigh technique:

Most of these techniques that were compiled by Harris and Lindblad involved collecting grain samples from the farmers and sending them to distant laboratories for further analysis and returning them afterwards; this back and forth movement of grain samples created of lot of delays for getting the results of the surveys. Hence the attempt by J.A.F. Compton and other researchers to devise rapid and improved methods, avoiding sending sampling grains to the lab. Instead, they devised visual scales (maize cobs) and standard charts (maize grains) to be used directly in the field during enumeration. Using visual impression, the enumerator is able to match the farmers' sample cobs with various classes of infested cob portrayed in the pictures handed over to them. The percentage weight loss assigned to the picture with corresponding appearance can later be entered as the weight loss for the cob. The enumerator can then sum up the number of cobs assigned to each class; the percentage weight loss for the maize stored in cob form is determined by using the following formula (J.A.F. Compton, A. Sherington 1998).

$$Vissloss = \frac{aN_1 + bN_2 + cN_3 + \dots\dots\dots + nN_i}{N_T}$$

Where
$Vissloss$ = weight loss estimated using the visual scale
a to n = damage coefficients for each class
N_1 to N_i = Number of cobs in each class
N_T = Total number of cobs in sample

In order to estimate the weight loss for maize stored in grain form, the enumerator uses a standard chart. The enumerator randomly selects separate samples of say 100 grains each from the farmers' maize. The enumerator then places the grains in a litre plate to physically count the damaged grain. The process is repeated for the samples and an average number of damaged grains per 100 grains is established. The number of damaged grains is read off against a predetermined regression chart to find the percentage weight loss.

With these new technologies the techniques have become faster and less cumbersome; in addition, they clearly demonstrate, once again that the sampling statistician (who might not know about biological laboratory calibration of experiments), has to work very closely with the biometrician and other food loss specialists to make these techniques successful.

The Thousand Grain Mass Method (TGM) is another method (Boxall 1986) that was advocated as capable of determining insect losses, and which can overcome the problems encountered with both the volumetric and the count and weigh method. It is a technique modified from a standard procedure of determining the weight of one thousand grains and is known as the thousand grain mass method (TGM). The multiple TGM technique, a variation of the TGM has also been proposed to take into account the variations in grain size and the difficulties in obtaining representative samples when using the traditional TGM.

The TGM is the mean grain weight multiplied by 1000, corrected to a dry weight; it is calculated by counting and weighing the number of grains in a sample; to avoid possible sources of error and bias, the sample is not adjusted to a specific weight or number of grains; a reference TGM is determined from a sample of grain collected at the beginning of the storage season and compared with subsequent measurement throughout the season. The weight loss in a sample of grains is given by the formula (Boxall, 1986):

$$\frac{Initial\ TGM - Sample\ TGM}{Initial\ TGM} \times 100$$

Dry weight TGM can be derived from the following formula:

$$M_D = \frac{10m(100 - H)}{N}$$

Where M_D = TGM (dry basis)
m = mass (weight) of grains in the sample
N = number of grains in sample
H = moisture content in sample

However, there was no account in the literature of a practical application of these TGM techniques in loss assessment studies.

Losses due to microorganisms (moulds)

Grains infected by microorganisms will lose weight at a rate which varies according to the grain moisture content, temperature, and the amount of physical damage to the grain. There does not seem to be much work done on the quantification of losses due to moulds at the farm level through the literature. The methods used to assess weight losses caused by insects can be used for assessing losses due to microorganisms. The loss in weight caused by microorganisms in a sample of grain can be calculated by a comparison of the damaged (infected) sample with a baseline (undamaged) sample. As in the case of insect losses assessment, the baseline sample should ideally be collected at the time the grain is stored.

Losses due to vertebrate pests (rodents, birds)

There is a lack of data and appropriate studies and techniques to assess losses due to rodents and birds in the literature. There have been proposals that in order to measure loss of grain cobs or heads caused by rodents, an estimate of percentage of grain removed has to be calculated first; second, undamaged cobs or heads of the same size as the damaged ones should be shelled or threshed and the grain weighed; last, the loss is calculated by multiplying the weight by the percentage of grain removed. It is not clear however, how this method should be used.

It has also been proposed in the literature that losses of threshed grain to rodents can be estimated by comparing weights of grain stored and removed, provided allowance is made for other losses, for example, losses due to insects. This can be really challenging with in farm-level studies because of the difficulty of monitoring all grain movements in and out of farmer store (unless the study is conducted in the experimental way under more controlled conditions).

There is no generally accepted methodology for assessing bird losses after harvest, though losses before harvest are known to be serious. The little guidance that exists revolves around estimating losses in the field. At some other stages of the post-harvest system, one can compare weights of grain entering and leaving the stage (correcting by moisture content) in order to estimate losses caused by birds. However, estimating losses caused by birds during storage still remains a difficult task.

Calculating total storage losses

When performing assessments of total storage losses at the farm level, losses calculated from samples should be related to the quantity of grains originally stored and to the pattern of grain consumption.

When grain is being removed at regular intervals during the storage season, total loss due to insects can be gauged by calculating the loss in each quantity of grain removed by comparing samples of grains collected from the removals with a sample of grains collected at the beginning of the season. Boxall (1986) gives the example as illustrated in the following table.

Table 2 - Relationship between weight loss and grain consumption

	Months during which grain is removed					
	1	2	3	4	5	6
Quantity (volume) of grain removed (%)	10	10	15	15	20	30
Weight loss in sample (%)	1	2	3	5	7	10
Weight loss (as percentage of total stored)	0.1	0.2	0.45	0.75	1.4	3.0
Cumulative weight loss (as percentage of total stored)	0.1	0.3	0.75	1.5	2.9	5.9

Ideally quantities of grain stored put into and removed from store should be weighed. In practice, this might be extremely difficult to achieve. Hence some sort of estimation of grain quantities has to be made.

In some studies, volume occupied by the produce in store was measured and transformed into a standard weight using some predetermined factor and quantities of grain removed calculated by reference to standard baskets. Grain removed was first placed in the basket; with prior knowledge of the dimensions of the basket used, the volume and weight of grain removed could be calculated. In other studies researchers had to rely upon the use of traditional/local volume measures to obtain estimates of quantities of grain stored and removed. Once the proper figures of average quantity of grain stored, aggregate loss of grain during the storage period and its break-down by causes of loss (insects, moulds, etc.) are obtained for the holding, stratum and regional estimates of the same indicators can be obtained using the estimation formulae similar to those derived at the threshing/shelling stage.

Losses during transport

Losses in transport at the farm level may occur in (a) transport from field to the threshing floor; (b) from threshing floor to the storage; and (c) from storage to the market, with different modes of transport being used at different stages. Losses are normally estimated as difference of weights between the quantity loaded and the quantity unloaded. When transport operations might take days, samples will be taken at the loading stage and at the unloading stage, and then examined for change in moisture content and qualitative damage during transit. Based on the percentages obtained, percentage losses for any given stratum/region can be derived using the procedure described in the threshing/shelling stage. Estimating percentage losses at the stratum/regional levels (based on percentages obtained at holding level follows the same procedure as indicated in the threshing/shelling stage.

Losses during processing

Traditional hand processing or mechanical processing is used to process grain through de-husking, milling and grinding of grains. At this stage, grain loss is normally expressed as a reduction in quality of finished product, although there may be some physical loss of grain through spillage. In large-scale, commercial mills, grain is usually processed in a continuous operation; grain can also be processed in small batches (hand pounding for instance), using querns or village custom mills. Loss assessment studies at farm level are mostly concerned with the latter mode of processing. In that case, it should be possible to weigh the grain before processing, and after to obtain a measure of physical loss. In addition, a comparison between the products of the process with that of a sample of grain carefully processed in the laboratory will provide an indication of the loss of quality.

Estimating percentage losses at the stratum/regional levels (based on percentages obtained at holding level follows the same procedure as indicated in the threshing/shelling stage.

Losses during packaging

Losses occurring due to defects in the methods of packaging and handling of grains can also be estimated. Data on different types of packaging could be collected for a selected sample of farmers to study the efficiency of alternative methods of packaging. However, within the context of the post-harvest value chain, the losses at this stage do not seem important.

Estimating percentage losses at the stratum/regional levels (based on percentages obtained at holding level follows the same procedure as indicated in the threshing/shelling stage.

Grain losses at intermediary level

In this category, reference is made to government distribution agencies, mills, marketing cooperatives, wholesale and retail traders. At this level, losses are to be estimated at the stage of transport, storage, processing, packing and distribution. For transport, storage and handling by market handlers, a sample of such handlers is to be selected and the required information collected. In the same way, random sample of mills/processing factories, may be chosen and the data collected. The design used for this stage calls for a two-stage stratified random sampling with the market of some sort as the primary sampling unit, and the intermediary as the secondary sampling unit. Then for each sampled intermediary, different kinds of percentage losses are computed and then grossed-up to stratum/regional levels using the same techniques as in the threshing/shelling stage. In the case of mills and similar units, a single stage sampling design will suffice and the estimation will get even simpler.

Grain losses at Government warehouses

These agencies and other public distribution agencies should maintain detailed administrative records of grains received and dispatched. Food technology specialists working in these agencies are expected to collect samples of grains periodically, and record pertinent information, such as moisture content, insect and pest infestation and other causes of damage. Hence these agencies should therefore have readily available comprehensive data on levels of losses and their causes. A number of these surveys have been conducted in various countries around the world mostly in India for food grains (maize, rice, sorghum, wheat, etc.). APHLIS has been very active in Southern and Eastern Africa regions concentrating on the maize crop. Selection of warehouses may be done by a single stage random sampling if they are many or all of them selected if they are only a few. Estimation of average and percentage loss can be worked out as in the case of mills.

The FAO approach to food loss concepts and estimation in the context of Sustainable Development Goal 12 Target 3

S. Tayyib | Statistics Division, FAO | Rome
N. Golini | Statistics Division, FAO | Rome
DOI: 10.1481/icasVII.2016.b15e

ABSTRACT

FAO is undertaking a two-pronged approach to building a dedicated global database on post-harvest/slaughter food losses (up to the retail level), and providing country level support to measure, estimate or impute the pertinent data. Country-specific food loss indices will then be calculated, and geo-aggregated up to a global level index. These indices will measure and monitor progress against one of the two components of Sustainable Development Goal 12 Target 3 (denoted as SDG 12.3).

Keywords: Food Balance Sheets, Food loss estimates, Food production/supply chain, Post-harvest/slaughter losses, SDG target indicators.

PAPER

1. Introduction

Due to the notorious acute lack of reliable data, assessing the magnitude and the economic, food security and environmental impacts of food losses and waste is an extremely challenging task. Nevertheless, basic data and observations clearly point to the large obstacles these two phenomena pose to global sustainable development. Some estimates indicate that the equivalent of some 24 percent of all calories produced for human consumption per year[1] are lost or wasted. Reducing food losses and waste is, therefore, a combined opportunity to mitigate environmental impacts (particularly greenhouse gas emissions), manage resources (energy and water) and better meet the challenge of improving global food security by means of increasing food availability[2] and smallholder incomes. All this is even more evident when considering the ever-increasing stresses on our planet's ecosystems, and the rising world population requiring more and more food.

The recently adopted SDGs[3], reflecting the importance of food loss and waste, have included the specific target 12.3 which aims to halve per capita global food waste and reduce food losses (see the section on the SDG further down). To monitor progress against this target, a country and then global Food Loss Index will be calculated by FAO.

Generally speaking, loss is the result of unintended actions, decisions or situations; while waste results from some elements of a discretionary process. That said, food losses and waste both occur, to different extents, along the whole food production and supply chain[4]. Consequently, it is understood that the labelling of the "loss" and "waste" parts of the food production and supply chain in this paper, while mainly for convenience, does tend to denote where one or the other is more likely to occur, and is in line with the terminology of the indicator of SDG 12.3.

In less advanced food systems, food loss is the largest component and generally occurs along the production chain as a result of wide-ranging managerial and technical limitations in harvesting, storage/cooling, transportation, processing, and infrastructure. By contrast, and mostly in advanced food systems, waste is the largest component and generally occurs along the supply chain as a result of retailer/consumer decisions to discard food that still has value[5].

[1] Global food losses and food waste. FAO (2011).

[2] One counter argument, however, states that the more food is available the lower its price and therefore the more likely it is to be wasted.

[3] September 2015 (http://www.un.org/sustainabledevelopment/development-agenda/).

[4] The production chain in this paper is considered to be from the post-harvest/slaughter stage till, and excluding, the warehouse. While the supply chain is considered to be from, and including, the warehouse, to retail, then to point of consumption and, ultimately, to the consumer.

[5] Global food losses and food waste. FAO (2011)

This paper will focus on FAO's work on food loss data, in the context of SDG 12.3, with emphasis on the model-based estimations within the context of the compilation of the FAO Food Balance Sheets (FBS). The FBS is a framework where the central concept is that the supply of food items in quantities equals its utilization. Within this context, food loss is treated as one of the utilization components, and includes all the losses incurred in all the other FBS utilizations (such as animal feed, industrial uses, the seeding process)[6]. The data aggregated to build the food loss index, to monitor SDG 12.3, are those loss numbers (official or imputed) in the FAO FBS database. Consequently, food waste from retail to consumer (the first component of the SDG 12.3) is beyond the scope of this paper. Furthermore, it should be noted that the term "food loss" in this paper refers to the primary quantities of crop and livestock commodities that can potentially be consumed by humans, either directly or after processing, and not to specific amounts of directly edible processed/derived products.

2. The two-pronged FAO approach to food loss data

Given the lack of reliable and nationally representative data on food loss as well as of an internationally agreed methodology for its measurement, FAO - in its role of custodian of the indicator(s) for measuring country and global progress towards reducing food losses and waste related to SDG 12.3 - is currently undertaking a two-pronged approach:

1) Assist countries in **collecting food loss data** along the production/supply chain (up to and excluding the retail level) by producing guidelines on cost-effective data collection methods and testing them in some pilot countries. This is an endeavour that will ensure global data coverage only in the long-term,

2) Assist countries in **estimating losses** of food-related crop and livestock commodities, within the framework of the Food Balance Sheets (FBS), using a hierarchical linear model, as an interim solution to filling data gaps.

Both „prongs" involve post-harvest/slaughter food commodity quantity loss data (e.g. tonnes of wheat, apples, meat, milk) up to and excluding the retail level of the production/supply chain. Such data contribute to monitoring the second component of the SDG 12.3.

Work related to the first of the two-pronged approach, development of a methodology for food loss measurement in developing countries (based mainly on sample-derived estimations), is being undertaken under the research programme of the **Global Strategy to Improve Agricultural and Rural Statistics** (GS). It will suffice here to mention that measurement of post-harvest food losses proposed by the GS is aimed at identifying the most cost-effective methodological options to measuring losses at different stages of the food production/supply chain (farm, intermediary, and warehouse levels), distinctively for the main food items.

Furthermore, the **Nutrition Division** of FAO (ESN) is conducting case studies in a number of countries to identify critical points along the value chain which have the highest impact on the extent of food losses and to design the appropriate mitigation measures. These food supply chain analyses are an important pre-requisite in deciding the scope and focus of the sample surveys.

Work related to food loss estimation, the second of the two-pronged approach, using a heirarchical linear model, and in the context of the FBS, is being undertaken by the **Statistics Division** of FAO (ESS). As the SDG process is intrinsically country-driven, this work will ultimately involve the countries through direct collaboration.

3. The FAO proposal to modify the SDG 12.3 indicator

Target SDG 12.3 states that "By 2030, *halve per capita global food waste at the retail and consumer levels and reduce food losses along production and supply chains, including post-harvest losses."*

To monitor progress against this target, the current proposed indicator, the Food Loss Index (FLI), only partially achieves this. This index is a quantity-based price-weighted aggregation of any available and reliable country-generated food loss data and, in their absence, of the model-based estimations. It is categorised as a Tier III indicator, meaning that the methodology, mechanisms and baseline involved have yet to be fully developed, tested and adopted.

Moreover, at a closer look, the food waste component of target SDG 12.3 is not covered at all by this indicator. The nature of the target with its two distinctly worded components, waste and loss, implies the identification of two separate indicators. While the two concepts are related and the precise boundaries between them may be blurred, differentiating between the two, however and as mentioned above, is important as they principally occur along different parts of the production/supply chain and are triggered by different dynamics which neccessitate different methodologies for measurement and estimation.

In this context, and for the above reasons, FAO would like to highlight the need to have an additional indicator for the SDG 12.3 that will focus on monitoring the food waste component.

6 http://www.fao.org/docrep/003/X9892E/X9892E00.HTM

Each of these two indicators will measure progress against their respective SDG target component by generating country level indices, and ultimately two global ones. A method of combining the two indicators, if feasible and significant, will be investigated at a later stage.

Furthermore, because these two proposed indicators require the introduction of new data measurement, estimation and collection methods, and potentially the establishment of new statistical programs of work at the country level, the close coordination of the FAO Statistics Division (ESS) with member countries will be essential to the success of this endeavour. National focal points and relevant national agencies charged with measuring progress on food loss and waste will be identified by coordinating with national SDG committees. Coordination and collaboration with other supranational and regional organizations (EU, World Resources Institute, UNEP, etc.) as well as with relevant private institutions will also be essential.

4. Challenges to the measurement or estimation of food loss data:

The challenge to measure or estimate internationally comparable food loss statistics is made all the more acute for the following reasons:

- No internationally endorsed food loss standard concepts and definitions exist. Several imprecise concepts and definitions, that differ in some key aspects (e.g. inclusion or not of non-edible parts; inclusion or not of food items destined to feed), are currently used and promoted by different key organizations. As a result non-comparable data across countries are generated, hindering any effective analysis.
- Current methods for measurement of food losses have not proved effective in generating data. The approaches proposed in these guidelines may be not so cost-effective and therefore are not being implemented by countries.
- Nationally generated reliable food loss statistics are extremely scarce. The proportion of official food loss data in the FAO FBS detailed database (the commodity-specific Supply and Utilization Accounts), over the last 25 years, amounts to only a mere 4% of total, the rest of the data cells (about 200,000) are all estimations. Considering that the FBS is a unique global database of time-series food loss data by country and commodity, the magnitude of the scarcity of reliable data is even more evident.

This lack of data is due to several factors which include the complexity of measurement along different stages of the production/supply chain; different distribution processes along the value chain for different commodities (e.g. pineapples follow a simpler chain than wheat); quality of the infrastructure (such as storage, transportation); the variation of weather/temperature patterns; and lastly, the actual investment (financial and human) that many countries do not appropriately make to measure and collect food loss data.

5. The concept of food loss in FAO agricultural statistics:

The food loss concept that should be reflected in FAO's statistical data[7], and the basis of which it would like to propose for international consideration is:

Food losses are all the crop and livestock human-edible commodity quantities that, directly or indirectly, completely exit the post-harvest/slaughter production/supply chain by being discarded, incinerated or otherwise, and do not re-enter in any other utilization (such as animal feed, industrial use, etc.), up to, and excluding, the retail level. Losses that occur during storage, transportation and processing, also of imported quantities, are therefore all included.

FBS data for food availability and for food losses include the commodity as a whole with its non-edible parts.

Out-graded quantities (not meeting certain specifications in terms of quality and/or appearance) that re-enter the supply chain (as feed or any other utilization) are not considered losses. Pre-harvest and harvest losses are a priori excluded since agricultural production data provided by countries to FAO refer to quantities net of harvest losses. Waste/loss that occurs at the retail level and all along the supply chain till the consumer is also excluded.

Food, in the above concept of "food loss", therefore refers to any substance, whether raw, processed or semi-processed (including drinks), that can be consumed by humans.

6. The Food Balance Sheets (FBS) and the food loss estimation model

The noted food loss data scarcity emphasises the necessity to have a robust statistical model that can generate estimations to fill in the many data gaps, with as much reliability as possible.

[7] As there is no internationally adopted definition of food loss, FAO cannot, therefore, be certain that the few countries that do report data on losses are doing so according to the FAO concept.

This is done in the FAO Statistics Division (ESS) within the framework of the FBS using a newly developed hierarchical linear model.

Very briefly, the FBS is a time-referenced food accounting framework whereby supply equals utilisation (in quantities). Each FBS is composed of numerous commodity-unique supply utilization accounts (SUA) that are balanced and aggregated, in primary equivalents[8], by commodity „tree" groups (e.g. wheat & wheat products). The supply side components are production, imports, and stock withdrawals, while some of the main utilization components are food (available for human consumption), animal feed, quantities destined for seeding, exports - and loss. The loss component does not refer exclusively to the "food" component, but covers all losses related to all the other components along the production/supply chain (such as quantities lost post-harvest on-farm, damaged while held as stock, lost during transport, and so forth). As already stated, very few of these loss data are obtained officially from countries, and so the vast majority has to be imputed. FAO, nevertheless, does request commodity-specific loss data directly from countries in the annual agricultural production questionnaires that are expedited to all countries. Furthrmore, all possible sources of loss data, from official statistical websites to national publications and published studies, are continuously scrutinized.

As highlighted earlier, the FBS framework is the only tool currently available capable of implicitly validating data on food loss. In fact, through the FBS balancing mechanism, the resulting food loss estimates make use of the magnitude and reliability of the data for the other components (such as animal feed, industrial use, etc.)

The **hierarchical linear model** that is presently[9] used, as an interim solution, to estimate data gaps in food loss consists of four levels: the lowest is country-commodity specific estimates, followed by commodity-specific estimates, then food group estimates, and finally by perishable food group estimates.

The coefficients in the model are estimated simultaneously to ensure they are consistent, and the resulting estimations are further validated through the FBS balancing process. To date, preliminary results have been produced but the model will be further refined by referencing case studies, reviewing empirical data, and by the review of national and international experts (such as the IAEG-AG[10]). Furthermore, FAO is poised to provide support and guidance to countries to enable the adaptation of the model to specific national data situations (e.g. by adding variables on quality of infrastructure and climatic conditions) in order to generate national estimates.

7. The food loss index (FLI)

To monitor progress against SDG 12.3, and by using the official and imputed loss data in the FBS database, individual country indices will be calculated which will then be combined using specific weighting to produce regional and global aggregates of the Food Loss Index (FLI). These indices are Laspeyres quantity indices based on the sum of the base period price-weighted[11] quantities of the food loss data. The country index shows the relative level of the aggregate quantity of losses for each year in comparison with a base period.

The choice of prices as weighting factor, is due to the fact that using calories may produce bias by possible over estimates in calorie per capita (kcal/caput) terms, as not all the food quantities involved in these calculations, in the FBS framework and as explained above, are strictly destined for human consumption.

8. FAO country support in the context of SDG 12.3

As the SDG process is intrinsically country-driven, the work carried out by FAO on food loss concept and methodologies of data estimations and index calculations will involve the countries through direct collaboration. A draft country-support programme of work focusing on the loss component of SDG 12.3 (the second of FAO's two-pronged approach) is being finalised, and includes:

- Promoting the FAO concept of food loss and related methodologies, and raising awareness on the links to SDG 12.3 (seminars and information/training material)

[8] Processed foods are derived from their primary/parent commodities with extraction rates that can be calculated. In the FBS methodology these processed quantities are converted back into their primary equivalents using the inverse extraction rates. For example, 10 kg of flour are equivalent to around 13 kg of wheat (with an extraction rate of around 75%)

[9] In the past, two different estimation methods were used/tested with unsatisfactory results. The first one, estimated the losses simply as a ratio of food supply. The second method consisted of an econometric model with the loss ratios in the SUA/FBS, in log scale, as response to time and to crop and country specific factors (regional/individual/commodity groups, percentage of paved roads and GDP). However, results have shown a poor predictive ability of the model highlighting the need for more reliable data and to use more sophisticated estimation techniques.

[10] The Inter-Agency and Expert Group on Food Security, Agricultural and Rural Statiscs.

[11] International commodity prices (ICP)

- Assessing national situations and capacities in food loss measurement (country/regional technical missions)
- Establish/strengthen data reporting and data exchange mechanisms between countries and FAO (e.g. online platform and questionnaire)
- Devising country-tailored food loss data estimation mechanisms and index calculations (in collaboration with the SDG national committee and the national statistical office) to monitor progress against SDG 12.3

9. Conclusions

In its role as custodian of the indicator(s) for measuring progress against SDG 12.3 FAO is undertaking a two-pronged approach comprised of assisting countries in developing techniques for measuring food losses along the production/supply chain; and in estimating missing data within the framework of the FBS.

The nature of the SDG 12.3 with its two distinctly worded components, waste and loss, implies that in reality two separate targets must be reached. For this reason, combining them both into one overall indicator will be problematic. As a solution, FAO is proposing the creation of two separate indicators and monitoring mechanisms distinguishing food loss and food waste. Furthermore, terminology, mechanisms and reporting must be defined and established with urgency to allow countries.

An internationally adopted concept of food loss (and waste) is essential to ensure global comparability and meaningful analysis. The hierarchical linear model that is presently used, as an interim solution, to estimate data gaps in food loss, has shown encouraging results, but is nevertheless being fine-tuned (e.g. inclusion of exogenous variables such as climate and infrastructure).

The resulting estimations are further validated through the FBS balancing process. In fact, the FBS framework is the only tool currently available capable of implicitly validating data on food loss by making use of the magnitude and reliability of the data for the other components (such as animal feed, industrial use, etc.). FAO country support should enable the generation of national food loss data necessary for the calculation of loss indices for monitoring progress against SDG 12.3.

DOI: 10.1481/icasVII.2016.c16

ABSTRACT

Volatility of global food prices has been increasing recently as has been empirical efforts trying to sort out their macroeconomic effect on the performance of small open economies. This study sought to measure global food price volatility and to establish its pass through effect on headline inflation in Zimbabwe relying on annual data observed from 1980 through 2007. Using the GARCH techniques to model volatility and a standard backward looking Phillips curve framework that controls for an output gap, the results of the study indicate that global food price volatility did not have any significant contribution on the worrisomeinflation levels suffered in Zimbabwe during the last decade. The result is plausible in light of price control systems in Zimbabwe as well as presence of a fragmented commodity market.

Keywords: Food Price Volatility, Pass through effect, Headline Inflation, GARCH, Zimbabwe

PAPER

1. Introduction

The last 6 years or so witnessed a proliferation of studies seeking to address the implications of volatile commodity prices on macro-performance of small open economies. This proliferation of empirical efforts born soon after the 2008 food price hike partly reflected the supremacy of the global food market in explaining volatility of domestic inflation. An area of interest in this respect has been establishment of the pass through effect; a phenomenon viewed primarily as the proportion of the world global price change that feeds into domestic inflation. From a macroeconomic viewpoint, food price volatility can be inflationary through the trade channel for developing countries that depend on the world food market to feed their populace.

The pass through can be complete or incomplete depending on such factors as an economy's level of global integration, provision of subsidies and so on. It is said to be complete if the entire global price change transmits into the domestic headline inflation and incomplete if part of the change is absorbed along the supply chain. A number of empirical studies (Zoli, 2009, Awokuse and Yang, 2002, Jumah and Kunst, 2007, Blomberg and Harris, 1995, Ferrucci,Jiménez-Rodríguezand Luca Onorante, 2010 and Jalil and Zea, 2011) have been conducted to examine the pass through effect of global food prices on domestic inflation in developing countries and majority of them confirm an incomplete pass through. Despite such an overwhelming board of related literature however, no known country specific study is available for Zimbabwe.

Relative to other countries, Zimbabwe is an eventful economy with respect to macroeconomic experiences. More important is that producers and consumers in Zimbabwe largely interact in fragmented and often disorganised commodity markets; a unique feature which makes a pass through analysis for Zimbabwe capable of producing unique empirical evidence and distinct results.On the other end, the economy of Zimbabwe went through flames of a remarkable hyperinflation in 2008 which exceeded1500 percent amid a concurrent global recession. This unprecedented hyperinflation was characterised by continuous efforts by monetary authorities to revalue the Zimbabwean dollar and this period saw a number of studies attempting to establish precipitating forces of inflation. Less effort in any case was made that time to formally understand the role of global food prices on inflation and this, combined with the presence of a fragmented commodity market makes a study of this sort worth undertaking. Probing the link between suppressed inflation and money demand, Muñoz (2006;4) notes that prices in Zimbabwe appeared to have responded to other factors other than changes in monetary policy but his limited scope and coverage with respect to underlying sources of inflation left open the question of how food price movements might relate to inflation. This analysis attempts to fill this gap by focusing on the role of global food price volatility on inflation in Zimbabwe. It is plausible to think of global food prices as a potential driver of inflation given that the hyperinflationary in Zimbabwe developed at a time when economy was under a dramatic transformation from being a bread basket to a net food importer.

Conventional wisdom posits that countries that largely depend on the global market are vulnerable to external shocks that may translate into increased domestic inflation. Food in Zimbabwe occupied a weight of around 31 percent in the consumer price index in 2001 (Muñoz, 2006) while total food imports accounted for more than 20% of annual GDP. The country's reliance on the global food market is therefore worrisome on account of global price shocks that are turning out to be a recurrent scenario. Being a price- taker with respect to the global market, the pass- through effect caused by changes in global commodity prices might compromise domestic macro-performance and the tremendous inflation growth witnessed in Zimbabwe during the last decade could be evidence of this situation.

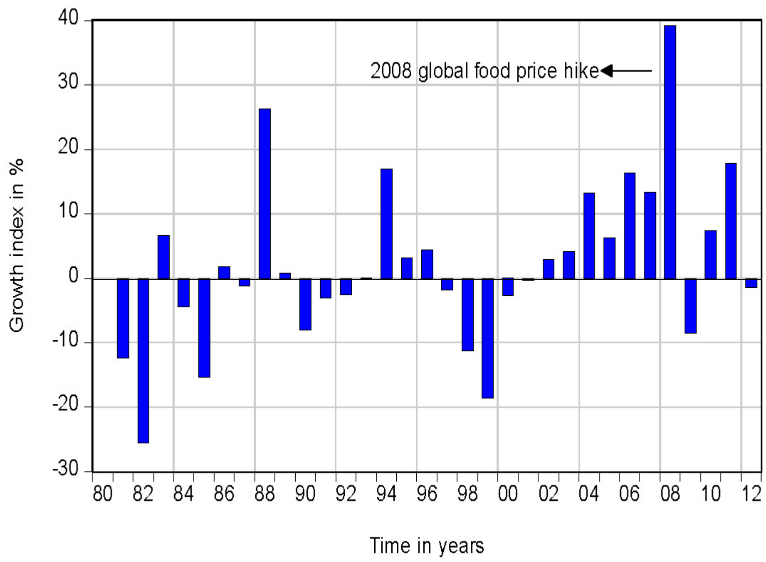
The central objective of this study is therefore to establish how volatility of global food prices explains variation in headline inflation in Zimbabwe. Food and Agricultural Organization (2014) provides a more recent study of this sort but they focus on regional level pass through which suffers from an unrealistic assumption of regional homogeneity with respect to policy responses from global food price movements. It is necessary to perform a country specific study that allows one to isolate the pass through effect on a particular country at the same time acknowledging the heterogeneity in policy responses across individual countries. We additionally do away with a generic approach of focusing on general price movements and focus primarily on the pass through effect of global food price volatility. World agricultural prices have been experiencing an increase in the degree of volatility in the last decade according to FAO (2011) and addressing the inflationary effects of such volatility is essential for designing appropriate monetary policy responses geared at local price stabilization.

The remainder of the study is organised as follows, section 2 provides a brief overview of global food price movements, evolution of inflation in Zimbabwe and review of related literature, section 3 highlights the econometric methods employed, empirical findings are presented and discussed in section 4 while a conclusion of the study and policy implications are provided in section 5.

2.0 Global Food Price Movements (1960-2012)

Figure 1 illustrates annual growth rates of global food prices from 1980 – 2012.

Figure 1 - Annual Growth Rates of Global Food Prices (1980 – 2012)



A visual inspection of Figure 1 shows that growth rates of global food prices have generally been fluctuating from 1980-2012. The 2008 food price hike is probably the highest since 1980. Also, episodes of upward and downward swings are almost equal in terms of frequency during the 32year period. Factors responsible for such worrisome price hikes vary in empirical literature but most accounts link them to the rapid population growth especially in East Asia, a higher demand for oil as well as the limited supply of agricultural commodities emanating from climate change (Shi and Arora 2012).

2.1 Evolution of Inflation in Zimbabwe (1980-2007)

The period 1980-2007 saw a massive economic meltdown. Growth was subdued starting from late 90s before getting worse post the new millennium. The central bank of Zimbabwe made regular attempts to defend the domestic currency to no avail as the Zimbabwe currency continued to lose value in relation to the currencies of its trading partners. Government interventions through price controls to protect consumers ended up in a situation where the remedy was worse than the disease. The interventions in particular created an informal market and the shortage of basic goods in the formal market coupled with excess printing of the Zimbabwean dollar by the Reserve Bank of Zimbabwe gave rise to a demand pull type of inflation. Domestically produced goods became too expensive and local consumers substituted domestic goods for foreign produced goods. Given that food occupied a larger proportion in the Consumer Price Index (CPI) as shown in table 1, the situation created further pressure on inflation.

Table 1 - Composition of the Consumer Price Index in Zimbabwe (2001)

Category	Weight (2001=100)
Food and Non-Alcoholic	31.9335
Alcoholic beverages and tobacco	4.9068
Clothing and Footwear	5.7061
Rent, Fuel and Power	16.2291
Furniture, Household Equipment and Maintenance	15.1069
Health	1.3055
Transport	9.7671
Communication	0.9875
Recreation and culture	5.7452
Education	2.8521
Restaurants and Hotels	1.5177
Miscellaneous goods and services	3.9425
Total	**100**

Source: ZIMSTATS

As illustrated in Table 1, food in Zimbabwe had relatively more weight as compared to other categories in 2001. This means that food contributed largely to movements in headline inflation during the study period. By 2007, annual inflation had grown by more than 1000 percent and the government finally opted to abandon its currency in favour of the multicurrency system.

2.2 Recent Inflation Developments

The multicurrency system adopted in 2009 brought about inflation stability. The current strength of the United States dollar against the Rand has encouraged more importation of food imports and when combined with the prevailing weak domestic aggregate demand, this has created a deflationary environment. Monthly food inflation dropped from -2.9 percent in April to -3 percent in May 2014. Overall inflation measured by the consumer price index has remained negative and is expected to remain so until June 2016 (ZIMSTATS, 2015).

2.3 Related literature

Conventional wisdom posits that headline inflation can be influenced by movements in global food prices and this can take place through the trade channel. In particular, an increase in global food prices implies that food imports become relatively expensive and therefore in the absence of trade restrictions, the price increase of the imported commodities from the world market is likely to get reflected in domestic headline consumer price indices. Empirical literature related to pass through effects is very rich though the results are not directly comparable due to the differences in data, study areas, model specification, estimation techniques and other methodological aspects by distinct authors. Zoli (2009), shortly after the 2007/2008 food price hike employed panel data techniques on 18 countries and observed that global commodity price shocks fed through to domestic headline inflation and the effect was asymmetric. Similar conclusions were reached by Awokuse and Yang (2002) and Jumah and Kunst (2007) despite the use of different methodological approaches.

Contrary to this theoretical prediction and empirical observation by Zoli (2009), Blomberg and Harris (1995) and Furlong and Ingenito (1996) had earlier confirmed no relationship between commodity prices and inflation. Though the authors could not explicitly show why this could be so, a recent empirical study by Ferrucci,Jiménez-Rodríguezand Luca Onorante (2010) provides a number of reasons why commodity price shocks may not necessarily translate into increased headline inflation. Firstly, they argue that external price shocks may not be inflationary if they get absorbed in producers' margins or neutralised by advances in domestic productivity. Secondly, global commodity price shocks may have no noticeable effect on inflation if local consumer pricesare subject to other offsetting internal shocks at any given point in time. Other related studies have been conducted at regional level and found that local food prices respond to regional price shocks, while global price shocks do not have any significant effect on headline inflation (Huh et al, 2012). The latter result could be taken as further evidence in favour Harris (1995) and Furlong and Ingenito's (1996) conclusion confirmed in the mid-90s which is almost two decades from now.

One of the contentious issues surrounding the pass through literature relates to the choice between focusing on headline or core inflation. Jalil and Zea (2011) address this issue when focusing on the pass through effect of global commodity prices, food inflation and core inflation for a set of Latin American countries. Like Huh et al (2012), the author employed a vector error correction model (VECM) which essentially describes the long run pass through and the corresponding short run dynamics. After controlling for other domestic monetary variables such as the exchange rate and the interest rate, the author found a limited pass through effect of global food prices on domestic food prices, a result that is very much in line with that confirmed by Huh et al (2012).Relative to estimation of a system of equations as did Huh et al (2012) and Jalil and Tamayo Zea (2011, a study by FAO (2014) prefers a unidirectional equation error correction model on grounds that the direction of the relationship, from international market prices to consumer prices, is clear given the two extremes of the value-chain to which these prices refer to. We therefore estimate a single reduced form equation for inflation. Despite the gain in asymptotic efficiency of parameters when one use a system of equations particularly VARs or VECMs, our analysis is based on low frequency data which might consume a number of degrees of freedom after controlling for additional lags of the explanatory variables in the system.

3.0 Methodology

3.1 Modeling Food Price Volatility

Volatility of global food prices is modelled here using the Generalised Auto-Regressive Conditional Heteroscedasticity (GARCH (1, 1)) model. GARCH models essentially characterize the conditional distribution of e_t by imposing serial dependence on the conditional variance of the innovations. Specifically, the variance model imposed by GARCH, conditional on the past, is given by;

$$var_{t-1}(y_t) = E_{t-1}(\varepsilon_t^2) = \sigma_t^2 \ldots\ldots\ldots\ldots\ldots.1$$

Where;

$$\sigma_t^2 = k + \sum_{i=1}^{p} G_I\,\sigma_{t-1}^2 + \sum_{j=1}^{q} A_j\,\varepsilon_{t-j}^2 \ldots\ldots\ldots\ldots\ldots\ldots 2$$

From equation 1 and 2, σ_t^2 is the forecast of the next periods variance given the past sequence of variance forecasts, σ_{t-1}^2 and past realisations of the variance of itself, ε_{t-j}^2. Equation 2 is referred to as a GARCH (p, q) model thus if $p = q = 0$, then the variance process will simply collapse to a white noise with variance . Volatility of global food prices will be confirmed here by presence of autoregressive conditional heteroscedasticity effects after estimation of a GARCH (1, 1) model by the maximum likelihood technique.

3. 2 The Pass-Through Effect on Inflation

The generated volatility series of global food prices is then inserted in the backward-looking Phillips curve specification similar to the one used by Gelos and Ustyugova (2012) and Christensson (2009) to appreciate its pass through effect. The model takes the following form.

$$\pi_t^{headline} = \gamma + \sum_{i=1}^{n} \delta_i\,\pi_{t-i}^{headline} + \sum_{i=0}^{m} \beta_i\,Output\ gap_{t-i} + \sum_{i=0}^{p} \theta_i\,Food\_price\_vol_{t-i} + \varepsilon_t$$

Since the model contains a lagged term of the dependent variable as one of the explanatory variables, the full pass through effect will be determined by;

$$\frac{\sum_{i=0}^{p} \theta_i}{1 - \sum_{i=1}^{n} \delta_i}$$

Where $\pi_t^{headline}$ denotes headline inflation at time period t, y, δ and θ represent unknown model parameters to be estimated. We consider an ARDL (1, 1, 1) model in order to establish whether or not volatility of local food prices could be prelude to headline inflation. The output gap is defined as the difference between actual output from potential output. During the study period, Zimbabwe suffered attendant short-term price rigidities and other demand shocks that could have partially altered the level of domestic output resulting in an increased gap and corresponding inflation. Output gap has been generally measured using the Hodrick and Prescott Filter method which essentially generates a smoothed series where deviations of actual output from this smoothed series are termed output gap. Despite its simplicity, this approach suffers from the weakness of having virtually no economic logic regarding the sources of growth. We therefore resort to the use of a production function which unlike the Hodrick and Prescott filter method takes into account economic forces of growth particularly factor accumulation and total factor productivity (Heytens and Zebregs, 2003). We do so by regressing[1] real GDP on labour and capital stock and define output gap as the disequilibrium residuals. Data on inflation and global food prices is obtained from the UNCTAD while real GDP, labour and capital stock is drawn from Penn World Tables 8.0. The study stretches from 1980 to 2008 and this period allows us to capture Zimbabwe's transition from being a breadbasket to a net food importer.

[1]The model is estimated using the Stock and Watson dynamic ordinary least squares technique (DOLS) which controls for endogeneity through inclusion of leads and lags of the first differenced endogenous variables. We use 1 lag and 1 lead based on the Schwarz Information Criteria.

3.0 Empirical Findings

A first step in our inquiry was computation of food price volatility using a GARCH (1, 1) model. Basing on information from the autocorrelation functions and the partial autocorrelation function, the residuals from the mean equation could be best described as an ARMA (1, 1) process. Due to failure of the normality assumption to hold, the GARCH model was estimated with a t-distribution to capture excess kurtosis. The estimated GARCH (1, 1) model was diagnosed of ARCH effects and their presence confirmed that global food prices were volatile during the study period. On the other hand, the sum of the ARCH and GARCH term in the variance equation were close to one signalling an inefficient global food market where unexpected shocks could remain persistent for quite a long period of time. This observation could perhaps justify why the upward swings in global food prices have turned out to be more of a recurrent scenario. With respect to output gap, another variable which we control for in the headline inflation model, we observed that for most parts of the time period between 1980 and 2008, actual output was way below the potential output signalling a negative output gap. Figure 2 which revealed the output gap is not presented here for brevity sake but can be made available upon request. A positive output gap was observed in the early and late 80s and late 90s respectively. Thepotential output series did recognise the economic slowdown suffered in Zimbabwe post 2000. The generated output gap was then inserted in the standard backward Phillips curve specification along with our food price volatility indicator to appreciate how they relate to headline inflation in Zimbabwe. The results are presented in Table 1.

Table 1 - Pass Through Effect of Global Food Price Volatility on Headline Inflation

Variable	Coefficient	Standard error	t-statistic
δ_i	0.413	0.451	0.915
β_i	1.472	1.528	0.963
θ_i	0.914	1.424	0.641
$\frac{\sum_{i=0}^{p} \theta_i}{1 - \sum_{i=1}^{n} \delta_i}$	0.59		
Ramsey RESET	0.219		
DW statistic	1.421		
ARCH test	0.045		
Serial LM test	0.294		

The full pass through is found to be 0.59 indicating that about 5.9 percent can be passed on to headline inflation in Zimbabwe following a 10 percent increase in global food price volatility during the study period. Surprising is that the coefficient is not significantly different from zero suggesting that volatility of global food prices is not significantly transmitted to headline inflation in Zimbabwe. This could be a reflection of massive government interventions particularly price controls that characterised the economy of Zimbabwe during the study period especially post the new millennium. The government of Zimbabwe regularly intervened in the market by setting maximum permissible prices, a situation which led to an establishment of a black market in the informal economy. Such price controls by the government of Zimbabwe forced local producers to absorb all external price shocks, a situationwhich could explain why in this study shocks in global food prices are not translated into headline inflation in Zimbabwe. A second possibility could be presence of a disorganised and fragmented commodity markets. This means that the increase in domestic headline inflation in the formal economy might cause consumers to divert their consumption towards goods offered in fragmented markets where prices are in most cases lower than those from the formal market. In any case, the results are consistent with those obtained by Blomberg and Harris (1995) and Furlong and Ingenito (1996). At regional level, Huh et al (2012) also found that global price shocks do not have any significant effect on headline inflation.

Conclusion

World agricultural prices have been experiencing an increase in the degree of volatility in the last decade, a situation which has ignited concern among researchers when it comes to their effects on the performance of small open economies. This study focused on the pass through effect of global food price volatility on headline inflation in Zimbabwe using annual time series data stretching from 1980-2007. The results of the study indicate that movements in global food prices have not had any noticeable effect on headline inflation. The same is true for the output gap. Policymakers in Zimbabwe should therefore not be wary of global food prices as their volatility is not significantly passed through to domestic headline inflation. The study can be extended by looking at asymmetric effects to establish whether or not upward or downward swings in food prices have uniform effects on headline inflation.

Modeling Spatial Price Volatility and Transmission: A Spatial Panel VAR Model for Cereal Price Across East African Community

J. B. Habyarimana | University of Rwanda | Kigali | Rwanda
T. Nkunzimana | Joint Research Centre (JRC/European Commission)

DOI: 10.1481/icasVII.2016.c16b

ABSTRACT

This paper adopts and explains the application of Panel Vector Autoregressive (PVAR) and Spatial Panel Vector Autoregressive (SPVAR) models to econometrically analyze food price volatility and transmission across countries members of East African Community (EAC). Results revealed that it takes time for spatial effects to influence the price happening at markets and results suggests that price volatility and transmission are more predictable in prices with spatial effects than in those without spatial effects. Impulse response functions show that a one unit shock in one cereal market create persistent and positive cereal price variations in that market and in the other markets. Variance decomposition results show that in terms of 100% variations caused by a one unit shock in the price of cereals at one market create strong variations that, in short and long-run, are reverberated in the price of cereals in the other markets. Two policy implications may flow from this paper: on one hand, policy makers should take measures to stabilize food prices across the EAC in order to ensure food access in the region; on the other hand, trade policies should be formulated considering the gains of trading with the near-neighboring markets in order to avoid delayed spatial effects on price volatility and transmission. The last, is explained by the fact that when a market j is not a neighbor of market i the delayed spatial effects depends on the number of neighboring markets between markets j and market i and on the price prevailing on those markets.

Keywords: Cereals, price volatility and transmission, PVAR and SPVAR, EAC.

PAPER

1. Introduction

Food price volatility is one of the most pressing problems to ensure food security in EAC. Food price volatility in EAC results from four main factors. First, the population growth in EAC is high which has a medium and long term effects on food demand in EAC. Second, EAC as other parts of the world experiences climate change, hence the accumulated effects of impact born from and/or caused by climate variability, result in crop yield and production instability. Third, the link between global food price volatility and agricultural production. From the combined effects of population and climate variability, EAC partner states became more reliant to one each other and to the world market especially in terms of cereals demand. Fourth, the food price volatility as result of spatial effects. Geographical location can determine food price volatility and transmission across the EAC because variations in the distance between a costal country i and non coastal country j or between country i neighbor/far from country j determines the cost of transport between those two countries i and j.

Therefore, this study tries to explore cereals price volatility and transmission among five countries of six member states of EAC (Burundi, Kenya, Rwanda, Uganda and Tanzania) and South Sudan is not included in the current analysis. These countries were chosen based on three dimensions. First, they are in the same community which has implement different agricultural policies to increase cereals productivity and with a common import tariff. Second, they are linked by two commercial corridors (the northern and central corridors) that can facilitate easy market integration in EAC and intra-imports of cereals. Third, they are different in terms of surface, population density and location which may define differences in the level of cereals production and demand across EAC member states and then trade level with the world market determined by the factor that coastal countries (Kenya, Tanzania) have easy access to world market than non-coast countries (Burundi, Rwanda and Uganda).

Given these three dimensions, this study aims to answer the following three main questions: i) Does the volatility in the market price of cereals occurs at the same degree in those five countries? ii) Is there any interrelationship between domestic markets price volatility and transmission in those countries? And iii) If there is any price transmission, what is the speed of cereal price adjustment from price variations caused by a one unit shock in one market to cereal price short-run and long-run equilibrium in other markets and in that market its self?

2. Methodology and data

The literature, James (1998), Michael and Daniel (2005), Michael and Daniel (2007), Jan (2009), Shuai (2012), Fabio and Matteo (2013), has shown the increasing use of PVAR and SPVAR models in measuring volatility and transmission in financial time series. This paper adopts and explains the application of PVAR and SPVAR models with multiple commodities to econometrically analyze food price volatility and transmission across countries members of EAC. The application of Panel VAR model with multiple commodities allows us to combine food commodities and countries to estimate price volatility and transmission. The PVAR and SPVAR models adopted in this paper are panel in the price of commodities at each market (in

this paper we consider each country member of EAC as a market) "Pc_{it}" where P stands for price and c stand for country/market and {Pc_{it}: Price of i^{th} commodity at time t in country/market c}.

Hence the PVAR model of lag 2 can be specified as:

$$Pc_{it}= V+ \beta_1 Pc_{it-1}+\beta_2 Pc_{it-2} +u_{it}(1)$$

where i represents different prices of cereal commodities (wheat, rice, maize, and sorghum); V is the vector of cereal price effect at each market (*Pb = cereal price at Burundi market, Pk = cereal price at Kenya market, Pr = cereal price at Rwanda market, Pu = cereal price at Uganda market, and Pt = cereal price at Tanzania market*); β_1 and β_2 are the coefficients of variables (*Pb, Pk, Pr, Pu and Pt*) in lag(1) and lag(2) and u_{it} is the vector of error terms.

The SPVAR of lags 2 can be specified as:

$$Pc_{it}= V + \beta_1 S_1 Pc_{it-1}+ \beta_2 S_1 Pc_{it-2} + u_{it} \text{ and } u_{it} =S_2 e_{it} \qquad (2)$$

where S_1 and S_2 are fixed matrix of spatial weights. In this SPVAR model, only the neighbors have dynamic repercussion on market c within one period while the rest is assumed to have negligible effects. SPVAR structure implies that a shock originating in market c can be transmitted after one period to market k if market k is a neighbor of market c. However, if market k is not a neighbor of market c, delayed effects are longer and will depends on how many markets are between market k and market c.

All the original data used in this paper are available and calculated from online database of the FAO that publishes data on the price of agricultural commodities. We consider to use the annual average of the producer price of four cereal commodities at five markets. We choose the sample period covering 1991 to 2014. For incomplete series like Uganda series, the price were sourced from other different sources and extrapolation and interpolation techniques were used to estimate the price of incomplete series. For the purpose of analysis, the price of each i cereal commodity is expressed in USD per Kg. A part from the actual price of cereals used in this paper, this paper acknowledge the effect of spatial distribution of markets across EAC on price volatility and transmission, here to capture the spatial effects we estimate the new prices at each market with spatial effects Pc^*_{it} (See Annex 1: Extended methodology).

3. Empirical findings and discussion

3.1. Unit root test

In order to infer the degree of integration and stationary properties of the respective variables and uncover if there are possibilities for undertaking panel co-integration tests, we rely on Pesaran (CIPS, 2007) test. Results in Table 1 reject the null hypothesis that all series are I(1) at 5% and 10% (without and with trend) in prices without spatial effects and at 1% and 5% (without and with trend) level of significance in prices with spatial effect. Therefore, cereal price at all the five markets are I(0). The precondition to test for cointegration is that all of the series must be integrated of order 1 "I(1)". However, as our data are integrated of order Zero "I(0)" we proceed with VAR and there is no evidence of testing for co-integration and then proceed with VECM. As we are using panel data, in this paper we estimate a panel VAR model and a Spatial Panel VAR both of lags(2) in the next section of this paper.

Table 1 - Pesaran (2007) Panel Unit Root test (CIPS)

	Without spatial effect		With spatial effect	
Variable	Without trend	With trend	Without trend	With trend

3.2. PVAR and SPVAR models estimation

We estimate PVAR and SPVAR using a least squares dummy variable estimator. The estimator fits a multivariate panel regression of each dependent variable on lags of itself and on lags of all the other dependent variables. The analysis of the PVAR and SPVAR models can be divided into three parts. First, PVAR and SPVAR by least squares dummy variable estimator method estimate model coefficients to explain the relationship among variables. Second, they estimate impulse response functions to draw the figures of dynamic shock responses, from which we can observe the dynamic changes of each variable under different shocks. Finally, they estimate result of variance decompositions for each variable, to evaluate the contributions of different stochastic shocks on the variables in the PVAR and SPVAR systems.

On one hand, when spatial effects are not taken into account, PVAR results in Table 2can be summarized under five headings:

- When Burundi cereal market is taken as dependent variable, a one unit shock at Burundi market one time back and Uganda market two time back increase the current cereal price at Burundi market to some degree (0.898 and 1.214) while a one unit shock at Kenya market two time back decreases the current cereal price in Burundi (-0.55).

- When Kenya cereal market is taken as dependent variable, a one unit shock at Kenya market one time back increases the current cereal price in Kenya at some degree (0.731).

- When Rwanda cereal market is taken as dependent variable, a one unit shock at Burundi market two time back decreases the current cereal price in Rwanda (-0.653).

- When Uganda cereal market is taken as dependent variable, a one unit shock in Burundi market two time back decreases the current cereal price in Uganda(-0.461).

- When Tanzania cereal market is taken as dependent variable, a one unit shock at Rwanda market one time back decreases current cereal price in Tanzania (-0.293).

On the other hand, when spatial effects are taken into account, results in Table 2can be summarized under four headings

- When Burundi cereal market is taken as dependent variable, a one unit shock in at Burundi market two time back increases the current cereal price in Burundi (0.785).

- When Kenya cereal market is taken as dependent variable, a one unit shock at Kenya market two time back increase the current cereal price in Kenya (2.681) while a one unit shock at Rwanda market and Uganda market decreases the current cereal price in Kenya to some degree respectively of -2.424 and 2.340.

- When Rwanda cereal market is taken as dependent variable, a one unit shock in cereal price at Kenya, Tanzania and Burundi markets two time back increase the current cereal price in Rwanda (2.89, 1.67 and 0.55), while a one unit shock at Uganda and Rwanda markets two time back decrease the current cereal price in Rwanda (-2.606 and -2.545).

- When Tanzania cereal market is taken as dependent variable, a one unit shock at Burundi and Tanzania markets two time back increase the current cereal price in Tanzania (0.715 and 1.650) while a one unit shock at Uganda and Rwanda markets two time back decrease the current cereal price in Tanzania (-2.281 and -2.608).

	cons	0.084	0.008	0.071	0.002	0.077	0.001	0.059	0.021	0.058	0.014

When results without spatial effects are compared with results that account spatial effects, it is clear to say that the level of two time back to predict variations in the current cereal price across countries member of EAC increases and the number of markets influencing the variations in the current price of cereal at any given market also increases. The typical examples can be taken at Kenya, Rwanda and Tanzania markets. This can be summarized under two headings:

- Results show that it takes time for spatial effects to influence the current price happening at markets (most significant effects are those from two time back from the current price).

- Results also demonstrates that the effects of price variations in one market to the price variations in the other market are high with spatial effects than those estimated without spatial effects. This suggests that price volatility and transmission are more predictable in prices with spatial effects than in those without spatial effects.

3.3. Impulse Response Functions

In order to assess the two-way cereal price effects among Burundi, Kenya, Rwanda, Uganda and Tanzania cereal markets, we compute impulse-response functions of the PVAR and SPVAR models. The usefulness of Impulse Response Functions is to describe the reaction of one variable to innovations in another variable of the system, while holding all other shocks equal to zero. In Annex 3, we present impulse-response functions plots, response being absorbed during 30 periods ahead and their results can be summarized as follows:

In cereal price without spatial effects,

- A one unit shock at Burundi market causes positive and measurable cereal price variations in all other four markets which effects may die out in long-run.

- A one unit shock at Kenya market causes positive and measurable cereal price variations in all other four market which effects may not die out in the long-run and remain positive.

- A one unit shock at Rwanda causes positive and measurable variations cereal price variations in all other four market which effects may die out in the long-run and remain positive.

- A one unit shock at Uganda market causes positive and measurable cereal variations in all other markets which variations effects may die out in the long-run.

- A one unit shock at Tanzania market causes negative and measurable cereal price variations in all other markets which variations effects may die out in the long-run.

In cereal price with spatial effects:

- A one unit shock at Burundi market causes positive and considerable cereal price variations in all other four markets which effects may not die out in the long-run and remain positive.

- A one unit shock at Kenya market causes positive and considerable cereal price variations in all other four markets which variations effects may totally die out in the long-run.

■ A one unit shock at Rwanda market causes positive but not considerable cereal price variations in all other four markets which effects may quickly and totally die out in short-run.

■ A one unit shock at Uganda market causes positive and considerable cereal price variations in all other four markets which effects may not die out in long-run and remain positive.

■ A one unit shock at Tanzania market causes positive and considerable cereal price variations in all other four markets which effects may not die out in long-run and remain positive.

Impulse response functions show that a one unit shock in one cereal market create persistence and positive variations in cereal price at that market its self and at the other markets. The only exceptions were observed when Tanzania is taken as impulse in only cereal prices without spatial effect and when Rwanda cereal market is taken as impulse in only cereal prices with spatial effects.

3.4. Variance Decompositions

Based on the impulse response function above, we can evaluate the relative importance of different structural shocks to endogenous variables by measuring the contributions of shocks on the variance changes of variables. Table 7 reports variance decompositions derived from the orthogonalized impulse-response coefficient matrices. The variance decompositions display the proportion of movements in the dependent variables that are due to their own shocks versus shocks to the other variables, which is done by determining how much of an s-step ahead forecast error variance of mean squared error (MSE) for each variable is explained by innovations to each explanatory variable (we report S until 30). From Table 3, we can highlight five following points:

■ A shock in cereal price in Burundi has the biggest impact on the variations of cereal price in Burundi in both short-run and long-run with a gradual declining trend. With spatial effect, a shock in Burundi, Kenya and Uganda has the biggest impact on the variations of cereal price in Burundi when compared to a shock in other markets.

■ A shock in cereal price in Kenya and Uganda has the biggest impact on the variations of cereal price in Kenya in both short-run and long-run. With spatial effect, a shock in Kenya and Rwanda has the biggest impact on the variations of cereal price in Kenya compared to a shock in other markets.

■ A shock in cereal price in Rwanda and Tanzania has the biggest impact on the variations of cereal price in Rwanda in both short-run and long-run. With spatial effect, a shock in Rwanda and Tanzania has the biggest impact on the variations of cereal price in Rwanda when compared to a shock in other markets.

■ A shock in cereal price in Rwanda, Uganda, Kenya, Tanzania, and Burundi has the biggest impact on the variations of cereal price in Uganda in both short-run and long-run. With spatial effect, a shock in Uganda, Tanzania, Kenya, Burundi and Rwanda has the biggest impact on the variations of cereal price in Uganda both in short-run and long-run.

■ A shock in cereal price in Tanzania has the biggest impact on the variations of cereal price in Tanzania in both short-run and long-run. With spatial effect, a shock in Uganda, Tanzania, Kenya, Burundi and Rwanda has the biggest impact on the variations of cereal price in Tanzania both in short-run and long-run.

Table 3 - Variance decomposition

		Without Spatial Effect					With Spatial effect

In terms of 100% variations along 30 steps ahead from the current price caused by a one unit of shock in the price of cereals at each market, results can be summarized under five headings:

- From a one unit shock at Burundi market, strong variations are reverberated in the price of cereals in Burundi and Uganda in the price without spatial effects, while with spatial effects strong variations are reverberated in the price of cereals in Tanzania.

- From a one unit shock at Kenya market, strong variations are reverberated in the price of cereals in Uganda and somehow in Kenya in prices without spatial effects, while with spatial effects strong variations are reverberated in the price of cereals in Tanzania.

- From a one unit shock at Rwanda, strong variations are reverberated in the price of cereals in Uganda in prices without spatial effects, while with spatial effects strong variations are reverberated in the price of cereals in Tanzania and somehow in Kenya.

- From a one unit shock at Uganda, strong variations are reverberated in the price of cereals in Uganda in the price without spatial effects, while with spatial effects strong variations are reverberated in the price of cereals in Tanzania.

- From a one unit shock at Tanzania, strong variations are reverberated in the price of cereals in Uganda in the price without spatial effects, while with spatial effects strong variations are reverberated in the price of cereals in Tanzania its self.

4. Conclusion

This paper adopts and explains the application of Panel Vector Autoregressive (PVAR) and Spatial Panel Vector Autoregressive (SPVAR) models to econometrically analyze food price volatility and transmission across countries members of East African Community (EAC). The main results of this paper suggest that it takes time for spatial effects to influence the current cereals price happening at markets. This paper uncovered that cereal price volatility and transmission across EAC are more predictable in prices with spatial effects than in those without spatial effects. Furthermore, the results of this paper demonstrate that a one unit shocks in one cereal market across EAC create persistence and positive cereal price variations in that market and in the other markets. Moreover, this paper shows that price variations caused by a one unit shock in the price of cereals at one market create strong variations that, in short and long-run, are reverberated in the price of cereals in the other markets across EAC.

It is very important for policy makers to recognize the relationship among different prices of cereals across different countries, because they provide us with new thoughts into food security analysis. Therefore, two policy implications may flow from this paper. On one hand, since there is a short-run and long-run relationship among cereals prices across EAC, agricultural policies should focus on ensuring crop yield stability and enhancing regional food distribution system in order to stabilize food prices across the EAC in particular and ensure and improve regional food access in general. On the other hand, as the main results of this paper show that spatial distribution of markets highly contributes to cereal price volatility and transmission across the region, trade policies should be formulated considering the gains of trading with the nearneighboring markets. This last may be taken into consideration in order to avoid delayed spatial effects on price volatility and transmission from which when a market *k* is not a neighbor of market *c* the delayed spatial effects depends on the number of neighboring markets between market *k* and market *c* and the price prevailing on those markets.

Annex 1: Extended Methodology

a. Hausman's (1978) test to choose between fixed and random effects model

Hausman's (1978) specification test compares an estimator $\ddot{\theta}_1$ that is known to be consistent with an estimator $\hat{\theta}_2$ that is efficient under the assumption being tested. The null hypothesis is that the

estimator is indeed an efficient (and consistent) estimator of the true parameters. If this is the case, there should be no systematic difference between the two estimators. The Hausman statistic is distributed as chi-square and is calculated as $H = (\beta_c - \beta_e)'(V_c - V_e)^{-1}(\beta_c - \beta_e)$. Where β_c is the coefficient vector from the consistent estimator, β_e is the coefficient vector from the efficient estimator, V_c is the covariance matrix of the consistent estimator and V_e is the covariance matrix of the efficient estimator. When the difference in the variance matrices is not positive definite, a Moore–Penrose generalized inverse is used.

b. Panel cross-section dependence tests

To test for cross-sectional independence in balanced panels,

$$H_0: \hat{\rho}_{ij} = \hat{\rho}_{ji} = cor\,(u_{it}, u_{jt}) = 0 \text{ for } i \neq j \text{ and } H_1: \hat{\rho}_{ij} = \hat{\rho}_{ji} \neq 0 \text{ for } i \neq j. \quad \text{(A1)}$$

Pesaran's (2004) CD test rely on the following formula

$$CD = \sqrt{\frac{2T}{N(N-1)}}\left(\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}\hat{\rho}_{ij}\right) \text{and } \hat{\rho}_{ij} = \hat{\rho}_{ji} = \frac{\sum_{t=1}^{T}\hat{u}_{it}\hat{u}_{jt}}{(\sum_{t=1}^{T}\hat{u}_{it}^2)^{1/2}(\sum_{t=1}^{T}\hat{u}_{jt}^2)^{1/2}}. \quad \text{(A2)}$$

Where $\hat{\rho}_{ij}$ is the sample estimate of the pairwise correlation of the residuals and $\hat{u}_{it}$ is the estimate of u_{it} (panel residuals). Under the null hypothesis, u_{it} is assumed to be independent and identically distributed *(i.i.d.)* over periods and across cross-sectional units. Under the alternative, u_{it} may be correlated across cross sections, but the assumption of no serial correlation remains. The number of possible pairings (u_{it}, u_{jt}) rises with N. The *CD* formula shows that under the null hypothesis of no cross-sectional dependence $CD \xrightarrow{d} N(0, 1)$ for $N \rightarrow \infty$ and T sufficiently large.

Friedman (1937) proposed a nonparametric test based on Spearman's rank correlation coefficient. The coefficient can be thought of as the regular product-moment correlation coefficient, that is, in terms of proportion of variability accounted for, except that Spearman's rank correlation coefficient is computed from ranks. In particular, if we define $\{r_{i,1},\ldots,r_{i,T}\}$ to be the ranks of $\{u_{i,1},\ldots,u_{i,T}\}$ such that the average rank is $(T + 1/2)$, Spearman's rank correlation coefficient is given by $r_{ij} = r_{ji}$ and Friedman's statistic which is based on the average Spearman's correlation is given R_{ave}. Hence

$$r_{ij} = r_{ji} = \frac{\sum_{t=1}^{T}\{r_{i,t}-(T+\frac{1}{2})\}\{r_{j,t}-(T+\frac{1}{2})\}}{\sum_{1=1}^{T}\{r_{i,t}-(T+\frac{1}{2})\}} \text{and } R_{ave} = \frac{2}{N(N-1)}\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}\hat{r}_{ij}. \quad \text{(A3)}$$

where $\hat{r}_{ij}$ is the sample estimate of the rank correlation coefficient of the residuals. Large values of Rave indicate the presence of nonzero cross-sectional correlations. Friedman showed that $FR = (T - 1)\{(N - 1) Rave + 1\}$ is asymptotically χ^2 distributed with $T - 1$ degrees of freedom, for fixed T as N gets large.

c. Unit root test

Pesaran's (2007) cross-sectionally augmented unit root tests are designed for cases where cross-sectional dependence is due to a single factor. Pesaran (2007) suggests a cross-sectionally augmented Dickey-Fuller (CADF) test where the standard DF regressions are augmented with cross-sectional averages of lagged levels and first differences of the individual series. He also considers a cross-sectional augmented IPS (CIPS) test, which is a simple average of the individual CADF-tests. Null for CIPS tests series is I(1) and CIPS test assumes cross-section dependence is in form of a single unobserved common factor.

d. PVAR model of lag 2

We can set the panel VAR model of lag two by writing (1) in matrix form as:

$$\begin{pmatrix} Pb_{it} \\ Pk_{it} \\ Pr_{it} \\ Pu_{it} \\ Pt_{it} \end{pmatrix} = \begin{pmatrix} V_{bj} \\ V_{kj} \\ V_{rj} \\ V_{uj} \\ V_{tj} \end{pmatrix} + \begin{pmatrix} \theta_{11i1} & \theta_{12i1} & \theta_{13i1} & \theta_{14i1} & \theta_{15i1} \\ \theta_{21i1} & \theta_{22i1} & \theta_{23i1} & \theta_{24i1} & \theta_{25i1} \\ \theta_{31i1} & \theta_{32i1} & \theta_{33i1} & \theta_{34i1} & \theta_{35i1} \\ \theta_{41i1} & \theta_{42i1} & \theta_{43i1} & \theta_{44i1} & \theta_{45i1} \\ \theta_{51i1} & \theta_{52i1} & \theta_{53i1} & \theta_{54i1} & \theta_{55i1} \end{pmatrix} \begin{pmatrix} Pb_{it-1} \\ Pk_{it-1} \\ Pr_{it-1} \\ Pu_{it-1} \\ Pt_{it-1} \end{pmatrix} + \begin{pmatrix} \theta_{11i2} & \theta_{12i2} & \theta_{13i2} & \theta_{14i2} & \theta_{15i2} \\ \theta_{21i2} & \theta_{22i2} & \theta_{23i2} & \theta_{24i2} & \theta_{25i2} \\ \theta_{31i2} & \theta_{32i2} & \theta_{33i2} & \theta_{34i2} & \theta_{35i2} \\ \theta_{41i2} & \theta_{42i2} & \theta_{43i2} & \theta_{44i2} & \theta_{45i2} \\ \theta_{51i2} & \theta_{52i2} & \theta_{53i2} & \theta_{54i2} & \theta_{55i2} \end{pmatrix} \begin{pmatrix} Pb_{it-2} \\ Pk_{it-2} \\ Pr_{it-2} \\ Pu_{it-2} \\ Pt_{it-2} \end{pmatrix} + \begin{pmatrix} \mu_{1it} \\ \mu_{2it} \\ \mu_{3it} \\ \mu_{4it} \\ \mu_{5it} \end{pmatrix} \quad (A4)$$

where i represents different prices of cereal commodities (wheat, rice, maize, and sorghum); v is the vector of cereal commodity effect at each market; θ are the coefficient matrices of variables (Pb, Pk, Pr, Pu and Pt) in lag(1) and lag(2).

e. The SPVAR model of lags 2

In matrix form, first, we start by estimating the W matrix reflecting first order rook's contiguity relations for the five markets which is a symmetric matrix. As we are dealing with the price of cereal commodities at five markets in EAC (Burundi, Kenya, Rwanda, Uganda, and Tanzania), W is a square matrix of 5X5 dimensions that record neighborhoods among the markets. From the first row: the neighboring markets to Burundi market are Rwanda and Tanzania. From the second row: the neighboring markets to Kenya market are Uganda and Tanzania. From the third row: the neighboring markets to Rwanda market are Burundi, Uganda and Tanzania. From the fourth row: the neighboring markets to Uganda market are Kenya, Rwanda and Tanzania. From the third row: the neighboring markets to Rwanda market are Burundi, Uganda and Tanzania. From the fifth row: the neighboring markets to Tanzania market are Burundi, Kenya, Rwanda and Uganda. Second, we transform W matrix in the way of having row-sums of unity to get a standardized first-order contiguity matrix noted as C. And then we combine C and Pc_{it} a vector column matrix to have new prices Pc^*_{it} with spatial effects. And for simplicity, the new price for i commodity at t time at each market is the arithmetic mean of the price of that i commodity at t time of neighboring markets:

$$W = \begin{pmatrix} 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 1 & 0 \end{pmatrix} and C \begin{pmatrix} 0 & 0 & 1/2 & 0 & 1/2 \\ 0 & 0 & 0 & 1/2 & 1/2 \\ 1/3 & 0 & 0 & 1/3 & 1/3 \\ 0 & 1/3 & 1/3 & 0 & 1/3 \\ 1/4 & 1/4 & 1/4 & 1/4 & 0 \end{pmatrix} \qquad (A4)$$

$$\begin{pmatrix} Pb^*_{it} \\ Pk^*_{it} \\ Pr^*_{it} \\ Pu^*_{it} \\ Pt^*_{it} \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1/2 & 0 & 1/2 \\ 0 & 0 & 0 & 1/2 & 1/2 \\ 1/3 & 0 & 0 & 1/3 & 1/3 \\ 0 & 1/3 & 1/3 & 0 & 1/3 \\ 1/4 & 1/4 & 1/4 & 1/4 & 0 \end{pmatrix} \begin{pmatrix} Pb_{it} \\ Pk_{it} \\ Pr_{it} \\ Pu_{it} \\ Pt_{it} \end{pmatrix} = \begin{pmatrix} 0.5Pr_{it} + 0.5Pt_{it} \\ 0.5Pu_{it} + 0.5Pt_{it} \\ 1/3Pb_{it} + 1/3Pu_{it} + 1/3Pt_{it} \\ 1/3Pk_{it} + 1/3Pr_{it} + 1/3Pt_{it} \\ 1/4Pb_{it} + 1/4Pk_{it} + 1/4Pr_{it} + 1/4Pu_{it} \end{pmatrix} \qquad (A5)$$

After then, we write (2) in matrix form as follows:

$$\begin{pmatrix} Pb^*_{it} \\ Pk^*_{it} \\ Pr^*_{it} \\ Pu^*_{it} \\ Pt^*_{it} \end{pmatrix} = \begin{pmatrix} V_{1j} \\ V_{2j} \\ V_{3j} \\ V_{4j} \\ V_{5j} \end{pmatrix} + \begin{pmatrix} \rho_{11i1} & \rho_{12i1} & \rho_{13i1} & \rho_{14i1} & \rho_{15i1} \\ \rho_{21i1} & \rho_{22i1} & \rho_{23i1} & \rho_{24i1} & \rho_{25i1} \\ \rho_{31i1} & \rho_{32i1} & \rho_{33i1} & \rho_{34i1} & \rho_{35i1} \\ \rho_{41i1} & \rho_{42i1} & \rho_{43i1} & \rho_{44i1} & \rho_{45i1} \\ \rho_{51i1} & \rho_{52i1} & \rho_{53i1} & \rho_{54i1} & \rho_{55i1} \end{pmatrix} \begin{pmatrix} Pb^*_{it-1} \\ Pk^*_{it-1} \\ Pr^*_{it-1} \\ Pu^*_{it-1} \\ Pt^*_{it-1} \end{pmatrix} + \begin{pmatrix} \rho_{11i2} & \rho_{12i2} & \rho_{13i2} & \rho_{14i2} & \rho_{15i2} \\ \rho_{21i2} & \rho_{22i2} & \rho_{23i2} & \rho_{24i2} & \rho_{25i2} \\ \rho_{31i2} & \rho_{32i2} & \rho_{33i2} & \rho_{34i2} & \rho_{35i2} \\ \rho_{41i2} & \rho_{42i2} & \rho_{43i2} & \rho_{44i2} & \rho_{45i2} \\ \rho_{51i2} & \rho_{52i2} & \rho_{53i2} & \rho_{54i2} & \rho_{55i2} \end{pmatrix} \begin{pmatrix} Pb^*_{it-2} \\ Pk^*_{it-2} \\ Pr^*_{it-2} \\ Pu^*_{it-2} \\ Pt^*_{it-2} \end{pmatrix} + \begin{pmatrix} \varepsilon^*_{it} \\ \varepsilon^*_{it} \\ \varepsilon^*_{it} \\ \varepsilon^*_{it} \\ \varepsilon^*_{it} \end{pmatrix} \quad (A6)$$

where i represents different prices of cereal commodities (wheat, rice, maize, and sorghum); v i the vector of cereal commodity effect at each market; ρ are the coefficient matrices of variables (*Pb*, *Pk*, *Pr*, *Pu* and *Pt*) with spatial effect in lag(1) and lag(2).

Cassava output supply response in Nigeria: A Vector Error Correction Model (VECM) approach

O. A. Obayelu | Department of Agricultural Economics, University of Ibadan | Ibadan | Nigeria
S. Ebute | Department of Agricultural Economics, University of Ibadan | Ibadan | Nigeria

DOI: 10.1481/icasVII.2016.c16c

ABSTRACT

The response of agricultural commodities to changes in price is an important factor in the success of any reform programme in agricultural sector of Nigeria. The producers of traditional agricultural commodities such as cassava face the world market directly. Consequently, the producer price of cassava has become unstable and this creates a dis-incentive for production thus making output and exports suffer. This study investigated cassava supply response to changes in price. Data collected from FAOSTAT from 1966 to 2010 were analysed using Vector Error Correction Model (VECM) approach. The results of the VECM for the estimation of short run adjustment of the variables toward their long run relationship showed a linear deterministic trend in the data and that Area cultivated and own prices jointly explain 74% and 63% of the variation in the Nigeria cassava output in the short run and long-run respectively. Cassava prices (P↓0.001) and land cultivated (P↓0.1) had positive influence on cassava output in the short-run. The short-run price elasticity was 0.38 indicating that price policies are effective in the short-run promotion of cassava production in Nigeria. However, in the long-run elasticity cassava does not responsive to price incentives significantly. This suggests that price policies are not effective in the long-run promotion of cassava production in the country owing to instability in governance and government policies.

Keywords: Cassava output price, Co-integration, long-run elasticity

PAPER

1. Introduction

In recent times, the producers of traditional agricultural commodities in Nigeria face the world market directly. They reap profits when prices are good but absorb shocks and suffer losses when prices fall. Consequently, the producer price of these commodities has become unstable and this creates a dis-incentive for production, thus making output and exports to suffer (Mesike et al., 2008). This could have negative implications for the agricultural industry and for the national income. Consequently, the prices at which cassava and other cash crops farmers in Nigeria are able to sell their output, to a large extent, depend on how they respond to both local and global demand. For many low income countries, the impact of structural reforms on economic growth and poverty alleviation crucially depends on the response of aggregate agricultural supply to changing incentives. The ability of the agricultural policy community to respond to this challenge is impaired by relative scarcity of current market prices and missing information of basic information about the supply of agricultural output, which makes the forecasting of supply response difficult. Agricultural supply response is the change in agricultural output owing to a change in agricultural output price (Mythili, 2008) and this may be policy-induced. In Nigeria, the producers of traditional agricultural commodities like cassava face the world market directly. They reap profits when prices are good but absorb shocks and suffer losses when prices fall (Obayelu and Salau, 2010). Consequently, the producer's price of these commodities has become unstable and this create dis-incentive for production and thus making output and exports to suffer (Mesike et al., 2008). This could have negative implications for the agricultural industry and for the national income.

In agricultural development economics, the most important issue is supply response since the responsiveness of farmers to economic incentives largely determines agriculture's contribution to the economy. The response of agricultural supply to price movements has been the subject of long and vigorous discussion, going back to Nerlove's classic treatment of the long-run supply elasticity for corn, cotton and wheat in the United States (Nerlove 1958). Estimates of supply elasticity (short-run and long-run) based on the Nerlove model vary widely by crop and region. Furthermore, the response elasticities are also important for policy decision regarding agricultural growth. Therefore considering of these limitations, the current study utilizes the new developments of econometric techniques in analysis that can estimate distinct short-run and long run elasticities to overcome the problem usually encountered in the traditional Nerlovian model. However, the Error Correction Model (ECM) with co-integration analysis is preferred to the Nerlovian model because it not only overcomes the restrictive dynamic specification of the Nerlove method, but also captures the forward-looking behaviour of producers optimising their production in dynamic situations. ECM is used to analyse non-stationary time series that are known to be co-integrated.

The measurement of agricultural supply response not only prove useful to policy makers, it also facilitates informed decision making by farmers and other players in the production marketing chain and ultimately better prices for the consumers. The responsiveness of farmers to price and non-price incentive or disincentives will provide a clear picture of contribution of agricultural sector to the economy and this will depend often on the responsiveness of domestic agricultural production to price in particular. In Nigeria, a substantial literature on agricultural output supply response exists but little of this is directly relevant to cassava. However, crop-specific data on supply elasticities are needed to ensure relevant policy analysis. Ojiako et al., 2008 studied cassava output supply response but limited their studies to non-price factors. Any attempt to reform the structure of incentives provided by cassava farmers will require a detailed knowledge of cassava supply parameters. Hence, the use of VECM approach to investigate the response of cassava output supply to the real prices with a lapse of time. This study therefore analyzes cassava farmers' responsiveness on the price from the period of 1966 (when the first military coup took place) to 2010.

2. MATERIALS AND METHODS

The study sourced data from Food and Agricultural Organization of the United Nation (FAO), Central Bank of Nigeria (CBN) and National Bureau of Statistics (NBS). The variables chosen include cassava output, area, real prices of cassava, land area cultivated. Raw cassava price data from 1966 to 2010 were deflated using 2012 consumer price index. Each of the series was then tested for the presence of a unit root by estimating an Augmented Dickey Fuller (ADF) equation. The first lagged difference of all non-stationary series and again estimated ADF equation both with and without the deterministic trend.

The cointegration and the Vector Error Correction Model (VECM) were estimated using the Johansen (1988) test which estimates Vector Error Correction Models (VECM) of the form:

$$\Delta Y_t = c + \sum_j \alpha_j \Delta Y_{t-1} + \delta D_t + \gamma T + \lambda \varepsilon_{t-1} + \vartheta_t \quad (1)$$

$$\varepsilon_{t-1} = lnY_{t-1} - \sum_j \beta_j Y_{jt-1} \text{ (error/equilibrium correction term)} \quad (2)$$

Where where Δ is the deference operator such that $\Delta Y_t = Y_t - Y_{t-1}$, Ys are the (assumed) co-integrated time series variables (including pervious supply levels $Y_{t-n}$and explanatory variablesX_{t-n}). D_t is a vector of stationary exogenous variables; δ is vector of parameters of exogenous variables; λ is the coefficient of error correction term ε_{t-1}. αj and βj are respectively vectors of short-run and long-run supply elasticities with respect to factor j.

The Johansen method provides two likelihood ratio tests, namely the Trace and the Maximum Eigen Value statistic tests, which are used to determine the number of co-integrating equations given by the co-integration rank r. A co-integration equation is the long-run equation of co-integrated series. The Trace statistic tests the null hypothesis of r co-integrating relations against the alternative of k co-integrating relations, where k is the number of endogenous variables for r = 0, 1,..., k – 1. The Maximum Eigen Value statistic tests the null hypothesis of r co-integrating vectors against the alternative of r + 1 cointegrating vectors.

When the co-integration rank r is equal to 1, the normalisation restriction for the parameters produces a unique estimate of what the economic theory suggests (Golinelli, 2003). However, when there is more than one co-integration equation the Johansen approach to co-integration analysis is preferred to the Engle-Granger approach (Thiele, 2003).

The VECM was specified as:

$$\Delta \ln Y_t = c + \alpha_0 \Delta \ln P_{t-1} + \alpha_1 \Delta \ln k_{t-1} + \alpha_2 \Delta \ln C_{t-1} + \gamma T + \lambda \varepsilon_{t-1} + \vartheta_t \quad (3)$$

Where $\varepsilon_{t-1} = \ln Y_{t-1} - \beta_1 \ln P_{t-1} - \beta_2 \ln K_{t-1} - \beta_3 \ln C_{t-1}$

For this study:

$$\Delta \ln Y_{t-1} = C + \alpha_0 \ln P_{t-1} + \alpha_1 \ln A_{t-1} + \varepsilon_{t-1} \quad (4)$$

Where:

Y_{t-1} = lagged Output

P_{t-1} = lagged price of cassava

A_{t-1} = lagged Area of land cultivated

C = Constant

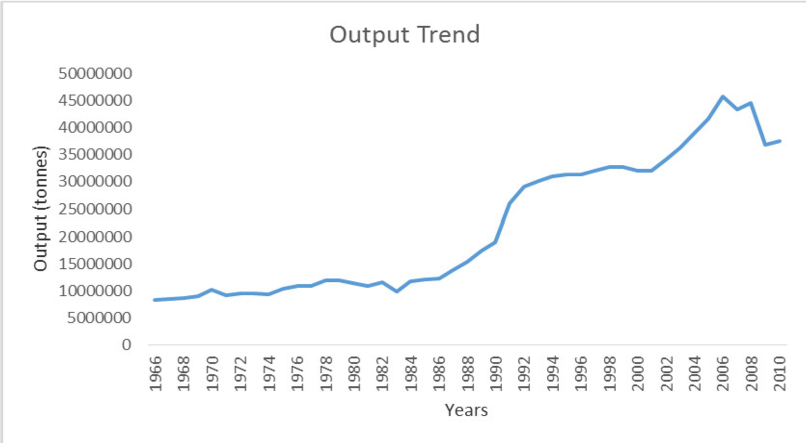
ε_{t-1} = lagged Error term

3. RESULTS AND DISCUSSION

The trend analysis in Figure 1 shows that between the periods of 1966-1985, what has popularly come to be known as the pre-Structural Adjustment Program (SAP) era, cassava production was at best described as stagnant as there was no real growth in the sector. This was the outcome of the oil boom of the 1970s, which later led to the "Dutch syndrome". In the late 1980s, the military regime international financial institutions supported the introduction of Structural Adjustment Programme (SAP) in Nigeria to correct market and price distortions. The SAP was a policy measure towards a more market-friendly trading system and the dissolution of commodity marketing boards as well as elimination of the heavy dependence on crude oil export and import of consumer and producer good (Ihimodu, 1993). During the SAP era, cassava output grew steadily from about 10 million tonnes (MT) in 1985 to 30 MT 1994. Thereafter, it took a downward trend but for the timely intervention of the Presidential Cassava Initiative under the Obasanjo regime from 1999 to 2007 and peaked in 2006 to about 49 MT.

Efforts of the Obasanjo regime to diversify the Nigerian economy from an oil-based economy led to growth in the agricultural sector including the exponential expansion of cassava production from 2003 to 2007. However, the glut created in the market, which coincided with a change in government and government policy focus, led to sharp decline in cassava output to about 35 MT in 2008. The seven-point agenda of the Yaradua government included agricultural sector development but were later actualised by Goodluck Jonathan regime. Local content policies, such as the popular cassava flour inclusion in the milling industry and bilateral agreements with multinationals in the textile and the pharmaceutical industries, resulted in the upward trend of cassava output in 2010.

Figure 1 - Trend Analysis of Cassava Production Output



Trend Analysis of Raw Cassava Prices

The agricultural production like any other around the world responds not only to non-price factors such as policies and weather but also to price incentives. Figure 2 shows that cassava prices were low and stable relatively during the pre-SAP period (1966-1985) but a sharp change is noticed in the price movement which also corresponds with exponential increase in production output immediately after the introduction of SAP. The sharp decline in the price of cassava around 2008 can be attributed to the glut in the market at the period. From then onwards, there has been an undulating increase in the trend of cassava price.

Figure 2 - Trend Analysis of Cassava Prices.

Stationarity Tests

The unit root test using the Augmented Dickey Fuller (ADF) is presented in Table 1 shows that that all the variables are non-stationary in their levels but are stationary at first differences. The test used the MacKinnon (1991) critical values for the rejection of the null hypothesis of no unit root. This indicates that the variables are I(1) and any attempt to specify the dynamic function of the variable in the level of the series will be inappropriate and may lead to spurious results and not such results cannot be used for prediction in the long-run (Mesike et al., 2010). Therefore, the test of co-integration was applied to the series data which were integrated in the same order I(1) and did not have a unit root.

Table 1 - Augmented Dickey Fuller (ADF) Stationarity Test Results

ADF Test Critical Values					
Variables	Statistics	1%	5%	10%	Inference
D(Y)	0.5469	-3.6056	-2.9369	-2.6069	I(0)
	-3.6416	-3.6105	-2.9390	-2.6080	I(1)
D(A)	-1.6330	-4.9809	-3.5155	-3.1883	I(0)
	-5.8244	-4.1865	-3.5181	-3.1897	I(1)

	-4.7951	-4.2050	-3.5266	-3.1946	I(1)

Key: ADF = Augmented Dickey Fuller; I(0) = non-stationary at level; I(1) = stationary at first difference; D(Y) = Output of Cassava; D(A) = Area; D(P) = Price of Cassava;

Cointegration Test

The Johansen's co-integration test shows the presence of three co-integrating equations at 5% level of significance implying that there is a common trends in the process (Table 2). The co-integration tests are to test whether there is a statistical significant linear relationship between the different time-series data. Test statistics from the maximum Eigen value are consistent in suggesting that there are two integrating vectors among the variables. This implies that the explanatory variables are co-integrated and have short run and long run relationships with the dependent variable.

The statistical evidence of co-integration supports the theory of long-run equilibrium between supply and output. It also supports three co-integration relation between the series and hence the decision regarding co-integration equation. The results, based on both the trace test and maximum Eigen value test showed the existence of three co integrating vectors and the rejection of the null hypothesis of r = 0. Thus, there is a long-run co-integrating relationship among the variables. This is consistent with the findings of Hallam and Zanoli (1992) as cited in Obayelu and Salau (2010) that where only one co-integrating equation exists, its parameters can be interpreted as estimate of long-run co integrating relationship between the variables concerned.

Table 2 - Summary of Co integration Test. (Result of Johansen Trace Test).

Hypothesised No. of CE	Null Hypothesis	Alt. Hypothesis	Eigen Value	Trace Stat.	5% Critical value
None	r = 0	r=1	0.6611	92.6800	69.8188*

Atmost 3	r<3	r=4	0.2974	12.4147	15.4949
Atmost 4	r<4	r=5	0.0122	0.4157	3.8415

Hp: rank = p(no deterministic trend in data) Hr: rank r<p Co integration relations.
** (*) denotes rejection of hypothesis at 5% (1%) significant levels. Test indicates 3 cointegrating equations(CE) at 5%.

Vector Error Correction Estimates

Lagged variables were used in the estimation of cassava output, as the production decisions of the famers are mostly made in the previous period and they are not altered on real time basis due to change in any of the variables. The result shows that the independent variables jointly explain 74.01% of the variations in the cassava output in the short-run. The elasticity of current production with respect to previous production is 37.7%. Most parameter estimates are within reasonable ranges and suggests a relatively strong short-run supply response to prices, meaning an increase in aggregate cassava output in the short-run will lead to a decrease in the price of cassava (Obayelu and Salau, 2010). The estimated speed of adjustment was significant at one percent and this reveal that cassava supply adjusts to correct for short-run disequilibrium between itself and its price. The error correction coefficient was very high (98%) and has a negative sign as expected, suggesting that feedback mechanism is high in converging cassava supply towards long run equilibrium despite the shocks in cassava supply and prices.

Production decisions are mostly made in the previous year and they are not subject to alterations on real time basis due to change in any of the variables (Ozkan, 2011). Thus, considering the annual structure of the cassava production, the amount of production in the previous year is correlated with the current production. The negative sign on the lagged cassava output suggest that when there is a market glut in the previous period, cassava could be replaced with its substitutes such as yam and sweet potatoes. In other words, an increase in cassava supply resulting in a decline its price will make the famers shift cassava production to its close substitutes like yam, thereby reducing its output supply. This makes them eligible for this substitution in the long-run. The opportunity to utilize substitutes is a key proviso that is attributable to the negative constant of the estimation. The cassava price elasticity and the elasticity of farm size in the short-run were 0.38 and 0.27 respectively suggesting that a percentage increase in both the lagged price of cassava and farm size price lead to a less than proportionate percentage increase in aggregate cassava supply in the short-run. This indicates that cassava supply is price inelastic in the short-run. Also, cassava farmers in Nigeria do not make adequate short-run production expansion adjustments in response to changes in expected prices. This may be due to relative price stability overtime and non-price determinants of supply response.

Table 3 - Short-run Relationship Estimates.

Variables	Co-efficient	St. Error	t. value
C	-270459.2	238197.5	-1.135441
D(Y-1)	-0.377316***	0.118843	-3.174918
D(A-1)	0.2749004*	0.141884	1.937497
D(P-1)	0.382407***	0.104133	3.672281
E-1	-0.980299***	0.148231	6.613324

Dubin Wat. St.	1.014693		

(***) * Significant at (1%) and 10% respectively

In the long-run all the explanatory variables explain 63 percent of the variations in the cassava output. The coefficient of the error term is significant and greater than unity in the long-run and is consistent with the findings of Obayelu and Salau (2010), implying a high speed of adjustment towards equilibrium. In other words, the speed at which cassava output adjusts to the explanatory variables in the long-run is 100.5%, which is a marginal increase from 98% in the short-run. However, lagged cassava price is not significant in the long-run suggesting that price policies are not effective in the long-run promotion of cassava production in the country owing to instability in governance and government policies. This is consistent with the findings of Ozkan et al., 2013 that current production did not respond significantly to the lagged own price of wheat in the long-run in Turkey. However, it contrasts the findings of Ogundari and Nanseki (2013) that maize supply responds significantly and positively in the long run to own price in Nigeria.

(***) significant at 1%.

4. CONCLUSION

The result of the trend analysis showed that cassava development and production output have risen over the years in Nigeria in the recent past and that price plays a significant role in production decisions as evidenced by the fall in production around the period of 2008. Cassava has the potential to feed the growing population and still have reserves for export purposes if the current policies, initiatives are maintained and improved upon. It is recommended that policy makers (e.g. government) should come up with a way of stabilising production and price by taking care of the glut in the system. The farmers can also protect themselves from the effects of price fluctuations are to diversify by providing other value addition on cassava.

The area elasticity coefficient from the short run VECM analysis shows that increase in the area cultivated will lead to an increase in cassava output, efforts should therefore be put in place by government and extension agents to increase the area cultivated and improve the yield potentials in terms of productivity of the fields thereby maximising output.

It has been observed from the short run VECM study, that cassava has high price elasticity. Policies should be put in place that stabilises the price of cassava in the market.

C16 # Did the Fertilizer Cartel Cause the Food Crisis?

H. Gnutzmanna | Faculty of Economics and Management, Leibniz Universität | Hannover | Germany
P. Spiewanowski | Institute of Economics, Polish Academy of Sciences | Warsaw | Poland

DOI: 10.1481/icasVII.2016.c16d

ABSTRACT

Food commodity prices escalated during the 2007/2008 food crisis, and have scarcely fallen since. We show that high fertilizer prices, driven by the formation of an international export cartel as well as high energy prices, explains the majority of the recent price spikes. In particular, we estimate the pure fertilizer cartel effect explains up to 50% of crisis food price increases. While population growth, biofuels, high energy prices and financial speculation doubtlessly put stress on food markets, our results help to understand the severity and sudden emergence of the crisis and suggest avenues to prevent its repetition.

Keywords: food crisis, fertilizer, cartel, competition policy JEL: F10, L40, Q02

PAPER

1. Introduction

During the 2007–2008 food crisis, commodity prices escalated leading to food insecurity and political instability in the developing world (Timmer, 2010). Simultaneously an export cartel for fertilizer, an essential input to industrial crop production, established itself and fertilizer prices tripled (Jenny, 2012). This paper estimates that the cartel directly led to a 40-50% overcharge in the fertilizer market, which – through cost passthrough to agriculture – translated into up to a 20% increase in food prices. Since food prices rose on average by 40% during the crisis, we can attribute nearly 50% of the price increase to the formation of the fertilizer cartel. Moreover, while the cartel channel has apparently been overlooked in the literature so far, it can explain not only the severity but also sudden emergence of the food crisis which other explanations – such as population growth or high energy prices – do not. More generally, our results indicate an urgent need to better understand the role of export cartels in addressing future challenges to food security (Grote, 2014).

Commensurate to the importance of the food crisis, a large literature is developing to estimate its causes[2]. On the demand side, analysts emphasize population growth and rising per capita meat consumption (Trostle, 2010). Mitchell (2008) focuses on the role of biofuel subsidies in raising demand for crops, although subsequent research is ambiguous at best (Serra and Zilberman, 2013). Adverse supply shocks due to high energy prices are a potential explanation (Harri et al., 2009), although challenged by Zhang et al. (2010). Bad weather in some regions certainly did not help (Headey and Fan, 2010, chapter 2), although harvests were not unusually poor during the crisis period. Synchronous low grain stocks, or more precisely low stockto-use ratios is also frequently blamed (Bobenrieth et al., 2013). Current research and debate largely focuses on determining the relative importance of these causal factors to the food crisis[3]. Additionally, a growing body of research investigates the role of financial speculation in the food crisis, e.g. Irwin and Sanders (2012); Fattouh et al. (2013); Sanders and Irwin (2010), although there is considerable evidence against herd behaviour (Steen and Gjolberg, 2013). Finally, trade shocks (Headey, 2011) may have been a factor.

[2] Headey and Fan (2010) provide a very comprehensive survey

[3] One view is succinctly expressed by then-President George W. Bush in a White House press conference on 29.04.2008: "I thought it was 85 percent of the world's food prices are caused by weather, increased demand and energy prices ... 15 percent has been caused by ethanol"

Fertilizer has so far been at best at the sidelines of the discussion. While high fertilizer prices during the crisis are sometimes noted, they are often attributed to high energy prices (e.g. Headey and Fan (2010, p. 25)). Mitchell (2008) notes that "energy–intensive" components of total production costs account for 6.7%–13.4% in USDA farm survey data; but we know from economic theory that prices depend on marginal cost in a competitive industry. According to USDA (2014a), the average fertilizer cost share in years 1975-2013 accounted for 32% of the marginal cost of wheat and 37% of the marginal cost of maize.[4] High fertilizer prices can also have adverse impacts on the government budget of developing countries; e.g. Dorward and Chirwa (2011) point out that high fertilizer prices increased Malawi's fertilizer subsidy expenditures in 2008/2009. Yet we are not aware of previous literature taking fertilizer seriously as a driver of the food crisis, or estimating a formal econometric model in this direction.

An appreciation of the role of fertilizer may be crucial to understanding the past food crisis and mitigating future ones. Given the large share of agricultural marginal cost accounted for by fertilizer, strong price passthrough from fertilizer to food is predicted by standard economic theory[5]; careful econometric analysis is thus needed. Second, fertilizer prices are at times determined by an international export cartel (Hoekman and Saggi, 2007) or the degree of market concentration (Hernandez and Torero (2013)) and not market forces. Understanding the extent of the cartel overcharge is crucial to estimating the potential effects international competition enforcement against such cartels could have on food markets– particularly on developing countries, where households spend roughly half their income on food (Mitchell, 2008).

Contribution: We contribute to the literature in three ways. First, using established time series methodology (cf. Baffes (2010); Nazlioglu and Soytas (2011); Zhang et al. (2010)), we establish the strong cost passthrough from fertilizer to food. Second, we estimate the cartel overcharge (Connor and Bolotova, 2006; Connor, 2010) in the fertilizer market during the crisis period. Finally, we conduct a simulation of food prices in the counter–factual case that no cartel would have been formed and show that the majority of the crisis food price increase can be explained by the fertilizer cartel alone.

This paper proceeds by briefly presenting the role of fertilizers in modern agriculture and describing the fertilizer market. Subsequently, data and methods are introduced in section 3, succeeded by a discussion of the economic motivation of the regression equation and our the estimation strategy. We present results in section 4, and place them in the context of the literature. Section 5 simulates the development of food prices had no cartel been in place. Robustness checks are collected in section 6. Finally, we conclude.

2. Fertilizers and Market

Mineral fertilizers - nitrogen, potassium and phosphorus are the key nutrients crucial for plant growth and hence modern agriculture. The increase in use of commercial fertilizers was the main component of the so called green revolution and at least 30 to 50% of crop yield is attributable to commercial fertilizer nutrient inputs (Stewart et al., 2005). Currently the world fertilizers market is worth approximately $170 billion annually.

The fertilizer industry is conducive to cartelization, for individual nutrients and all three nutrients together. This feature of the fertilizer industry is based on heavy concentration of the essential mined inputs - potassium and phosphorus - where reserves are being exploited only in few countries and by few firms. Together with the high investment required in mining operations and the presence of export associations such as e.g. PhosChem and Canpotex, the fertilizer industry provides favorable conditions for collusion; indeed, cartel episodes have been documented since the late 19th century (see Taylor and Moss (2013) for a detailed study of the industry). Since the main input for nitrogen fertilizer is energy (used to convert atmospheric nitrogen to a nutritionally available form via the Haber-Bosch process), one would expect a higher degree of competitiveness on that market. However, many of the major phosphorus producers also manufacture nitrogen fertilizer, partly because a source of nitrogen is required to stabilize phosphorus, and partly because many fertilizer manufacturers sell blended nitrogen-phosphorus-potash fertilizer at wholesale and retail (Taylor and Moss (2013).

Furthermore, producers of fertilizers are often central to their local economies – e.g. PotashCorp for the Sasketchewan region of Canada – or indeed leading national exporters, as in the case of Office Cherifien des Phosphates (OCP) in Morocco or the Belarusian Potash Corporation, they are politically entrenched and backed by legal or de facto exemptions from usual antitrust enforcement.

[4] Those figures represent the share of marginal costs. For total costs one must add an overhead – largely the rental cost of capital and land, since US agriculture is not labor intensive. These overheads can be interpreted as a largely fixed cost, which should not affect competitive market prices.

[5] See section 3 for details

Dating the Cartel: The propensity of the fertilizer industry to establish cartels is well known (al Rawashdeh and Maxwell, 2014). However, competitive periods – after breakdown of a cartel – also occur. This makes it imperative to precisely date cartel periods for empirical analysis. Taylor and Moss (2013) conduct a detailed micro–level study to distinguish different phases of market competition in fertilizers. They conclude, based on qualitative and quantitative evidence, that the cartel exercised in market power in the 2008–2012 period[6].

Furthermore, there exists evidence suggesting a successful attempt to form a Moroccan–lead phosphates cartel in 1974. In that period, Morocco's share of the international market was 40 percent, and with the other African and Middle Eastern producers, Morocco controlled 55 percent of world trade in phosphates (Johnson, 1977). However, due to significant decrease in exports (by 30 percent) during 1975, Morocco was forced to announce a price reduction in January, 1976. Later that year the Afro-Arab Phosphate Commission (APC), an export group to which Morocco, Tunisia, Senegal, and Jordan belong, announced that they would not further tighten the supply highlighting that they only pursued price stabilization and a guaranteed minimum price.

3. Data and Methods

Model Specification: Our interest is in determining the price passthrough from fertilizer and energy indices on food prices. Thus, based on annual time series data, we estimate reduced form regressions explaining food commodity prices as a function of fertilizer and energy indicies, controlling for inflation and allowing a linear time trend. This yields the regression model:

$$\begin{aligned} log(X_t) &= \mu + \beta_1 log(\mathrm{FERTILIZERS}_t) + \beta_2 log(\mathrm{ENERGY}_t) \\ &+ \beta_3 log(\mathrm{MUV}_t) + \beta_4 log(\mathrm{USD}_t) + \tau t + \epsilon_t \end{aligned} \quad (1)$$

where t denotes a year between 1960 and 2013, $\mathrm{FERTILIZERS}_t$ is the index of fertilizer prices and ENERGY_t the index of energy prices; moreover, a price deflator, denoted MUV_t, US dollar exchange rate USD_t and linear time trend *t* are a ded as controls. The dependent variable is denoted X_t; in our analysis, we consider a general food price index FOOD as well as prices for main agricultural commodities, wheat and maize, soybeans, barley, sorghum and rice. To facilitate comparison with the existing literature, we also estimate a reduced model where the restriction 1 = 0 is imposed. Furthermore, similarly to Nazlioglu and Soytas (2011) we present a specification without MUV and similarly to Baffes (2010) a model without the exchange rates.

Finally, we estimate the reduced model with the fertilizer index as the dependent variable. Throughout, we follow Engle-Granger methodology, i.e. we use OLS as our estimation method and carefully check for non-stationarities using appropriate versions of the Augmented Dickey Fuller (ADF) test. We assume that unobserved variables (e.g. other cost–push factors such as wages) are uncorrelated with the error term; further properties of the error time series will be subjected to statistical testing below. Specifying the model as in equation 1 we implicitly assume existence of a single cointegration relation between all variables in the equation. We find no evidence to reject this hypothesis if the residuals of the regression from equation 1 are stationary, as non-stationarity of the error term invalidates the OLS approach. If we can't reject the hypothesis about residuals non-stationarity, we reject the hypothesis of a single cointegrating and are unable to interpret the model parameter estimates.

This statistical model can be given a structural economic interpretation. Consider a competitive industry, where each firm produces according to a constant returns to scale Cobb–Douglas production function. Then, the unit marginal cost function has the functional form of (1), allowing for a time trend in total factor productivity and possibly non–neutrality of money (unless β 3 = β1 β2). Coefficients 1 and 2 can thus be interpreted as the factor weights in the production function; moreover, the predicted cost share of each factor corresponds to the coefficients i. For proof see the appendix.

Data Sources: Our commodity price series is based on the World Bank Global Economic Monitor Commodities database (World Bank, 2014). We study the broad–based food price index (series IFOOD), which includes grains, cereals and oils among other food items as our dependent variable of interest; furthermore, key commodities – maize, wheat, soybeans, barley, sorghum and rice – are studied separately. Our explanatory variables are the fertilizer index (series IFERTILIZER), which includes all widely used fertilizer types: potassium, nitrogen and phosphate rock, and energy prices (IENERGY index). More detailed description of the composition of each of the indices is presented in the appendix.

Individual commodity prices are given in nominal USD; indices are also of nominal prices, with 2010 as the base year. The Manufactured Unit Value (MUV) index, also provided by the World Bank, is included in the regressions as a deflator.

[6] Since the fertilizer export cartel is not constrained by usual anti–trust enforcement, the cartel is relatively transparent. For example, according to the Potash Investing News, potassium producers simultaneously announced in 2009 an intention to further reduce output (Toovey, 2009). Following a rapid collapse in fertilizer prices, Uralkali Chief Executive Officer Vladislav Baumgertner was detained in a prison in Belarus in August 2013 after talks on restoring the cartel were apparently unsuccessful (Fedorinova and Kudrytski, 2013)

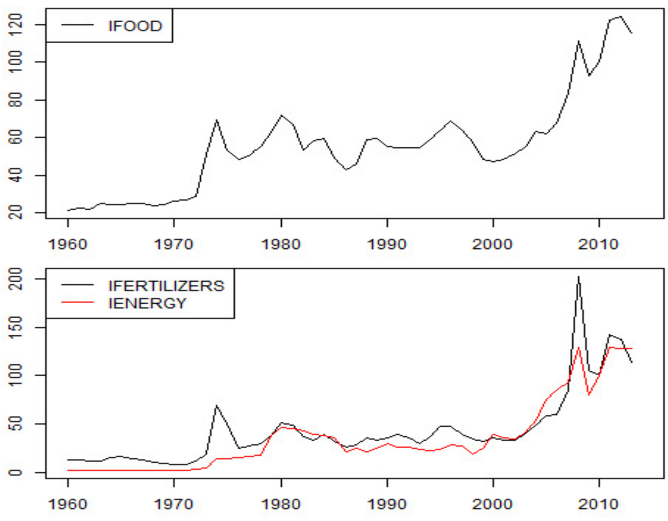
Furthermore, we account for USD real exchange rates, based on Breugel Institute's monthly data series[7] (Darvas, 2012). Data were current as of December 2014. The dataset is closely related to Baffes (2010), who studies the 1960–2008 period; however, his analysis omits consideration of fertilizer prices as an explanatory variable.

Descriptive Analysis: The starkness of the ongoing food crisis is illustrated in figure 1. Food prices are drawn in the top panel; in 2010, they were 40% higher than two years previously; moreover, after a brief recovery in 2009, prices at the end of the sample period exceed the peak of the crisis level. Simultaneously with the food crisis, energy prices also rose – yet more mildly, by merely 25% over the same period. But by far the most drastic change in the crisis period took place in the fertilizer market: by 2010, fertilizer prices *more than tripled* compared to 2006 levels.

All time series are trending upwards; this includes those in the data set that are not drawn in the figures. By visual inspection, one may suspect nonstationarity in the form of a unit root; this intuition is supported through autocorrelation functions. Below, we conduct an ADF test to test this view against the alternative hypothesis of a trend stationary process.

Fertilizer-Energy Link: Fertilizer and energy price indices are closely linked. This is apparent from visual inspection: from the mid-1970s to 2005 or so, energy and fertilizer indices move almost entirely in parallel. This is explained by the fact that fertilizer production is highly energy-intensive, be it due to mining (potassium, phosphate rock) or as a direct input (e.g., natural gas in the Haber-Bosch process). Yet there is independent variation in fertilizer prices: in both 1973/1974 and 2007/2008, fertilizer prices are much higher than one would expect from energy prices. Moreover, in both of these periods food prices were abnormally high – indeed, at crisis levels. It is this variation that underlies the more formal analysis below and allows us to estimate the direct impact of fertilizer prices on food commodities.

Figure 1 - Trends in food and energy/fertilizer prices



4. Fertilizer Matters

Unit Root Tests: We use the Augmented Dickey-Fuller (ADF) test testing the null hypothesis of a unit root against the alternative of a stationary autoregressive process. The optimal lag order is determined through the Akaike Information Criterion (AIC); results are presented in table 1. It is evident that for the levels series – displayed in the left panel – the ADF test largely fails to reject the unit root hypothesis. For the fertilizer and USD, there is weak evidence for stationarity at the 10% level; we consider this significance level insufficient to reject the null. Thus, all levels series are considered to have a unit root. In the right panel, the corresponding ADF test for the first-differenced series is displayed. Here, results are rather straightforward: the null hypothesis is rejected at the 1% level for all series. Hence, the evidence suggests that our data follows an $I(1)$ process.

The $I(1)$ finding has profound implications for our econometric analysis of model (1). On the one hand, standard errors and the R2 statistic are biased towards excessive significance (the "spurious regression" problem); hence significance tests need to be interpreted with care. On the other hand, as we show below, the model in fact provides a *cointegrating regression*; hence the error term t will be stationary and, importantly, OLS parameter estimates are super consistent, i.e. they converge to the population at a faster rate than in an $I(0)$ regression with the same sample size.

[7] Official FED USD exchange rates are reported only since the collapse of the Bretton Woods system in 1971.

Estimation Results: Table 2 collects estimation results. Given the I(1) data, universally high values of adjusted R^2 are expected, therefore the statistics are not reported in the regression tables; encouragingly, we are able to reject statistical significance of some parameters. In particular, there appears to be essentially no time trend in commodity prices. Moreover, the deflator MUVt is mostly insignificant, reaching the 5% level only in few specifications. In regressions (1-3), which include the fertilizer index, there is robust evidence in favor of cointegration. The Augmented Dickey Fuller test, computed on residuals of the estimated equation, is able to reject the null hypothesis of a unit root in all cases at the 5% level. There is mixed evidence regarding cointegration in the restricted model which omits the fertilizer index (specifications 4-6). The no cointegration null hypothesis cannot be rejected even at the 10% level in specification (4), in which as in Baffes (2010) only energy and price index are included. In specification (5), as in Nazlioglu and Soytas (2011), i.e. with energy and exchange rate indexes the no cointegration null hypothesis can be rejected only at the 10% level. Once both USD exchange rate and the price index are included the no cointegration null hypothesis can be rejected at the 5% level. Relatedly, Zhang et al. (2010) also reject both cointegration and Granger causality from fuel to food in a different dataset. Baffes (2010) found cointegration for a similar dataset to ours, but with a shorter time period. In line with Harri et al. (2009), our results indicate lack of a robust cointegration relationship between energy and food across different commodities.

Fertilizer is a consistently statistically and economically significant price driver in food markets. Estimates for $\beta 1$ range from 0.28 to 0.42 depending on the specifi cation; this implies that a doubling in fertilizer prices would be predicted to lead to at least a 28% increase in food prices. The estimates may, at first, seem surprisingly high, but they indeed stay very much in line with the fertilizer cost shares in variable costs from the USDA farm cost surveys as shown on figure 2. We compare cost share coefficients from the reduced form regressions (see appendix for the regressions tables) and the average fertilizers share in the variable production cost using USDA data for years 1975-2013[8] (USDA (2014a)). The data points on figure 2 lay along the 45, which indicates that a nearly perfect match is achieved, thereby confirming the validity of the approach.[9]

There is mixed evidence supporting statistically significant effect of energy on food prices once fertilizer is included. This finding is especially striking in light of the spurious regression problem: due to biased standard errors, it may be difficult to reject truly insignificant parameters. The estimates at around 5-13% stay in line with USDA survey suggesting that the combined costs for "fuel, lube and electricity" account for 9% to 12% of operating costs for the main crops (USDA, 2014a). Note that since commodity prices are generally quoted "free on board", the bulk of transportation costs does not enter directly in the data.

The energy–food price link reappears once fertilizer prices are excluded. Our estimates suggest an cost elasticity in the range 0.3 of food prices with respect to the energy index; these findings are close to earlier estimates in the literature[10].

Combined with the lack of cointegation between energy and food, this suggests that earlier studies – which omitted fertilizer – may have identified only the *indirect* impact of energy on food, channeled through higher fertilizer prices.

At an estimated 38-62% cost share (specifications 7-9 of table 2), energy prices have a very strong cost passthrough to fertilizer prices. Due to the energy–intensive production of fertilizers – with energy costs accounting for up to 90% of nitrogen fertilizer cost (Headey and Fan, 2010, p. 25) – the estimate is plausible.

[8]The estimates are based on producer surveys conducted about every 4-8 years for each commodity and updated each year with estimates of annual price, acreage, and production changes. Estimates for non-survey years use the actual survey year as a base and use price indexes and other indicators to reflect year-over-year changes. The cost estimates include both cash expenditures and non-cash costs that constitute an economic cost. The USDA cost classification was changing over time. To reconstruct a cost category "Total, variable cash expenses" available only for the older series, hired labor costs were added to category "Total, operating cost".

9For the analysis all food commodities for which data are available in both USDA and GEM databases except for rice. The exclusion of rice from the analysis is on both on econometric and economic grounds. The former are due the the fact that we can't reject the hypothesis that rice price is I(0). From more economic perspective, rice markets are very thinly traded and the market price is often driven by import and export regulations and not by the cost factors (see e.g. (Timmer, 2010)).

[10]Baffes (2010), using a similar data set until 2008, estimates an elasticity of 0.28; due to persistently high energy and food prices, the correlation appears to be stronger in the extended sample used in the present analysis. Relatedly, Gilbert (1989) estimates an elasticity of 0.25 using quarterly data from 1965.Q1 to 1986.Q2

5. Did the Fertilizer Cartel cause the Food Crisis?

During the "perfect storm" of 2007/2008, the food crisis coincided not only with an energy crisis but also the establishment of a fertilizer cartel. Given our estimation results above, we are interested in isolating the effect of the cartel formation on fertilizer prices, and hence, ultimately on food. To this end, we first seek to date the recent cartel period in the fertilizer industry and then we estimate an augmented fertilizer pricing equation in the spirit of model (1). Based on predicted fertilizer prices in the counter–factual case of no cartel formation, we then simulate what food prices would have been had a cartel not been formed.

Estimating Cartel Overcharges: We seek to estimate a model that disentangles the impact of energy prices and cartel formation on fertilizer prices. To this end, we augment the version of model (1) already used to estimate potash prices with the cartel variables. To accommodate for the non-competitive periods in the fertilizer industry described in section 2 we introduce a new dummy variable CARTEL0812t, which takes value 1 in those years and zero otherwise (i.e. 1960–2007 and 2013). To account for the Morocco-lead phosphates cartel from the 1970s we introduce a dummy variable CARTEL7475t, which takes value 1 in year 1974 and 1975 and zero otherwise. The cartel impact on fertilizer prices is very strong, as shown in table 3. According to the model, the 2008 cartel formation was associated with a 42-51% overcharge in the fertilizer market. The previous attempt to form a cartel resulted in slightly higher overcharge at approximately 51-65%. Statistical significance at the 1% level, in spite of only few years of observations with the cartel in place, is a reflection of the magnitude of the economic effect. Such large overcharges are not uncommon: in a meta–study of cartel overcharges, Connor and Bolotova (2006, table 3) report an average overcharge of 54.2% for international cartels based on a sample size of 365 cartel episodes. Allowing for the cartel reduces the earlier estimate of energy passthrough on fertilizers; this is intuitive, since the cartel period coincided with high energy prices.

A possible threat to the estimation strategy is the impact of the oil crises on the relation between energy and fertilizer prices and the market turbulences in the aftermath. Therefore, to check the robustness of the results we introduce dummy variables for the 1973-74 and 2007-08 oil crises years (DUMMY7374 and DUMMY0708 respectively). The inclusion of additional out-of-the-sample information affects the results only marginally reassuring that strong fertilizer price spike was not caused only by the increase in energy prices.

Impact on the Food Crisis: The fertilizer cartel can potentially explain up to a halve of food price increases during the crisis time. According to our earlier estimates, the 42-51% fertilizer cartel overcharge would be expected to lead to a 12-21%[11] increase in food prices. Given the observed increase in the food price index of 40%, our model attributes 29-53% of the crisis price hike to the fertilizer cartel. Figure 3, based on specification (1) in table 3, shows the counter–factual food and fertilizer prices without cartel formation side–by–side with actual values: it is apparent that, according to our estimates, food prices could have remained nearly stable over recent years in the absence of the cartel.

[11] The lower bound is given by the lowest estimates from tables 2 and 3 (0.276*0.423=11.7%) while the upper bound calculated based on the highest estimates (0.419*0.508=21.3%)

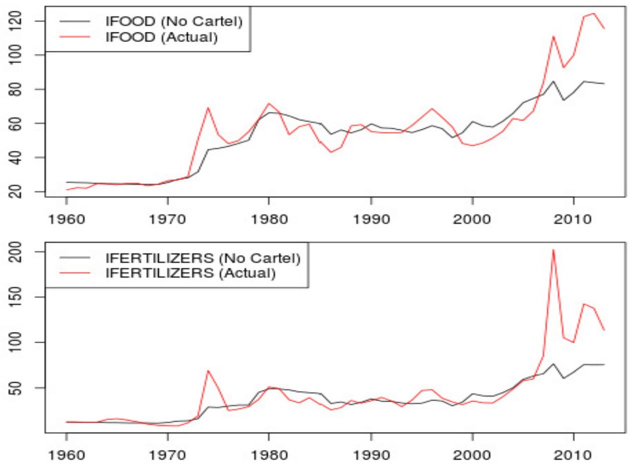
ADF stands for ADF test statistic on residuals of the long run model.

Figure 3 - Actual and counter–factual food and fertilizer prices without cartel formation



6. Robustness Checks

To assert a robust impact of fertilizer prices on food commodities we replace the food price index with the main food commodities as the dependent variable in equation 1. More specifically, we test the following commodities: wheat, maize, soybeans, barley, sorghum and rice. Similarly as in section 4 we proceed with stationarity tests reported in the appendix. As we can't reject the hypothesis about stationarity of the rice price time series we limit our attention to the remaining commodities in the cointegrating regression. The regression results suggest a strong impact of fertilizer consistent across specifications and commodities. In all specifications the coefficient on fertilizer is highly significant and in line with the USDA cost survey data presented on figure 2. The fertilizer cost share for soybeans is significantly lower than for other crops due to legumes' nitrogen-fixing abilities. The ADF test on residuals suggests the existence of a cointegrating vector between the commodities. Results of specification (1) from table 2 are presented in columns (1-5), specification (2) in columns (6-10) and specification (3) in columns (11-15) of the table in the appendix.

The availability of storing technology distorts the standard Marshallian supplydemand cross (Wright, 2011). To control for the possible impact of storage on price dynamics, stock-to-use ratios for each of the commodities have been added to the regression. Although, the stationarity of commodity prices suggests that food stocks are not used as an investment device for arbitrage opportunity seeking investors, the distortions caused by state buffer stocks cannot be excluded. Therefore, similarly to Baffes and Dennis (2013) we include the stock-to-use ratio directly in the regression framework[12]. The estimates on stock-to-use ratio are potentially biased due to endogeneity problems, however good instruments were not available to us. Except for wheat, stock-to-use ratios for all commodities are *I*(1) so we include them in the cointegrating regression. Results presented in specifications (16-20) in the appendix show that while being highly significant and negatively correlated with commodity prices, stock-to-use ratios do not affect the coefficients on fertilizers. This suggests that any endogenity problems in the stock-use-ratio do not affect our estimates of the fertilizer effect.

[12] We calculate stock-to-use ratio following the methodology and data (USDA, 2014b) as suggested by Bobenrieth et al. (2013)

The broad range of regressions performed robustly show the importance of fertilizers in determining food prices. For each of the five food commodities, in each of the four regression specifications, fertilizers persistently prove to be a major cost contributor of food commodity prices. Importantly, the changes in the specifications do not significantly affect the estimates of the fertilizer effect.

7. Conclusion

Since the Green Revolution, the increased application of fertilizer has been instrumental in raising crop yields worldwide. But, as this paper shows, this dependence on fertilizer is not merely technological, but economic: high fertilizer prices directly translate into high food prices. This link is crucial to our understanding of the recent food crisis, during which prices rose by 40% on average. We estimate this was largely caused by the formation of an international export cartel for fertilizers. According to our model, the cartel overcharge in the fertilizer market amounted to nearly 50%. his directly led to a 26% increase in the food price index. In other words, the formation of the fertilizer cartel explains up to a halve of the crisis price increase.

While many factors doubtlessly contributed to the food crisis, we believe the role of fertilizer should be taken seriously. First, while our results are stark, they are in line with the related literature. We estimate fertilizer cost passthrough from aggregate time series data running many years; but the share of fertilizer in marginal cost implied by our model is close to estimates obtained from production budgets and farmer surveys. Our estimated cartel overcharge of 42-51% is typical for international export cartels. Finally, we control for energy prices; according to our estimates, food prices would certainly have been high in 2007/2008 – due to the simultaneous energy crisis – but they would not have reached crisis levels. These results highlight the importance of addressing fertilizer cartel – the "OPEC of world potash markets" (Scherer, 1996) – in combating food crises. In recent history, various export cartels have at different times dominated the fertilizer market (cf. al Rawashdeh and Maxwell (2014); e.g. Newman (1948) discusses the role of the German potassium cartel in the Nazi economy). These cartels flourished, with either explicit or implicit state backing, because of the absence of effective international competition authorities and enforcement (Marquis, 2014)[13]. Sokol (2008) discusses possible institutional reforms to mitigate export cartels; Taylor and Moss (2013) make the case for global antitrust enforcement in the fertilizer industry. Perhaps above all, this paper is a call for further research. Since the "fertilizer hypothesis" is new, it is in need of further corroboration for additional food commodities and from other datasets. The recommended steps include data disaggregation. The analysis performed on the indices may miss some important subtleties of the fertilizer and energy markets. It would be very valuable for the agricultural policy to understand the co-movement of prices of nitrogen, potassium and phosphorus fertilizers. Furthermore, the recent dramatic shocks to the fertilizers markets caused by the cartel formation and the significant decrease of natural gas prices may help to identify the links between the different fertilizer types. Furthermore, a focus on the oil and natural gas prices rather than the analysis compound index would allow to separate the effect of cartel formation from the recent processes that change the shape of the relation between food, energy and fertilizer prices - the introduction of the fracking technology and the recent increase in the use of biofuels. Finally, we treated fertilizer cartel formation as exogenous; but a better understanding of the reasons for success and breakdowns in fertilizer cartels over time is sorely needed.

Appendix

Food, Energy and Fertilizers Indices Composition

The main objective of this study is to understand the change of food prices. We use various World Bank's price indices, the composition of which may not be clear to the reader. Indeed, the information about how price indices are constructed is surprisingly scarce. Therefore, to inform about what is actually being measured in this paper we reconstruct the price indices used throughout the the text.

To reverse-engineer the indices we perform OLS regressions of indices against all commodities included in the database from the given commodity group. To solve the collinearity problem first differences of all variables of interest are taken. If constant weights were used throughout the sample period to construct the indices of interest, this approach allows for full index reconstruction.

The number of food commodities in the data base is close to the number of observations, which leaves few degrees of freedom for the estimation of food price index, therefore, we take a two stage approach. First, we identify the subindices also included in the GEM database that IFOOD is made of. Subsequently, we identify components of each of the subindices. Finally, we verify if , indeed all components of subindices are included in the IFOOD index.

The IFOOD index is built of three subindices - IFATS_OIL with over 40% and IGRAINS and IOTHERFOOD with approximately 30% share each. The detailed composition of IFOOD with it's shares (using 2010 prices) and weights with which particular prices enter the index presented in the table below.

Soybeans prices (beans, meal and oil) are by far the most important component of the IFOOD index with over 25% weight. Also changes in palm oil, maize and sugar prices can significantly affect the index with each commodity having an over 10% share in the index.

Simialr analysis has been performed on the other two indices. Fertilizer price index has 4 components - potash, phosphate rock, TSP (triple superphosphate) with around 20% share each and urea with 40% share with details presented in table A.2. The energy price index is dominated by crude oil with 85% share equally divided between Brent, WTI and Dubai classifications. The remainder is coal (5%) and natural gas (10%) averaged over the European, US and Japanese prices, as shown in detail in table A.3.

Cost shares - a proof

Suppose that food production function is given by:

$$FOOD = A * FERT^{\beta}$$

Where A represents all other costs other than fertilizers. Cost share is given by:

$$\text{Cost }\% = \frac{p_{FERT}}{p_{FOOD}} * \frac{FERT}{FOOD}$$

Table A.1 - FOOD price index decomposition

	Food index share	Weights (OLS results)	t value

PAPER

I. Executive Summary

This report reviews the agriculture support policies of 18 Latin American and Caribbean (LAC) countries, which together account for 92% of the region's agriculture value added. Although agricultural policies and programs in LAC are heterogeneous, there are clear trends and commonalities. The review measures agriculture support policies and programs using the OECD Producer Support Estimates methodology[1].

Collectively, during the last year when data was measured, the LAC countries covered in this review transferred an annual amount of US$27.2 billion to farmers, and they spent an additional US$ 5.8 billion on agriculture public goods and services (here called general support services or GSSE). LAC Countries (as other emerging economies) have gone from taxing their agriculture sector in the 1990s to providing net levels of support. On the other hand, the level of support from high-income (OECD[2]) countries has been reducing, therefore showing some convergence and the opportunity for the agriculture sector of LAC to compete in a more level playing field. 7% of the gross agricultural receipts (agriculture income) of an average farmer in the LAC countries covered under this review (2010-2014) came from agriculture support policies and programs. This is very low compared to 18% in OECD countries (2014). There has also been an important shift within LAC in moving from market price support (MPS) which distort market prices for agriculture products, to direct farmer support (through fiscal support). However, 37% of producer support still comes from MPS.

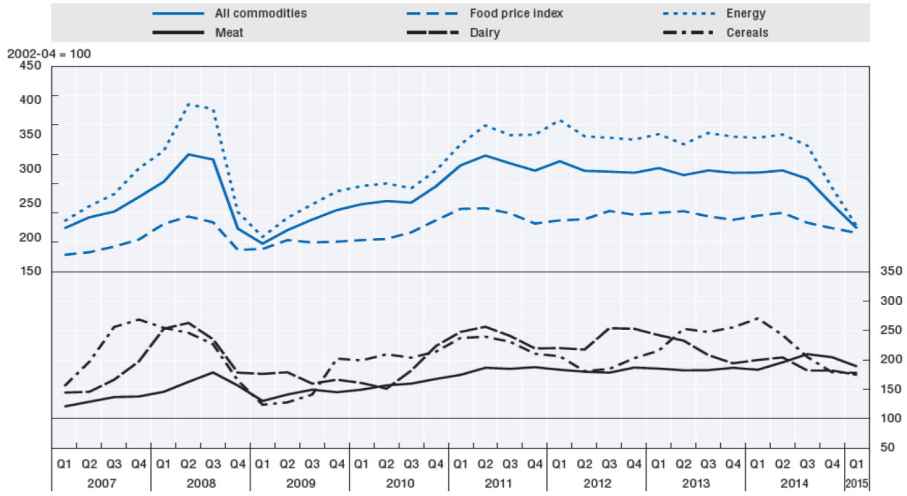
II. Economic and Agriculture Market Developments in LAC

Over the last two decades, LAC countries have shown positive trends for agriculture development, and in particular agricultural trade. Although trade in agricultural products has declined as a percentage of overall trade worldwide, its value has grown substantially. The LAC region has captured an increasing share of this growing market and currently holds a much larger portion of world trade in agriculture (13 percent, up from about 8 percent in the mid-1990s) than in minerals and metals (8 percent) and manufactured goods (3 percent). Agriculture and food now represent about 23 percent of the region's exports and 10 percent of global trade. Over the period 1995–2009, export growth averaged 8 percent a year. Temperate products (cereals, oilseeds, and livestock products) accounted for more than half of this growth. Seafood, fruits and vegetables contributed around 15 percent, followed by processed products like beverages and tobacco. Of course, this pattern varies by sub-region, with, for example, fruits and vegetables being the dominant contributor in Mexico and the Andean region. Almost all LAC countries contributed to the export growth, but Brazil made the largest contribution by far (more than 35 percent), followed by the Southern Cone (around 30 percent). Except Colombia, the region's largest exporters have all increased their global market shares.Among the second tier of exporters, Peru, Ecuador, Paraguay, and Uruguay have also increased their market share. Central American and Caribbean countries, except Costa Rica and Guatemala, have maintained or lost their market shares. Though the EU and the United States remain LAC's most important destinations—accounting for a combined 45 percent of LAC's exports in 2009, down from 57 percent in 1995—developing countries are becoming the most dynamic destination for the region's exports (UN COMTRADE Data). Over 1995–2009, China and the rest of the world, with a combined 30 percent of the market share, contributed 36 percent of the growth of exports from the region, nearly the 38 percent contribution of the EU (20 percent) and the United States (18 percent).

[1] See: www.oecd.org

[2] Please note that there is one country in LAC, Mexico, which is part of the OECD, and therefore is counted in both groups..

Graph 1 - Commodity world price indices, 2007-2014



Source: OECD (2015). Agriculture Policy Monitoring and Evaluation 2015. Highlights.

Also, while developed economies imported primarily fruits, animal fodder, coffee, beverages, and seafood from LAC, products from the soybean complex (seeds, oil, and cake), meat, and sugar represented almost 60 percent of the trade with developing economies. However, commodity prices declined broadly in 2014 (see Graph 1) and this has put some downward pressure on sector profits and government revenues from the sector. In their own agriculture trade policies, LAC countries have made great strides since the 1960s and 1970s, when highly protectionist trade policies and exchange rate regimes promoted industry-led development. This created in LAC and most other developing countries a strong anti-export and anti-agriculture incentive structure. Relative rates of assistance show the protection of manufacturing compared with that of agriculture, with negative values indicating an anti-agricultural bias (Graph 2). In LAC, the overall incentive structure has been close to neutral since the early 1990s. By contrast, some developing regions (including Africa) still maintain a net taxation of agriculture, while others have moved to the agricultural subsidization model of the high-income countries. This does not imply, however, that there is no need for further reform in LAC. The overall neutral structure masks a greater protection of import substitutes than of exportables, creating an anti-export bias for agricultural production. Nonetheless, this difference has greatly diminished since the 1980s, indicating that this anti-export bias has lessened, and one of the latest important changes has been the elimination of almost all agriculture export taxes by Argentina at the end of 2015.

III. Main agriculture policies and programs in LAC

Agriculture policies and programs of LAC countries are diverse and change quickly in several countries. While many countries have a mix of policy measures and programs, policy designs differ between countries. The landscape of agricultural policies can be characterized by five different approaches:

1. **Market Price Support (MPS), through border measures**: Those policy instruments prevail in terms of Producer Support Estimates (PSE) in Uruguay, Peru, Suriname, all 5 Central American countries[3], Jamaica, Ecuador and Colombia.

---

[3] Includes Nicaragua, El Salvador, Honduras, Costa Rica and Guatemala. Excludes Panama and Belize.

2. **Reducing costs of purchased inputs and capital**: Subsidies to farm-purchased variable inputs, such as energy and fertilizers have recently become more important in Brazil, Chile and Mexico. Concessional credit schemes to stimulate agricultural investments are cornerstone policies in Brazil and Colombia.

3. **Emphasis on policies that mitigate the downside risks to revenue and income**: This hasrecently been reinforced in Peru, Brazil and Mexico.

4. **Emphasis on extension services to farmers**: Recent increase in provision of extension services to farmers were observed in Chile, Peru, Paraguay and Uruguay.

5. **Emphasis on enabling business environment for agriculture**: Countries that focus their policy instruments on general services with a public good character include Chile, Peru, and Uruguay.

The specific dualistic nature of the sector leads to a twin-pillar policy approach. One set of policies addressing the competitive commercial segment, and another set addressing a struggling small-scale segment. Brazil and Chile explicitly differentiate their policies between those segments and typically provide support to small farmers through a variety of measures that reduce costs of capital and other purchased inputs and facilitate better market integration.

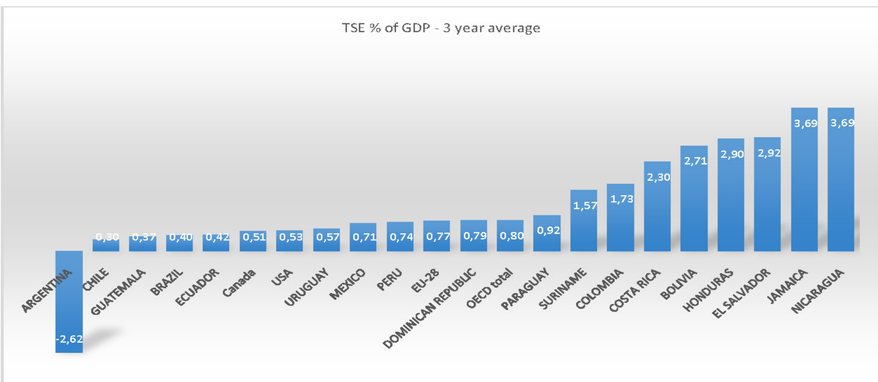
Several countries make efforts in agricultural innovation systems to improve productivity and sustainability in the long term. Much of those efforts occur outside the field of more narrowly defined agricultural policies, which would typically cover expenditures on extension and farm advisory services, and are embedded in national innovation strategies. Finally, with agriculture contributing directly and indirectly about a quarter of global greenhouse gas (GHG) emissions, climate change mitigation is increasingly on the agricultural policy agenda. With a few exceptions (like Brazil and Uruguay[4]), actual policy efforts are relatively limited, however.

IV. Review of agriculture support estimates

Here we present the estimates of agriculture support policies and programs for LAC to assess the type of supports, the composition of supports, and its evolution over the past few years. The 18 LAC countries reviewed are the ones with data on agriculture support estimates published in the IDB Agrimonitor database[5]. However, it is important to note that for practical purposes, in some of the graphs and analysis undertaken in this section, Argentina was left out as it is an outlier in LAC, showing large negative support estimates (total and producer support estimates) due to the export taxes in place until 2015. Also, when looking at the average of OECD countries, note that Mexico is part of the OECD data. This section begins with assessing the Total Agriculture Support Estimates (TSE), its composition and its evolution. It then reviews the Producer Support Estimates (PSE), its composition, and evolution. Finally, the section focuses on Consumer Support Estimates (CSE) and General Support Services Estimates (GSSE) or agriculture public goods and services. Total Support Estimate (TSE), expressed as a percentage of GDP, illustrates the weight that countries assign to agriculture support policies. The TSE combines transfers to agricultural producers individually (measured by the Producer Support Estimate, the PSE), policy expenditures that have primary agriculture as the main beneficiary, but that do not go to individual farmers (measured by the General Services Support Estimate, the GSSE) and budgetary support to consumers of agricultural commodities (the Consumer Support Estimate, CSE, net of the market price element that is already accounted for in the PSE).

a) Total Support Estimates (TSE) and its composition (as percentage of Ag GDP and GDP)

Graph 3



(*) Note: The 3-year average takes the last 3 years when data is available on agriculture support estimates (see Agrimonitor database: http://www.iadb.org/en/topics/agriculture/agrimonitor/agrimonitor-pse-agricultural-policy-monitoring-system,8025.html). These 3-year averages can go from 2007 to 2014.

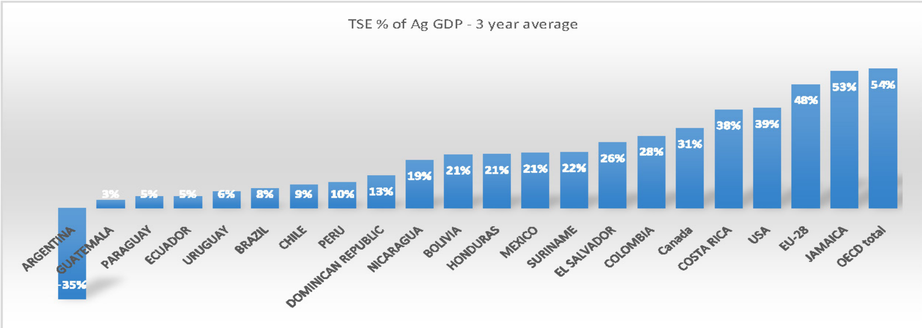
---

[4] Brazil has a large climate smart agriculture (CSA) policy, promoting CSA technology adoption (Programa Agricultura de Baixo Carbono – ABC. See: http://www.agricultura.gov.br/desenvolvimento-sustentavel/plano-abc). Uruguay also has a major public policy on climate change adaptation (see: http://www.mgap.gub.uy/portal/page.aspx?2,MGAP,mgap-desarrollo-y-adaptacion-al-cambio-climatico,O,es,0,).

[5] See: http://www.iadb.org/en/topics/agriculture/agrimonitor/agrimonitor-pse-agricultural-policy-monitoring-system,8025.html

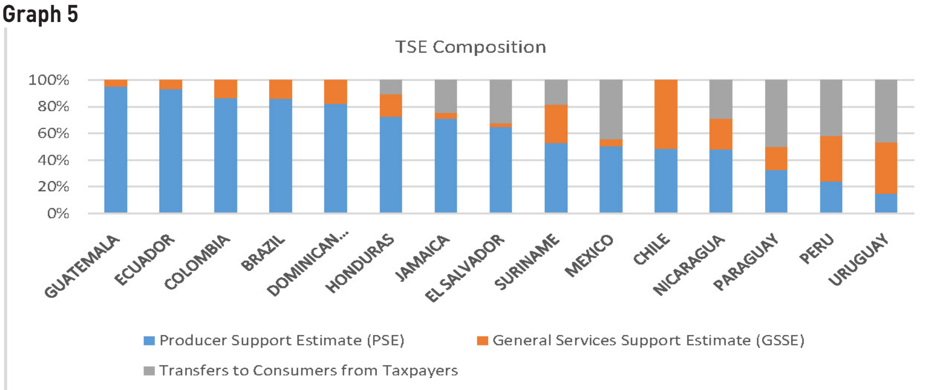
Graph 4 below shows that, with the exception of Jamaica, LAC countries provide a lower level of agriculture support (measured as TSE as % of their Agriculture GDP), than OECD, USA, and EU countries. We observe that countries in the southern cone (Argentina, Paraguay, Uruguay, Brazil, Chile and Peru) tend to have lower TSE% (less than 10%) than the rest of the LAC region. However, when comparing the TSE to overall GDP (see Graph 3 above), we observe that the TSE% is lower for OECD, USA, and EU countries than several LAC countries. This reflects the fact that agriculture represents a lower share of the total GDP of high-income countries, and therefore, although the TSE is high relative to the sector, it is low relative to the economy as a whole. On the other hand, several countries in LAC, in particular in the 5 Central American countries, have an agriculture sector that is more important in relation to the overall economy, so the size of supports to its agriculture will be larger in relation to its overall GDP than in high-income economies where agriculture represents a smaller share.

Graph 4

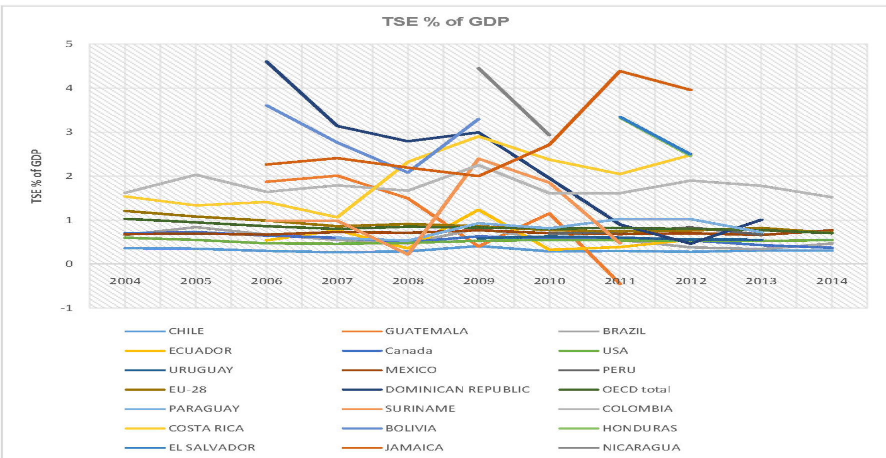


The composition of TSE (see Graph 3 below) shows that support to the producer support (PSE) is the main type of agriculture policy in LAC, with the exception of Paraguay and Uruguay, where transfers from consumers to taxpayer and general support services (GSSE) are more important respectively. Also, the evolution of TSE as % of total GDP (see Graph 5 below) shows that with the exception of Jamaica and Costa Rica, TSE has been decreasing, as it happened in higher income countries. While in 2004 more than half of LAC countries' TSE was above 1% of GDP, by 2013-2014, most were under 1%. Finally, the evolution of the composition of TSE (see Graph 6 below) shows that although PSE is still the main type of agriculture policy in LAC, it has been decreasing in importance in several countries. Chile, Colombia, Dominican Republic, Honduras, Paraguay, Peru and Uruguay have seen its PSE (as % of TSE) be reduced in importance while GSSE and increase. On the other hand, Brazil, Ecuador, Jamaica, Argentina, Guatemala and Mexico has seen its PSE increase (as % of TSE).

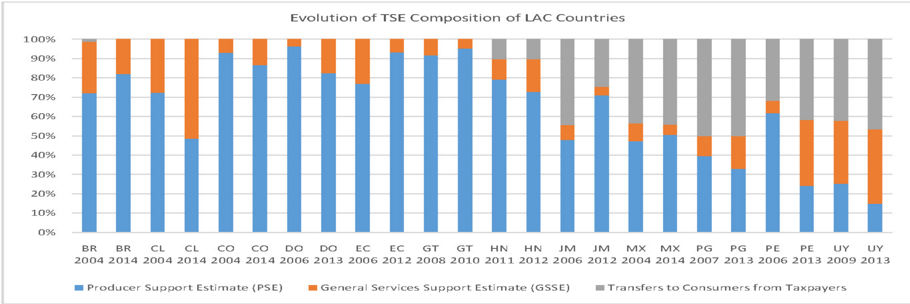
Graph 5



Graph 6

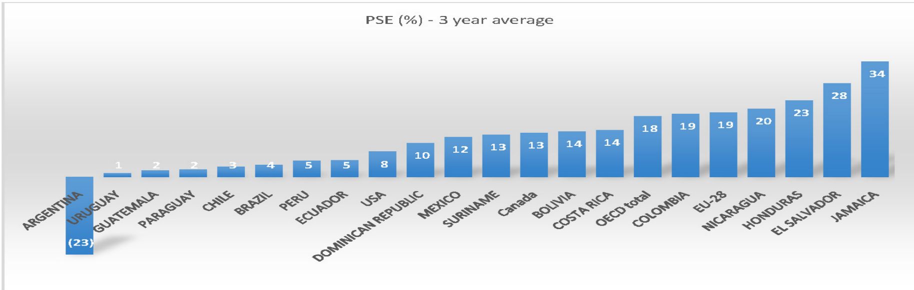


Graph 7



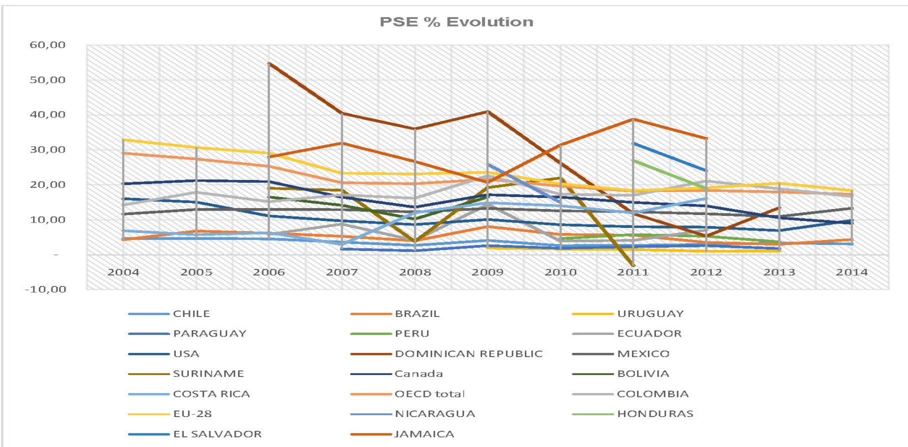
b) Producer Support Estimate (PSE) and its evolution (as percentage of gross farm receipts)

Graph 8



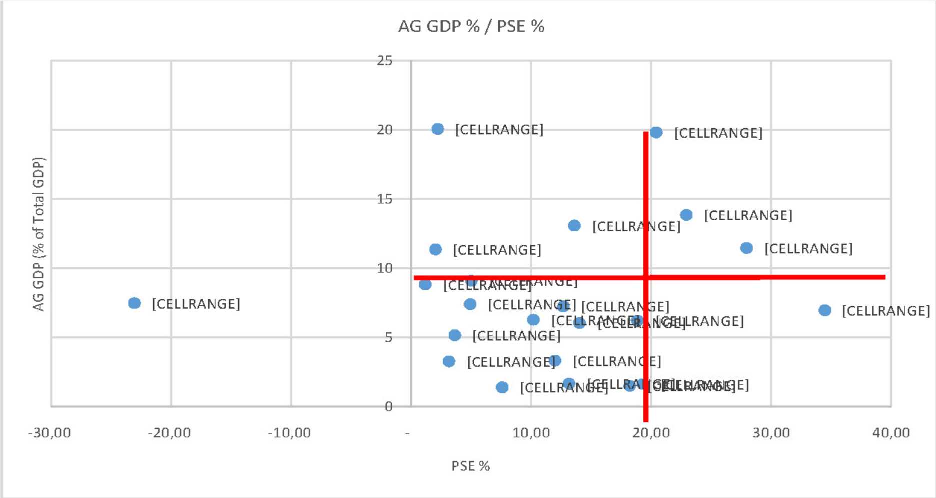
In terms of Producer Support Estimate as a percentage of gross farm receipts (PSE%), we observe again (see Graph 8 above) how Southern Cone countries have lower levels of support than the other LAC countries (with the exception of Guatemala who scores lower than Paraguay, Chile and Brazil). It is important to note the group of LAC countries with levels at or above the OECD / EU (PSE% above 18%): Colombia, Nicaragua, Honduras, El Salvador and Jamaica. This Graph 6 show important differences in terms of PSE% between LAC countries, even neighboring ones. For example, 2% of the farm income of an average farmer in Guatemala comes from agriculture support policies and programs, while for an average farmer in neighboring El Salvador it is 28% (more than a quarter of farm income). The evolution of the PSE% over time (see Graph 9 below) shows that there has been a decline in PSE%, with the exception again of Jamaica and Costa Rica, which have seen their PSE% increase. In 2004, several LAC countries showed PSE% above 20%, while by 2014, all countries with data were under the 20% mark.

Graph 9



c) Correlations between PSE level for each country and other variables (like GDP/capita, rural/urban population, agriculture GDP)

Graph 10

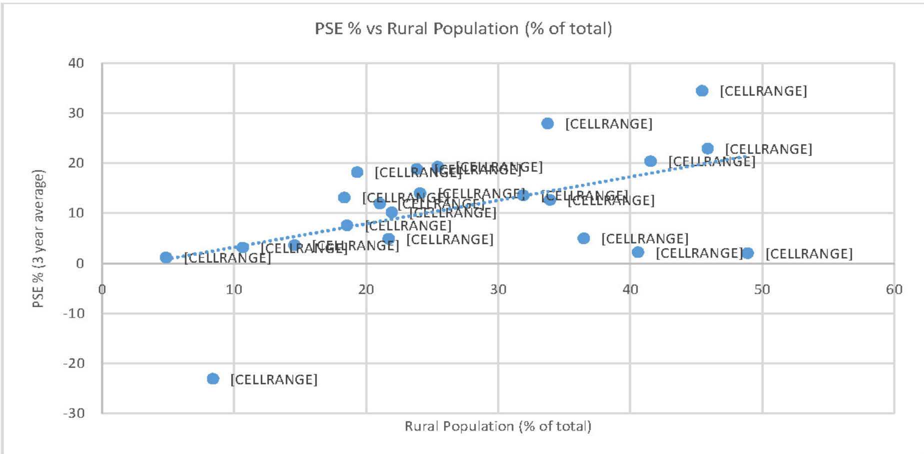


When comparing the weight of the agriculture GDP in the total GDP with the PSE% (see Graph 10 above), it is clear that most countries with an agriculture sector that represents less than 10% of its total GDP have PSE% of less than 20%. This means that less than 20% of farm income of the average farmer in most countries in LAC (as well as OECD, Canada and the US), comes from agriculture support policies and programs. However, countries like Guatemala, Paraguay and Bolivia, also show relatively low levels of PSE% (less than 20%), but their agriculture sector represents more than 10% of their total GDP. For these countries where agriculture is a large portion of the country's total GDP, the challenge is how to support their agriculture sector without burdening taxpayers (as the fiscal resources needed would need to be large as percentage of the country's total public budget).

Another group is Nicaragua, Honduras and El Salvador; countries that have agriculture sectors that represent an important size of their economy (more than 10% of total GDP), but with relatively high levels of PSE%. For these countries, both fiscally, but also for consumers, supporting the agriculture sector is a relatively large burden. Improving agriculture public expenditures and ensuring that farmers improve their competitiveness by reforming agriculture policies and programs towards non-distortive approaches should be at the center of the agriculture policy dialogue of these countries. Finally, Jamaica, a country with an agriculture sector that represents less than 10% of its GDP, but with the highest PSE% of LAC, shows that the economy and its taxpayers and consumers are heavily supporting its farmers, and that this may be afforded as its agriculture sector is relatively small compared to other LAC countries.

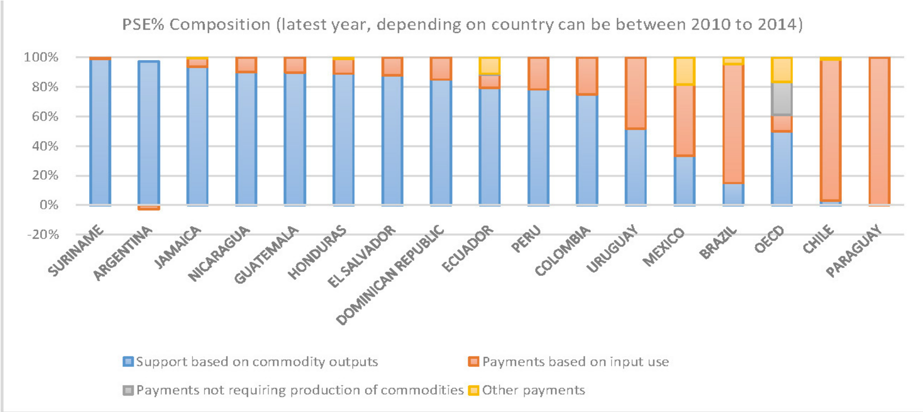
Therefore, although Graph 10 shows no clear correlation between agriculture GDP (as % total GDP) and PSE%, there are groupings of countries that emerge. A group in the lower left hand quadrant of the Graph 10, where most countries are, with low levels of agriculture GDP (as % of total GDP) and low levels of PSE%. Then there are three smaller groups (with three countries or less, each). One small group (composed of Guatemala, Paraguay and Bolivia) with a high importance of agriculture GDP in their economies, but with low levels of PSE%; another small group (composed of Nicaragua, Honduras and El Salvador), with high levels of PSE% and an important role of the agriculture sector in total GDP; and the third one composed only of Jamaica with high levels of PSE% but a relative small agriculture sector in relation to total GDP.

Graph 11



When looking at PSE% in relation to the importance of the rural population (as % of total population), we observe a correlation (see Graph 11 above). The countries with relatively larger rural populations have higher levels of PSE%. This could be due to the importance that these countries place on supporting the rural population, as agriculture incomes tend to be the single most important source of income for rural households in LAC. The higher levels of PSE% in Central American and Caribbean countries could be driven by the weight that the rural population places on prioritizing agricultural public policies and programs. However, there are some exceptions (outliers) to this correlation, specifically, Guatemala and Paraguay, which have a relatively large rural population but low levels of PSE%.

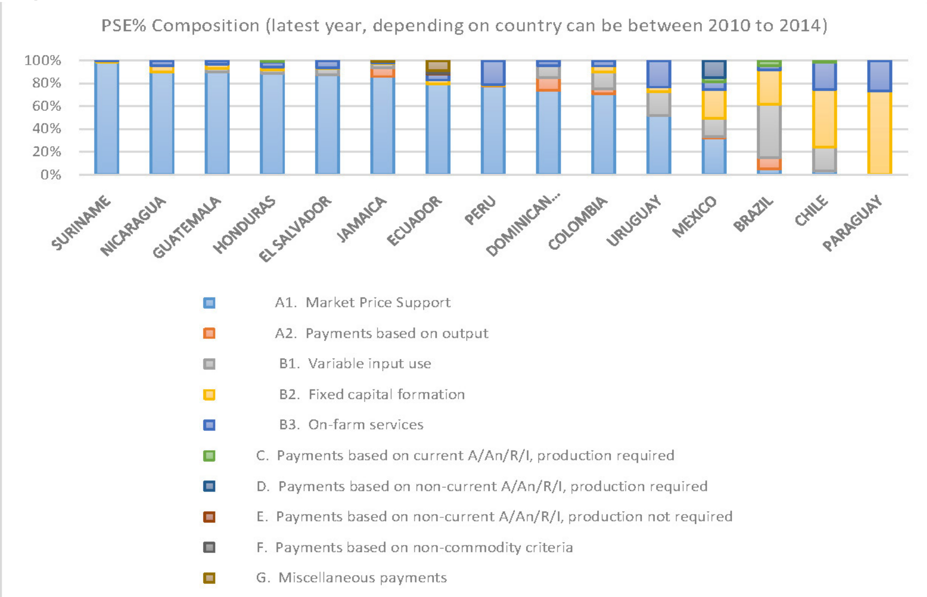
Graph 12



d) Composition of fiscal support of PSEs per country (as percentage of PSE)

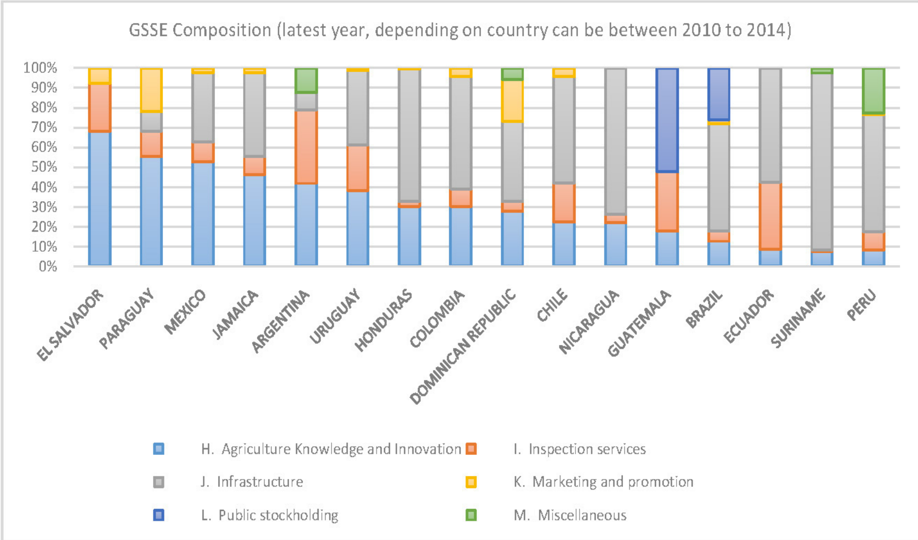
Graph 12 above shows the composition of PSE for LAC countries and the OECD. There is a clear heterogeneity in the composition of PSEs in the region. While OECD countries show a more balanced mix of supports, LAC countries rely heavily on supports based on commodity outputs, and in some countries like Chile, Brazil, and Paraguay, on payments based on inputs. A closer (more disaggregated) view of these PSE compositions (see Graph 13 below) reveal that the larger part of the support based on commodity outputs is derived from Market Price Support (MPS), which represents transfers from consumers to farmers through higher domestic prices due to tariff and non-tariff barriers. MPS does not require public expenditures, while the other types of supports do. In countries such as Chile, Brazil and Paraguay, with very little or no MPS, we observe that the supports are mainly focused on on-farm services (extension) and fixed-capital formation (asset creation), while in Brazil and Chile, supports based on variable inputs are also important.

Graph 13



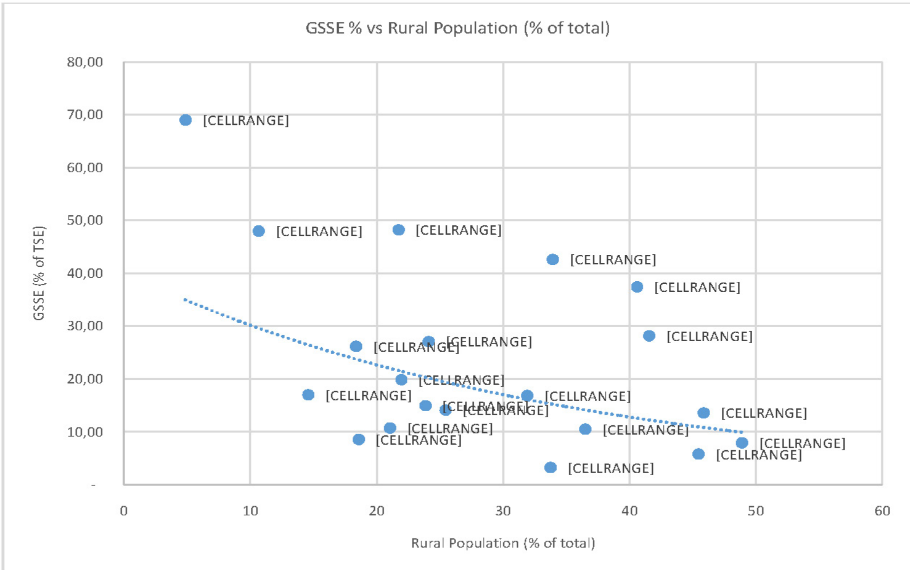
e) Composition of GSSE per country (as percentage of GSSE, US$ and percentage of Ag. GDP).

Graph 14



The composition of General Support Services (or agriculture public goods and services) is also heterogeneous across LAC (see Graph 14). Regardless of the level of GSSE, some LAC countries like Argentina, Uruguay, El Salvador, Jamaica and Paraguay spend a larger portion of GSSE resources on agriculture knowledge and innovation compared to OECD countries. Suriname, Peru, Honduras, Nicaragua, Ecuador, Colombia, Chile and Brazil spend more on infrastructure development and maintenance compared to OECD countries. Finally, only Paraguay and the Dominican Republic spend more than the OECD in marketing and promotion. Public stockholding is virtually non-existing in most LAC countries, but it is a key GSSE category for Brazil and Guatemala.

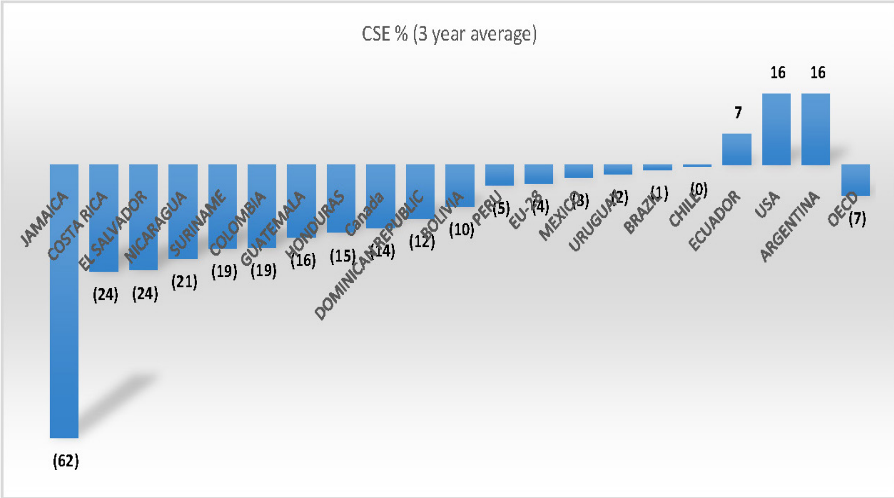
Graph 15



Contrary to the correlation between PSE% and the importance of rural population (Graph 14), Graph 15 shows that GSSE (as % of TSE) is negatively correlated with the share of the rural population in the entire population. This means that in countries where the rural population is larger (as % of total population) GSSE investments decrease in importance as a percentage of TSE. This could be reflecting a tendency for agriculture public policy to move towards direct farmer supports (PSE) in order to provide income support to low income farmers, while reducing the allocation towards GSSE. The incidence of poverty (and in particular extreme poverty) is higher in rural areas, and in countries with large rural populations, targeting agriculture as income support could be an effective way of helping reduce rural poverty.

Consumer support estimates as percentage of overall food consumption expenditures (CSE%) show that most countries (including Canada, EU, and OECD) have negative CSE (see Graph 16), meaning that consumers pay a higher price domestically than they would pay in the absence of agriculture policies and programs. Ecuador and USA have positive CSE% given that these countries provide support to consumers for food consumption (i.e. in the USA, the main program is foods stamps). Argentina has positive CSE% due to the high export taxes on agriculture products, which dampens the domestic food prices (until 2015).

Graph 16



f) Consumer Support Estimate (CSE) per country (as percentage of expenditure at farm gate)

V. Conclusions and proposed future agenda for agriculture policy reform

Collectively, the LAC countries covered in this report (excluding Argentina) transferred annually an average of USD 26.3 billion to agricultural producers in the years 2012-14 (compared to USD 601 billion of the OECD countries) and theyspent an additional USD 5.5 billion (compared to USD 135 billion of the OECD countries) on general services that support the functioning of the sector. Those transfers are burdening consumers and taxpayers, and reforms could improve the effectiveness and efficiency of policies.

However, in LAC as a whole (with the exception of Costa Rica and Jamaica), gradual progress has been made in reducing the level of support to farmers and in introducing less distorting forms of support. The level of support was reduced and the share of production and trade distorting support fell. Those changes occurred to different degrees and at different speeds, with slow changes particularly in the group of countries that rely heavily on instruments that support prices

and production. The GSSE tends to focus on agriculture knowledge and innovation and infrastructure, with less resources going to inspection and promotion and marketing. At the same time, the large use of instruments such as market price support and input subsidies in countries like Peru, Ecuador and the 5 Central America is worrying as this increases distortions on domestic and international markets and is a rather cost-ineffective way to provide assistance.

Given the competitive position of LAC in food production and trade, it is important to think about reducing vulnerability to shocks and adapting to climate change, in order to maintain a constant and reliable food supply both domestically and abroad. OECD countries, including USA and EU, are already reforming their agriculture support structures to become more competitive in the global agricultural arena. There needs to be an increase in investment in agriculture public goods and services in order to improve the capacity of the agricultural sector of LAC to respond to those challenges and to realize its full economic potential. This also reinforces the need to improve the wider policy environment in which the sector operates so as to attract financial and human resources and to foster an innovative agricultural sector that responds to societies' needs.

Such a broader re-orientation of policy approaches require a clear vision of the end-point of policy reforms at national and international levels. In the short term, an agriculture public policy dialogue needs to be undertaken in LAC countries in the following areas:

- **Prioritize investments in agriculture public goods and services**: There is a need in LAC to move away from farm income support to invest in knowledge, education and strategic infrastructure that can help improve the long-term productivity, sustainability, and profitability of the sector. This has shown to reap larger economic returns than direct income support to farmers.

- **Within agriculture public goods and services, invest in agriculture knowledge and innovation**: There is a need to strengthen the governance of innovation in agriculture to improve the strategic orientation on long-term issues. Several LAC countries invest less in agriculture knowledge and innovation than OECD countries.

If direct farmer support is needed, it is important to engage in a policy dialogue in the following areas:

▪ Market price support should be reduced, replacing it with non- distortive direct supports and/or agriculture public goods and services. LAC consumers pay the bill of MPS, especially low-income households. However, fiscal space must be available to do that, and therefore external financing could support this transition. It also delinks farmers from market signals and has been shown to be highly distortive for production and trade.

▪ Input subsidies are inefficient in assisting farmers as they increase the risk of over- or misuse of farm inputs such as fertilizers which can be environmentally harmful. Concessional credit schemes can pose a big burden to government budgets, as it is the case in Brazil. Variable input support has also been shown to be particularly production and trade distortive. Transforming from such subsidies to decoupled subsidies (as was done in Mexico and Paraguay) would need to be on the agenda in the short term.

▪ Direct payments, as was done with the PROCAMPO in Mexico, may be an efficient means in specific policy areas such as to achieve environmental benefits and supporting farm incomes. However, they need to be linked to clear objectives and targets, and well-tailored to the problem at hand. Direct payments can play an important transitory role in the process of reforming agricultural policies in LAC.

ABSTRACT

It is important to measure and analyse the impacts of policy design on agricultural markets. Indirect measurement of incidence, e.g. nominal rate of protection (NRP), is one reliable method to do this, as it relies on price gaps between what producers see and what is prevailing in international markets. Ag-Incentives Consortium, a collaboration effort among international organizations that work on measuring distortions to agricultural incentives, is a new initiative that attempts to bring clarification, harmonization, and methodological guidelines to the forefront. This study, based on but not limited to Ag-Incentives, computes NRPs based on a combined input data from all IOs. The results show that high income countries have decreased protection over time, whereas middle income countries have increased it. Low income countries have higher variation in protection, and respond to food price crises of 2008 and 2011 different than high and middle income countries.

Keywords: agricultural incentives, Nominal Rate of Protection, Nominal Rate of Assistance, Producer Support Estimate

PAPER

1. Introduction

In an environment of growing demand and limited natural resources, the importance of correct policy measurement, categorization, and interpretation for the optimal design, monitoring and evaluation of agricultural, environmental, and trade policies cannot be stressed enough. In this context, it is also crucial to identify which parts of agricultural distortions are due to market failure and to distinguish these from the part that is due to effective policy intervention. Agricultural distortions, originating from either policy design or other sources, also create and influence value chains within a country or across countries. With the observed expansion of regional and global value chains, the measurement of distortions along the agricultural value chain is necessary for effective policy design as well.

There are multiple methodologies utilized and different data sets employed in the literature and by international organizations (IOs) to measure distortions to agricultural incentives. In terms of institutional efforts, World Bank started with Nominal Rate of Protection (NRP) database and updated later with Nominal Rate of Assistance (NRA). OECD has continuing efforts with Producer Support Estimate (PSE) database that has been expanded to non-OECD countries. At the same time, new efforts have taken place, such as FAO-MAFAP that focused on Africa and is now expanding to Asia. IDB-Agrimonitor uses OECD methodology and focuses on Latin America and the Caribbean countries.

With different datasets, assumptions, methodologies, and time spans, a consistent long-term measurement across all developed and developing countries has eluded policy makers. This has made it difficult for them to correctly measure, compare, and interpret the impact of their policy designs across commodities, countries, and time spans. To facilitate this, an Agricultural (Ag) Incentives Consortium has been brought into fruition including OECD, FAO-MAFAP, IDB, WB, IFPRI, and CGIAR PIM. The Ag-Incentives Consortium focuses on organizing collaboration among IOs. One pillar of this is generating a common chest of clearly defined and well-documented common indicators, with a focus on prices. Second pillar is about expanding country and product coverage. Third pillar is providing a platform for tackling new issues and improving methodologies.

In this paper, we first present a summary of the efforts in the literature to measure distortions and the relevant methodological discussions. Next, we present a synopsis of the Consortium and its goals, as well as data processing conducted for the databases of members of the Consortium. We, then, present and discuss the NRPs computed based on, but not limited to, the Ag-Incentives Consortium efforts followed by a conclusion.

2. Methodologies in the literature

There is a wide literature as well as multiple IO databases that measure agricultural incentives. Both the literature and the IOs use two main approaches: indirect measurement of incidence and direct measurement of policies.

For indirect measurement of incidence methodology, NRP estimates by Krueger, Schiff and Valdes (1988) were the first major attempt to look at both direct sector specific and indirect economy-wide policies on agricultural incentives in various developing countries. Direct effect was measured by the proportional difference between the Producer Price and border prices adjusting for distribution, storage, transport, and other marketing costs (Reference Price). Therefore, Direct NRP would be

$$NRP_d = ((PP_i / RP_i) - 1)$$

Indirect NRP is measured in two parts, first, through the impact of the unsustainable portion of the current account deficit and of industrial protection policies on the real exchange rate and thus on the price of agricultural commodities relative to non-agricultural non-tradable commodities. Second, through the impact of industrial protection policies on the relative price of agricultural commodities to that of non-agricultural tradable goods.

Anderson et al. (2008) expanded this effort by measuring NRA and outlined the many methodological issues with deriving such numbers. Different components of NRA were identified and defined, such as NRA to farm output conferred by border price support, NRA to output conferred by domestic price supports, NRA to inputs, among others. Furthermore, there is clearer identification of non-distortionary price wedges, which help in location and evaluation of prices being transmitted along the value chain.

For direct measurement of policies, OECD has continuing efforts with PSEs (OECD 2015). For OECD, PSE is more complex and is a part of the Total Support Estimate, which is an indicator of the annual monetary value of all gross transfers from taxpayers and consumers arising from policy measures that support agriculture, net of the associated budgetary receipts. Here, the percentage PSE represents policy transfers to agricultural producers, measured at the farm gate and expressed as a share of gross farm receipts.

OECD also calculates the Nominal Protection Coefficient (NPC) that includes budgetary outlays and treats input markets differently. It is the Producer Price relative to the Reference Price, with the unit value of payments based on output also included.

$$NPC = (PP + (\text{payments based on output/production quantity}) / RP)$$

Transfers included in the PSE are composed of market price support, budgetary payments, and the cost of revenue foregone by the government and other economic agents as over time. The PSE has evolved from being just a measure of market price support to including payments based on output as well as well as expanding beyond taking into account just direct payments to multiple sources of payments. The Market Price Support (MPS) for a commodity is estimated either by adding together transfers to producers from consumers and taxpayers or by multiplying the quantity of production by the market price differential (the difference between farm and border price). The MPS component of PSE is similar to NRP in that it also depends on price gaps.

FAO-MAFAP (MAFAP 2016) and IDB-Agrimonitor (2016) use methodologies developed by the World Bank and OECD respectively. Country and commodity coverage show some overlaps with these IOs.

3. Consortium structure and database

The objectives of Ag-Incentives Consortium are to bring together the findings from the organizations active in this field on a continuing basis in order to develop a global view of incentives, and to shine a light on incentives in some of the smaller economies where distortions to agricultural incentives have a particular impact on the poor. Ag-Incentives Consortium achieves these through creation of a community of practices, work on harmonization and consolidation of a database, and providing quality control and scientific rigor.

As seen in Table 1, all IOs publish measurement of distortions with some overlap across geographical and sectoral coverage and time span. The goals of the Consortium, therefore, include maintaining the mandate and the independency of each IO, and creating a collaborative approach for database, with a clear recognition of IPR.

Table 1 - Country and commodity coverage by IOs

International Organization	Economic Clusters Covered	Number of countries	Time Period	Total Commodities	Metrics Reported
OECD	OECD + Emerging	23	1986-2014	58 individual, NONMPS, Total	PSE, MPS, NPC, MPD
World Bank	various	82	1955-2007, updated 2011	72 individual	NRP, NRA
FAO-MAFAP	Selected African	9	2005-2013	27 individual	NRA
IDB-AGRIMONITOR	Latin America and Caribbean	17	2004-2013	37 individual	PSE, MPS

Note: Not all countries report all data for all commodities listed and all years

The initial focus of the Consortium has been on price distortions, with a consolidated indicator based on each IO database. We selected NRP, based on Krueger, Schiff, and Valdes (1988) to be computed and made publicly available. NRP is the ratio between the price gap and the observed reference price measured at the same point in the value chain.

We use the method for Direct NRP from Krueger, Schiff, Valdes (1988) to create a consolidated NRP with the underlying price metadata from IOs. We also compute average NRPs for the agricultural sector or a country, and global NRP for a commodity.

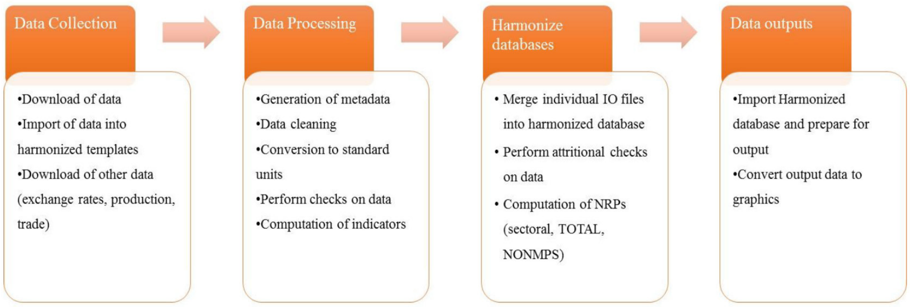
$$NRP_{TOTAL} = ((sum_c(PP_c {*} Q_c) / sum_c (RP_c {*} Q_c)) - 1)$$

$$NRP_{SECTOR} = ((sum_i(PP_i {*} Q_i) / sum_i (RP_i {*} Q_i)) - 1)$$

We use NRPs to measure distortions based on the law of one price, where the goods must be comparable (in terms of quality, processing level, and location). Reference price is border price evaluated at official nominal exchange rate adjusted for transport, storage, distribution, processing, and quality differences based on input data provided by each IO.

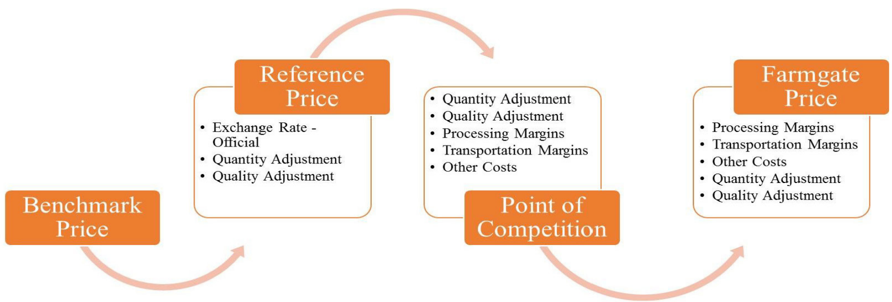
The first step before computing NRPs, is the harmonized metadata template that incorporates input data for all IOs involved and deals with and computes NRPs for commodities and countries as described in Figure 1.

Figure 1 - Harmonized data template process



We construct the harmonized metadata template is constructed to identify the path of price transmission across the Value Chain and measure changes in price along this path while computing reference price at the same point in the value chain. This is described in Figure 2.

Figure 2 - Price Transmission across Value Chain



Based on input data from IOs, we computed a continuous series of NRPs. Since there is some overlap across IOs in terms of commodity and country coverage, we use a hierarchy to select the final NRP. When there is an overlap for a period, country or commodity, the first selection for NRP is OECD database, followed by MAFAP-FAO, IDB, and World Bank. This selection process may create an NRP coverage for a country where one commodity NRP is from one data set and another commodity NRP is from another data set. Same issue exists for the time span of a commodity coverage.

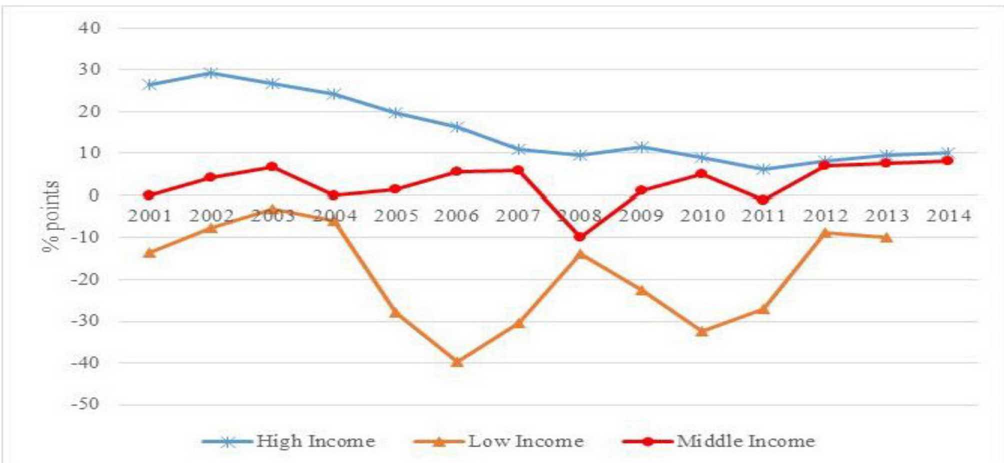
4. What do we learn from NRPs?

Figure 3 below presents average global NRPs weighted by production quantity as seen in above equations. Figure 3 also includes FAO Food Price Index based on international prices weighted with the average export shares of each of the groups for 2002-2004. As seen below, there is some, but not significant, variation in global NRP for the agricultural sector, although values are positive (except for 2008), showing that overall agricultural policies have protected farmers. As expected, we see that average NRPs and average Food Price Index move in opposite directions. When global food prices are rising, governments are insulating consumers, by reducing or eliminating import duties or adding export taxes that in turn reduce protection afforded to producers. The clearest example is in 2008 and 2011 food price crises, with the drop in global average NRP and the jump in Food Price Index.

Figure 3 - Average NRPs for agricultural sector globally and FAO Food Price Index.

In Figure 4, we present the average NRPs for the agricultural sector categorized by income levels of countries. For the period shown, high income countries have higher protection for their farmers, although the average protection rate has declined in the last decade. Although middle income countries, had lower NRPs on average than high income countries, protection to farmers has been increasing steadily and reaching the level of high income countries by 2012. Low income countries have negative NRPs in the period shown in Figure 3, as the agricultural sector is seen as a source of government revenue (mostly in Africa) and export commodities are taxed. One thing to note is the difference in NRPs for countries during the 2008 food price crisis. High and middle income countries lowered their NRPs in response to 2008 food price crises, with middle income countries' NRP dropping to negative values, choosing to insulate consumers from price increases, rather than protecting producers. However, low income countries have higher NRPs during this period for protection of farmers. This may be attributed to agriculture being a significant source of income for these countries' population, and governments' efforts to keep farm gate prices high.

Figure 4 - Average NRPs for agricultural sector by income category.



In Table 2, we present global NRPs by commodity. We observe the variation to be even higher at individual commodity level, relative to the agricultural sector NRP. Producers in livestock and dairy sectors have much higher protection relative to crop sectors. Cash crops, such as coffee and tea, have negative NRPs, as these are export commodities with exports taxes keeping farm gate prices down. Another example of this is negative palm oil NRP, with demand for palm oil exports increasing.

Table 2 - Global NRPs by Commodity

Commodity	2001	2005	2009	2014
Maize	3.16	7.73	1.59	12.64
Wheat	-0.77	-2.06	6.42	12.93
Soybeans	1.59	-1.30	-3.14	-7.59
Palm Oil	-8.80	-1.56	-0.15	-8.52
Cassava	-3.08	-8.01	10.44	31.74
Coffee	-6.21	-12.48	-12.11	-58.50
Tea	-12.88	-9.76	-12.72	
Milk	34.58	26.96	18.14	7.69
Poultry meat	7.64	8.02	13.69	4.42
Bovine meat	27.31	21.77	16.39	23.66
Pig meat	3.17	15.19	12.57	12.28

3. Conclusions

Ag Incentives Consortium is a broad collaborative effort on part of multiple IOs to create a common set of indicators that measure distortions to agricultural incentives, with a focus on prices. The Consortium also aims to create a community of practices and provide quality control and scientific rigor, not only for the common indicators but also for the individual IO efforts.

The initial output of the Consortium is a global data set of NRPs based on combined IO data. This paper presents NRPs based on, but not limited to, the Ag-Incentives Consortium efforts. The results show that global average NRP moves in opposite direction of Food Price index, indicative that government policies reacted to food price crises of 2008 and 2001. Furthermore, trends of NRPs differ by income category, with high income countries lowering protection of producers, and middle income countries increasing protection. There is significant variation in average agricultural sector NRPs for low-income countries, consisting mostly of Africa.

One aim of this exercise was to provide a unified measurement of distortions by agricultural policies for a wide audience of academics and non-academics. This type of unified approach would help governments design policies and measure them effectively. The global NRPs rely on the same methodology, utilizing each IO database, in a consistent manner. They provide continuous and consistent measurement across a wide sectoral and geographical coverage, allowing stakeholders interpret the implications of agricultural policy design in an effective manner.

DOI: 10.1481/icasVII.2016.c17c

ABSTRACT

African governments have widely acknowledged the important role that the agricultural sector plays to reduce poverty and improve food security. Nonetheless, governments' stated policy objectives, the policy measures implemented to achieve these objectives and the effects they generate are often not in line. As a result, there are still many ambiguous and inadequately targeted trade and domestic agricultural policies in place aiming to protect certain interest groups, or directed to achieve certain policy goals that come at a cost for specific (non-targeted) groups within the country's or region's population.

The Monitoring and Analysing Food and Agricultural Policies (MAFAP) Project, initiated by the Food and Agricultural Organization (FAO) of the UN, works closely with governments and national agencies in order to establish monitoring and analysis systems to assess the effectiveness, efficiency and distribution effects of agricultural policies and public expenditure, in an environment where market inefficiencies are often prevalent and significant. The project focuses on key agricultural value chains with domestic relevance in terms of production, trade and food security, in order to provide governments with evidence based reform options. MAFAP is implemented in Benin, Burkina Faso, Burundi, Ethiopia, Ghana, Kenya, Malawi, Mali, Mozambique, Nigeria, Rwanda, Senegal, United Republic of Tanzania and Uganda and is expanding to include further developing economies. The dataset established by MAFAP provides quantitative indicators over the period from 2005 to 2014 that estimate the scale of distortions, market inefficiencies and development challenges faced by the agriculture sector at different points of the commodities' value chains.

MAFAP's database and methodology has been utilized to assess the incentives and disincentives faced by producers and consumers of agricultural commodities by providing best possible information and analysis on the effects of policies and public expenditure influencing food security within the country and in the region. Especially during times of high international food prices, policy measures are used by governments in order to protect highly vulnerable consumers. The policy instrument of choice (e.g. export restrictions) is commonly selected under time pressure and without considering the effects on other countries' agricultural sectors and food security. In return, countries affected by policy actions of their trading partners react by adjusting their own trade and agricultural policies. At the same time, governments often seek to increase self-sufficiency in staple foods through their own production capacities to become less reliant on imports. To support informed policy dialogue at national, regional and international levels, MAFAP provides sound evidence and analysis to help directing policy actions and reforms in the agricultural sector and beyond. Balancing sometimes conflicting policy priorities within a country, region and internationally is a challenging exercise that governments have to face and MAFAP provides adequate support.

Keywords: Policy support, price incentives, public expenditure, Sub Saharan Africa, MAFAP.

PAPER

1. Introduction

Most countries in the world adopt policies that impact their agricultural sector. In doing so, governments seek to influence behaviour of economic agents in agricultural value chains and especially farmers. Trade and domestic market policies intend to affect the prices farmers receive for their produce or the price of inputs they purchase. Governments typically also use budgetary transfers to support specific agents either directly or indirectly through investments in public goods (research, infrastructure, etc.).

While these policies and their incidence have long been monitored for member countries of the Organization for Economic Cooperation and Development (OECD), there is scarce literature on policies and policy monitoring efforts in developing countries and especially in Sub Saharan African (SSA) countries. This is largely because of the challenges in data availability and quality.

Throughout the past decades with many policy changes affecting the agricultural sector in high-income and developing countries, it has been difficult to assess the effectiveness of the various policy reforms in developing countries, as no monitoring system was in place to continuously measure the effects of policy interventions on the basis of comparable indicators across these countries and over time (Angelucci et al., 2013).

In this respect, the work undertaken by Anderson and Valenzuela (2008) as part of the World Bank's research project on Distortion to Agricultural Incentives (DAI) constituted a major breakthrough. It was then possible to observe whether SSA countries were gradually moving away from a situation of net taxation of agriculture by analysing the indicators over more than five decades. The study also allows to compare the evolution of policy indicators at different stages of countries' development and the impacts that policy reactions by large global players can have on other countries. This is important since in a global market one country's policy action can have a major effect on other countries agricultural sector.

In the same spirit and more recently, FAO's Monitoring and Analysing Food and Agricultural Policies (MAFAP) programme started in 2009 with the objective of establishing country owned and sustainable systems to monitor, analyse, and reform food and agricultural policies to enable more effective, efficient and inclusive policy frameworks in support of agricultural development in a growing number of developing and emerging economies.

This paper provides an overview of recent trends in policy support level and composition for a selection of SSA countries. The data available paint a picture of generalized heterogeneity across countries. Overall, the level of distortions seems to decline on average as the average aggregated NRP across countries and commodities is converging to zero or slightly above. The objective of the paper if is to provide an early snapshot from the emerging data and suggest how we should think about this picture.

The remainder of the paper is structured as follows. Part 2 presents the methods and data used. Part 3 proposes a discussion of the main results distinguishing the analysis of price incentives and the discussion of budgetary transfers in support of the sector. Part 4 concludes.

2 Method and data

This paper builds on two strands of methodologies commonly used to assess the extent of policy support in agriculture. On one side, a well-established methodology based on the price differential between domestic and reference markets, which is used to estimate price incentives. On the other side, an equally well established methodology is used to estimate the budgetary expenditures in support of producers and the agricultural sector as a whole to account for direct and indirect social transfers. Both components are necessary to undertake comprehensive policy analysis, including an assessment of policy coherence with respect to the development objectives stated by governments.

2.1 Price incentives analysis

Estimates of the nominal rates of protection (NRPs) are used in this paper as indicators of the policy effort through their impact on prices. Some of the most seminal applications of NRPs and related concepts include Krueger et al. (1988), Krueger et al. (1991), Monke and Pearson (1989), Tsakok (1990), and Anderson and Valenzuela (2008) and Anderson and Nelgen (2013). A detailed comparison of the applications of NRPs and related concepts can be found in Balié and Maetz (2011). Consistent with the approach proposed by Krueger et al. (1988, 1991), NRPs have mainly been used to examine two situations: (i) direct taxation (or support) of the agricultural sector or a specific value chain through direct sector-specific price policies (or interventions), and (ii) indirect taxation (or support) through trade policies, exchange rate and any other macroeconomic policies or non-agricultural sector specific policies.

In most cases, the expected direct policy effect is equivalent to a tax on exportable goods and to a subsidy for importable goods while the indirect effect also results in taxes on agriculture which generally dominates the direct effect. For example, Quiroz and Valdes (1993) argue that, in the case of Zambia and Zimbabwe during 1980-87, there was a negative trend in nominal protection rate that was the result of increasing transport costs due to deterioration of infrastructure, lack of spare parts, and other factors that could be due to both policy and market failures.

Some variations on NRPs found in the literature include the nominal protection coefficient (NPC), which expresses the result as a ratio rather than as percentage change.[1] The nominal rate of assistance (NRA) at the farm gate is the sum of the NRP plus subsidies paid to the farmer expressed as a percent of the border price. The subsidies also include the value of input subsidies whether provided as payments directly to the farmer or indirectly through policies which affect farm prices (Monke and Pearson, 1989). In a developed country context, NPCs are calculated by the OECD using the Producer Support Estimate data base (OECD, 2010).

[1] The NPC is the ratio of the domestic price to the border price. The NRP is the difference between the domestic price and the border price divided by the border price.

The point along the value chain where the NRP or any other such indicators are calculated plays a key role. As described by Tsakok (1990), the border price and domestic price need to be compared at the same point in the value chain. This leads to a number of challenges in real world applications in terms of data requirements but also makes the calculation of these indicators meaningful for policy. The methodology in this paper is closest to Tsakok (1990) with NRPs estimated at the farm gate, wholesale, and retail level, which helps locate market and policy failures along the value chain.

To compare prices in a wholesale market for an imported commodity, the border price that is used for comparison needs to be modified in such a way that it accounts for the costs incurred to take the commodity from a CIF position to sale in the wholesale market in question:

$$BP_w = P_b + TC_{b.w} + MM_{b.w} \quad \textbf{(1)}$$

where BP_w is the CIF price (or average unit value) of the commodity converted into domestic currency using an exchange rate;[2] TCb.w includes all handling costs at the border, transportation and any processing costs between CIF and placement of the commodity on the wholesale market; and MMb.w are the importers' normal marketing margins between the border and the wholesale market. The signs would be reversed in the case of an export and with the border price being a FOB price (or unit value).

Note that the border price does not include the tariff and tariff equivalent charges. Similarly TCb.w includes only the resource costs of moving the commodity between border and wholesale, and MMb.w is a 'normal' marketing margin. The adjusted border price at the farm gate would be

$$BP_f = BP_w - TC_{f.w} - MM_{f.w} \quad \textbf{(2)}$$

where $TCf._w$ include all handling costs at the border, transportation and any processing costs between the farm gate and placement of the commodity on the wholesale market; and $MMf._w$ are normal marketing margins between the wholesale market and the farm.

The NRP, expressed as a percentage, can then be calculated as the difference between the adjusted border price and the domestic price at wholesale and/or the farm gate:

$$NRP_w = 100\% \times (WP - BP_w)/BP_w \quad \textbf{(3)}$$

$$NRP_f = 100\% \times (FP - BP_f)/BP_f \quad \textbf{(4)}$$

As will be seen below, explicit trade of domestic policies are not always the main drivers of price incentives as captured by the NRP. In developing and emerging economies in particular, market imperfections and other factors (see below) play a substantial role wither exacerbating the effects of explicit policies or offsetting them. To illustrate this point, we refer to the simplest case where tariffs are the only market intervention and imperfection. Anderson and Valenzuela (2008) show that the NRP at the border is equivalent to a tariff if no other market interventions and imperfections are in place. In other words, in the absence of domestic market interventions and imperfections between the border and wholesale market, it can be shown that NRP at wholesale for an imported commodity is equal to the tariff and other tariff equivalent charges multiplied by the ratio of the border price to the border price used for reference at the wholesale level.

As a matter of fact, the calculated NRP, in addition to the effect of the tariff, includes the effects of market imperfections (asymmetric access to information, market power, etc.) as well as the effect of other policy measures (such as market regulations), other fees and levies, and other measures adopted by governments to generate revenue, address market failures or pursue other objectives, all of which distort price transmission between the border and the farmer. To account for that, MAFAP estimates an additional indicator, called the adjusted NRP. This measure aims to identify excessive access costs in comparison to a more efficient or ideally functioning value chain. If excessive costs are identified, they are excluded in the calculation of the adjusted costs that are used in the calculation of the family of adjusted indicators. The main concepts that are subject to revision in order to provide adjusted measurement are the exchange rate, the benchmark price and access costs at different points of the value chain.

To expand the analysis in order to particularly capture inefficient market functioning, such as poor infrastructure, high processing costs due to obsolete technology, government taxes and fees (excluding fees for services), high profit margins captured by various marketing agents, illegal bribes and other informal costs which are particularly relevant in developing countries, MAFAP introduces the indicator of the Market Development Gap (MDG). This indicator represents an aggregate estimate of the effect of excessive access costs within a given value chain on prices received by producers.

[2] The exchange rate used should reflect opportunity costs and should itself be adjusted in cases when the domestic currency is overvalued. African currencies have often been overvalued but most have been determined by market forces since about the 1980s. An exception is the CFA franc region in West Africa that has been tied to the French franc (and now the Euro) and Malawi for about 2008-10. Burkina Faso and Mali are included in the CFA franc region (Etta-Nkwellea et al., 2010).

These market imperfections can impede the transmission of world prices onto domestic markets, reflecting a bigger or lesser degree of immaturity. The more markets are integrated (i.e. the more the observed price gap is the effect of explicit trade and market support policies), the more the MAFAP MDG will resemble the total MDG in the country. In theory, the MDG reflects the opportunity costs that these inefficiencies represent for producers. It is the portion of the price gap that can be attributed to "excessive" or inefficient access costs within a given value chain (see Anyango, 1997) and imperfect functioning of markets.

2.2 Public expenditure analysis

Governments from developing countries often lack organized information that would enable them to systematically analyse the performance of expenditures affecting the food and agriculture sector (UN, 2014). Key actors at national level recognize the need for the availability of such information on a regular basis in order to make rational, evidence-based policy choices, and that the development of appropriate indicators is an important prerequisite for policy analysis and efficient budgetary processes.

The Public Expenditure in Agriculture (PEA) indicators proposed by MAFAP seek to keep track of both the level and composition of public expenditures in support of food and agricultural sector development, and to establish a link between aid allocations and national expenditures. The MAFAP-PEA indicators aim to assess whether resources are being allocated to priority areas, whether they address investment needs, and whether they are consistent with government policy objectives. They also reveal whether aid allocations are coherent with national priorities. Moreover, the detailed nature of the MAFAP indicators permits investigation into the incidence of PEA on agricultural growth, poverty reduction and other development variables, contributing to further research and analysis in that domain (, Hazell et al., 2010, Benin et al. , 2008, Benin et al., 2009).

The methodology proposes to capture all public expenditures in support of food and agricultural sector development, ideally going back a minimum of nine years. That includes expenditures from the national budget undertaken by either a central or regional government, regardless of the ministry or agency that implements the policy, and external aid provided either through local governments or specific projects and programmes conducted by development partners. Public expenditures considered in the MAFAP-PE methodology are those of the food and agricultural sector, including forestry and fisheries. In addition, the MAFAP-PE methodology includes all public expenditures in rural areas, as they may also play an important role in agricultural sector development, even if they are not specific to the sector. The information on public expenditures in rural areas also aims to establish a view of a country's general policy environment and whether there may be a pro or anti-rural bias in expenditures on such significant areas as infrastructure, health and education.

In order to capture all public expenditures in support of the food and agricultural sector, the MAFAP programme has established the following distinctions:

i. A broad distinction between expenditures that are agriculture-specific (direct support for the agricultural sector), agriculture-supportive (indirect support for the agricultural sector) and non-agricultural.

ii. Within the agriculture-specific category, a distinction between support for producers and other agents in the value chain (e.g. input subsidies), and general or collective support for the sector (e.g. research). The agents in the value chain include farmers (producers), input suppliers, processors, consumers, traders and transporters.

Agriculture-specific expenditures generate monetary transfers to agricultural agents or the sector as a whole. Those agents (or the sector as a whole) must be the only, or the principal recipient of the transfers generated by the expenditure measure. 6 Agriculture-supportive measures are not strictly specific to the agricultural sector but have a strong influence on agricultural sector development such as investment in rural education or rural health. All measures that meet these criteria are considered in the analysis, regardless their nature, objectives or perceived economic impacts. The detailed classification of support follows the OECD's principle of classifying policies according to their economic characteristics (i.e. the way they are implemented), which provides the basis for further policy analysis (OECD, 2008)[3].

[3] The fact that MAFAP classifies policies according to their economic characteristics should not be confused with the distinction made by the IMF between economic and functional classifications of expenses. In the IMF Government Finance Statistics (GFS) Manual (IMF, 2014, p.114), the following definitions are provided: "the economic classification of expense identifies the types of expense incurred according to the economic process involved" and "the functional classification of expense provides information on the purpose for which an expense was incurred". In this regard, the COFOG classification is functional in nature. However, the MAFAP classification considers policies and information on the way in which they are implemented (which can be both quantitative and qualitative) as the starting material for the attribution of the PEA categories. This is a consequence of the fact that the MAFAP classification is an analytical tool and not a reporting tool. Therefore, the distinction between functional and economic classifications in the sense given by IMF does not apply to the MAFAP classification, contrary to what could be suggested by the indication that policies are classified by function of their economic classification.

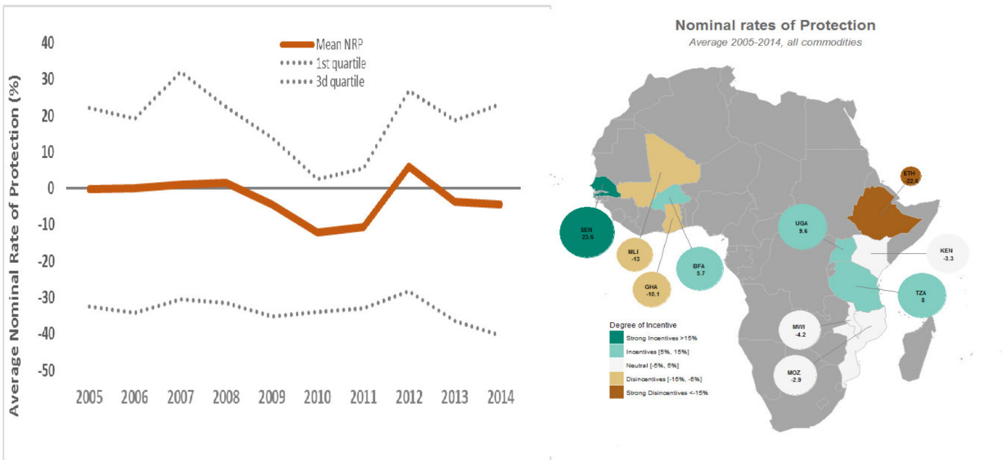
3 Results

3.1 Price incentive analysis

Results presented hereafter are based on Nominal Rates of Protection (NRP) estimates which serves as an indicator of incentives or disincentives to production and the Market Development Gap (MDG). The NRAP indicator is essentially based on the comparison between domestic market prices (observed prices) and reference prices free from domestic policy interventions (see above).

3.1.1 Aggregated results

Figure 2 - Nominal rates of protection, 10 African focus countries, unweighted average 2005-14



Source: Author calculations based on MAFAP, 2015.

The line representing the average NRP for all MAFAP countries in Figure 2 may give the impression that distortions are very low and almost negligible in the analysed time period from 2005 to 2014. The price distortion indicator is indeed close to zero on average for the analysed products and years, at least until the food price crises and then goes back to a value just under zero after the fluctuations caused by the crisis. However, the shown 1st and 3rd quantiles indicate that there is more to consider when analysing the price distortions affecting farmers in the observed countries.

The map in Figure 2 shows the important and substantial heterogeneity of the aggregated results across countries. Out of the ten countries analysed, we find that half exhibit average incentives for all commodities throughout the review period.

- The strongest incentives to farmers are to be found in Senegal with an NRA of 23.6%, followed by Uganda with 9.6%, Tanzania with 8%, Burkina Faso with 5.7% and Kenya with 5.5%.

- The strongest disincentives to farmers are observed in Ethiopia with an NRA of -22.6%. Mali has an NRA of -13% and Ghana -10.1%. Lower distortions are observed in, Mozambique with -2.9%, Kenya with -3.3 and Malawi with -4.2%.

It is important to keep in mind that the results are often driven by strong interventions for individual commodities that the governments pay particular attention to. The section on the commodity specific NRPs will provide more insight into these individual distortions by commodity.

Figure 3 - Market Development Gap, 11 African focus countries, unweighted average 2005-14

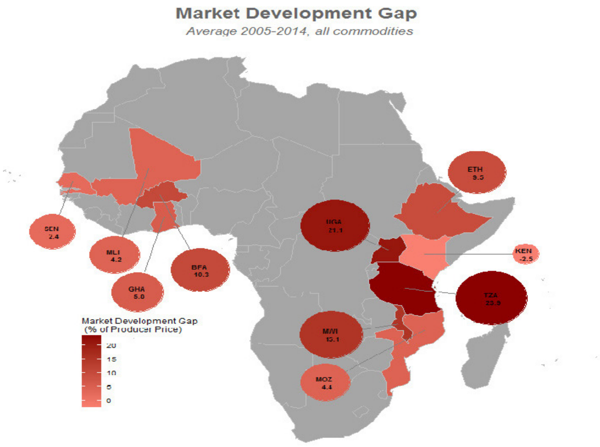


Figure 4 - Market Development Gap (total), NRP adjusted and observed (%), 11 African focus countries, unweighted average 2005-14

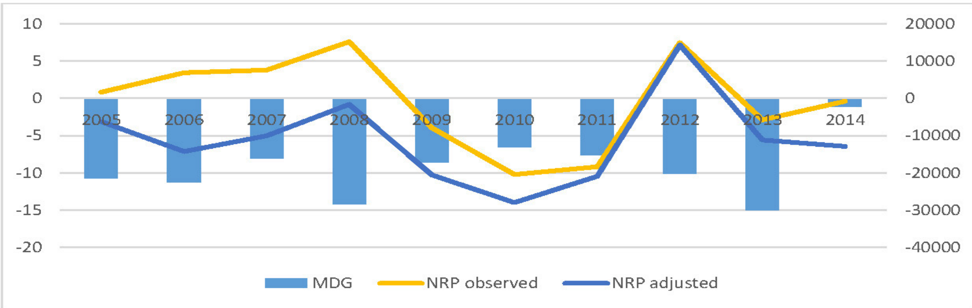

Figure 3 shows the Market Development Gap (MDG) indicator for the analysed countries. In Tanzania, the MDG is observed to be 23.9%, which means that market inefficiencies contribute highly to disincentives for farmers in Tanzania and therefore lead to overall disincentives for farmers, despite the positive observed NRP. In Uganda, the MDG is 21.1%, followed by Malawi with 15.1% Burkina Faso with 10.3%, Ethiopia with 9.5, Ghana 5.8%, Mozambique 4.4%, Mali 4.2%, Senegal 2.4%, and Kenya 2.5%.

The development of the MDG over the studied time period indicates the increasing role that market inefficiencies have in generating price incentives compared to trade, price or other market policies in all analysed countries. Reasons for these inefficiencies are mainly government taxes and fees, bribes, high transport and processing costs and the concentration of profits among intermediaries.

3.1.2 Cotton

This section reports the results analysed for cotton in seven countries: Burkina Faso, Kenya, Mali, Malawi, Mozambique, Tanzania and Uganda. Cotton is currently one of the most valuable cash crops despite the negative effect of subsidies and high levels of protection of many of the OECD countries on world prices (Baffes, 2002, Baffes et al., 2010; de Gorter, 2012). In 2010, cotton was by far the most important export crop in Burkina Faso and Mali, third most important and only slightly behind coffee and tobacco in Tanzania, fourth in Mozambique and Malawi, and seventh in Uganda.

In each country analysed, only a small number of companies, public or private, operate ginneries, each of which deals with a large number of small-holder farmers. All seven countries studied have one or more agencies or parastatal organizations charged with promoting the cotton sector, but the degree of centralized direction exercised varies considerably from country to country. However, in all countries studied ginneries operate well below capacity.

The private sector is now responsible for cotton ginning in all of the countries studied except for Mali and Burkina Faso where responsibility for cotton marketing is still vested in parastatals. Governments of both countries have set up regional companies that provide inputs to, and collect seed cotton from village level producer associations, process it in their ginneries and market the cotton lint, cottonseed and other by-products of the ginneries. They also play an important role in setting producer prices for seed cotton.

The industry is only slightly less concentrated in Mozambique. The Mozambique Cotton Institute (IAM) is the main cotton parastatal with responsibilities for the production of seed cotton, protection of stakeholders and fostering the development of the industry. It licenses eight ginneries which each have exclusive concessions to buy seed cotton in a specific region, fixes minimum pan-seasonal and pan-territorial prices and is the buyer of last resort if the ginneries are not willing to buy seed cotton from some producers.

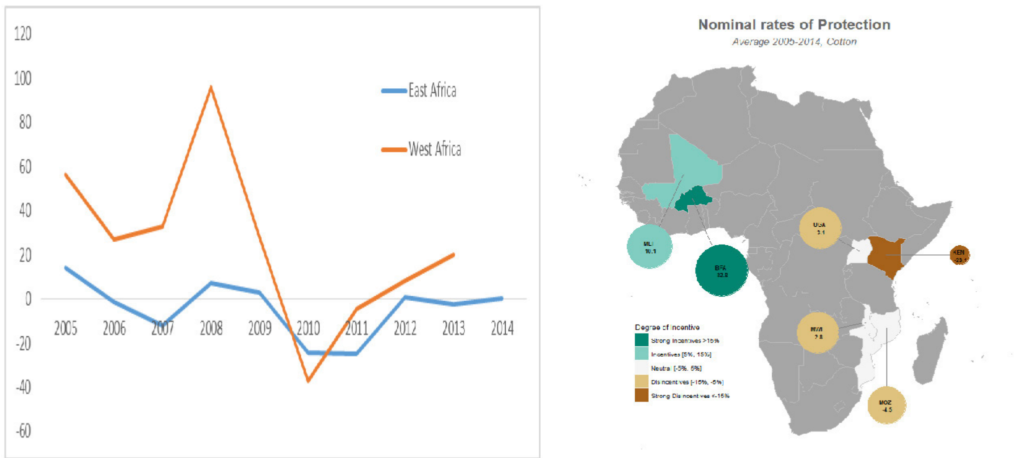
The cotton value chains in the other three countries are far more market-oriented. The Tanzania Cotton Board (TCB) is primarily a regulatory agency that promotes the development of the cotton sector through setting quality standards, licensing post-farm gate businesses involved in cotton trade and processing, farmer education and ensuring the seed cotton market is competitive. There are about 500,000 cotton farmers in Tanzania who sell their seed cotton to cotton traders or directly to one of the 40 to 60 ginneries. Since 2007, a new contract farming system has been made available in Tanzania in which farmers can get credit and other inputs from a ginnery and agree to sell their seed cotton to the ginnery according to the terms of the contract. The TCB also operates a network of about 8,000 'buying posts' for farmers not selling their seed cotton under contract.

The Ugandan cotton sector is organized much like that in Tanzania. Ginneries in Uganda are privately owned and operated companies that market the cotton lint and cottonseed they produce. The Government of Uganda mandated the Cotton Development Organization (CDO) to promote, monitor and regulate. The ginneries in Uganda are also required to provide a certain amount of cotton seed to the CDO which in turn provides good quality, treated seed to cotton farmers without charge.

Malawi's Cotton Development Trust (CDT) brings together all stakeholders in the value chain: farmers, input suppliers, ginners and the Malawi Ministry of Agriculture and Food Security. It recommends a minimum price for seed cotton each year to the government and advises on other aspects of policy for the cotton value chain.

In Kenya, despite the sector's decline in recent years, cotton is still considered one of the few cash crops with real potential for increasing employment opportunities and food security through income generation in the Arid and Semi-Arid Lands (ASALs) of Kenya (CODA, 2008). Kenya is endowed with a well-developed textile industry that requires a constant supply of cotton lint. The cotton market in Kenya has been fully liberalized and is now in the hands of the private sector. CODA as a regulatory body is charged with coordinating and regulating cotton marketing. Cotton marketing is facing difficulties due to the weak cotton cooperatives and organized farmer groups resulting in poor farmers bargaining power and lack of economies of scale (CODA, 2010). Despite a growth in exports, very few benefits have been realized by local cotton producers due to the fact that Kenya's textile industry continues to import most of its factory inputs rather than purchase domestic cotton lint. The ginnery industry appears to be operating at a 24 percent of its capacity due to short supply of cotton. As a result, the industry is highly dependent on imported inputs mainly from Uganda and Tanzania.

Figure 5 - Nominal rates of protection for cotton, unweighted average by region, 2005-2015



Source: Author calculations based on MAFAP, 2015.

Results presented in Figure 5 clearly show that the level of support to the cotton sub-sector is stronger in West Africa (Burkina Faso and Mali) than in Eastern and Southern Africa (Malawi, Mozambique, Kenya, Tanzania, and Uganda). Two periods can be easily distinguished. Between 2005 and last 2009, producers in West Africa received particularly strong price incentives to produce cotton while producers in Eastern and Southern Africa experienced only moderate incentives or disincentives. The cotton price crises of 2010 is visible in both West and East Africa regions with NRPs becoming substantially negative especially in the case of West Africa. The post crises period, when international prices of cotton started rise again, is characterised by the emergence of a common pattern of support in both regions although Western Africa started to diverge as of 2013 while price incentives remained neutral in East Africa.

Figure 6 - Nominal Rate of Protection for cotton seed in the MAFAP countries

Source: Author calculations based on MAFAP, 2015.

We observe that **Burkina Faso** is by far the country providing the highest level of support at roughly 33% while the average NRP is only 13% over the analysed period. Burkina Faso is the first cotton producer of West Africa with 766,000 tonnes of seed cotton produced in 2013-14. For the whole period analysed, producers have received strong price incentives while the main ginning company SOFITEX controlled by the State has been selling cotton at price lower than the international price which implies a substantial cost for the national budget especially when international prices are low.

In **Mali**, a similar price mechanism as the one observed in Burkina Faso operates. Although this stabilization fund creates incentives for production when international prices are low (2005-2009 period), this mechanism limits the transmission of prices and penalizes producers when prices are high (2010-2012). However, the incentives were not sufficient to stimulate the production of cotton, which declined between 2005 and 2008. In 2009, through direct support in the form on inputs subsidies, the government managed to boost production despite the price disincentives received by producers until 2012 when international prices were particularly high.

Contrary to the case of Burkina Faso and Mali, **Kenya** exhibits the highest level of disincentives at roughly -23% on average over the period. However, Kenya is a net importing country while Burkina Faso and Mali are both net exporters. The absence of production incentives may suggest an implicit support to the cotton processing industry in Kenya. The main driving factor for the price disincentives at the primary level of the cotton value chain is the distribution of the market power along the value chain which influences the cotton pricing. The minimum pricing model used by stakeholders appears to be an inadequate tool since it is based on FOB price rather than the CIF price of lint which is inappropriate for a net importing country.

In **Mozambique**, cotton producers have seen the level of support decline to pronounced negative levels in 2010. The situation improved as of 2011 to stabilize to moderate levels of either price incentives or disincentives depending on the years in a situation that seems to be characterized by instability. The minimum price policy allowed farmers to receive prices higher than what they should have received when international prices are low but this system has probably also be used to set low reference prices when international prices spike. The concession system has also made it easier for ginners to pay prices lower than what they should have paid to farmers when international prices are high. Over all the sector is affected by a low productivity, which increases the risk and limits the capability of the actors to respond effectively to changes in exchange rates and international prices.

In **Tanzania**, cotton producers have moved from a situation of net taxation until 2009 to a situation of support thereafter. Incentives to farmers at the farm gate have been increasing as the government has recently enacted further support projects including contract-farming solutions for farmers that guarantee higher prices. This has enabled further growth within the sector as more farmers are incentivized to grow seed cotton as assurance of price structures as well as marketplace to buy their lint is provided

In **Uganda**, producers have received price disincentives or moderate incentives for the most part of the analysed period except in 2012 when international prices were very high. The major driving force for the generally positive indicators is the cotton pricing system adopted which is based on world prices for lint prevailing at time of price announcement. The indicative price often becomes a price ceiling. However, the variability of the indicators is caused mainly by highly volatile world price of cotton and the difference in price between the price announcement and the realized export price for lint. Regardless of the price incentives to producers, the poor performance of the cotton sector In Uganda is related to factors including low productivity caused by the low use of purchased capital inputs and low profitability which is directly related to crop yields and output prices and inversely related to the cost of production.

Better policies and targeted public investments could help increase cotton productivity and production resulting in higher competitiveness of the cotton value chain across countries. Additional export opportunities could play an important role as a source of income and income diversification contributing to poverty reduction in these areas. It could also support the development of an African textile industry, in Kenya for example, to further integrate the economies of the East Africa Community (EAC).

3.1.3 Rice

This section reports the result for rice in nine countries: Burkina Faso, Burundi, Ghana, Kenya, Mali, Mozambique, Senegal, Tanzania, and Uganda. Most rice is produced using various irrigation systems although some rainfed rice production takes place in all the countries studied. There are a number of different irrigation systems in the Niger basin in Mali and Burkina Faso but irrigated rice production in other countries is mostly on irrigation schemes that were established by the governments concerned.

Although rice is mainly produced by small-scale farmers in the nine countries studied, it is not primarily a subsistence crop consumed on farm. Even in Mali with by the far the greatest consumption per capita, only 37 percent of the rice produced is consumed on-farm (Samake and Bélières, 2007). In general, rice is a cash crop produced in competition with imports and consumed in urban areas mainly by middle- and high-income consumers or on special occasions. The demand for rice is therefore expected to grow rapidly with rising incomes and urbanization.

The price spike in global commodity markets in 2007/08 was greater for rice than any other cereal (FAO, 2010; Headey and Fan, 2010). The price spike together with import dependence and the prospects of rapidly increasing domestic demand triggered concerns on rice policy in most of the countries studied. Policymakers in the countries studied also appeared to be convinced that there were good prospects to increase rice production by their small-scale farmers. It is this combination of factors that made rice a priority commodity for policymakers in the countries studied.

This priority given to rice by policy makers is illustrated in three policy areas: the National Rice Development Strategies (NRDS)[4], additional budgetary resources for infrastructure for rice production and the tariff regimes that appear to protect rice more than other staple commodities. Tanzania's objective, for instance, was to double rice production by 2018 to "develop the agricultural sector in order to attain the desired food security situation and growth for poverty reduction". Other countries included in this study have similar goals and ambitious targets.

Many of the countries studied also have parastatals for marketing major staple commodities. These generally have a dual function: to maintain a buffer stock that can be used to respond to exceptional shortfall in production resulting in a food security crisis for some segment of the population and to intervene when market prices for consumers rise above a ceiling level or fall below floor level for producers.[5]

Regional and local governments in all countries studied may also affect rice markets by charges they levy. In Tanzania, for instance, a district sales tax is charged on grain "exported" from the district to any destination. The tax rate varies from district to district between one and five percent. There are fees in some countries for grain transported through a district and for marketing it in local markets. Police checks along major transportation corridors are common and provide a venue for collecting district fees and an opportunity for extra-legal charges to avoid costly delays and/or avoid compliance with load limits and other regulations, all of which are a distributional inequity type of non-market failure.

4 All of the countries studied have prepared NRDSs in partnership with the Coalition for African Rice Development (CARD). CARD was established by the Japan International Cooperation Agency (JICA), the Alliance for a Green Revolution in Africa (AGRA) and the New Partnership for African Development (NEPAD). The CARD strategy focuses on strengthening the production and multiplication of certified seed, research, and agricultural extension, the development of agricultural land and water resources, and improved small-scale, post-harvest rice processing equipment.

5 The use of stocks to stabilize cereal prices has been criticized for at least three reasons: they replace private stocks, they were found to be poorly managed, and they distort market signals (Jane, 2011; Tangermann, 2011; Timmer, 2011; Demeke et al., 2014).

Burkina Faso and Mali have introduced new marketing policies or reverted to some pre-liberalization policies in response to the commodity price crisis of 2007/08. While it has been the case in Mali since 2003, Burkina Faso began including rice in its food security stocks in 2008. Both countries used a direct price control approach to stabilize prices rather than the indirect approach of buffer stocks. Mali established price ceilings at both wholesale and retail in 2008/09.

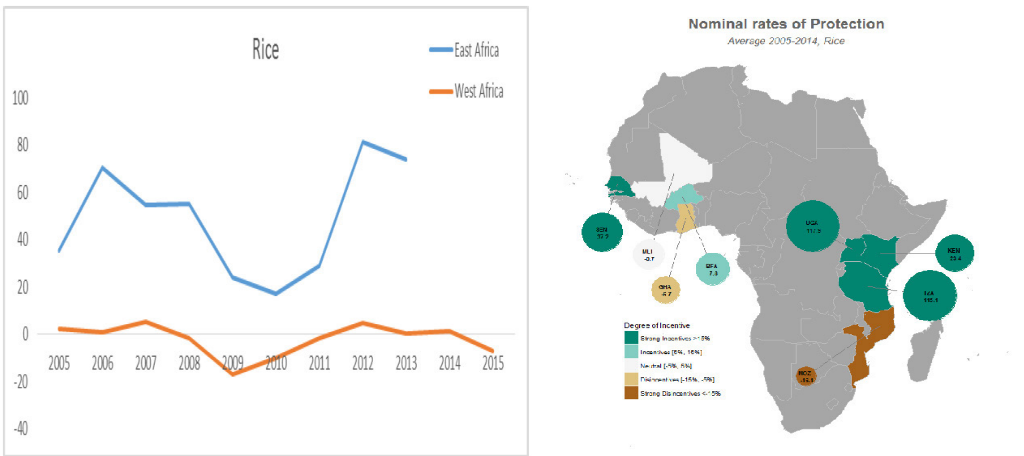
Burkina Faso prices were based on estimated costs of production plus a producer margin throughout 2008 -2010. They also set margins through the rest of the supply chain implicitly controlling prices at all levels.

All the countries studied belong to one or more preferential trade agreements (PTAs) which discipline their tariffs with each other and the rest of the world. They also seek to limit the effect of non-tariff barriers. Kenya, Uganda and Tanzania are members of the EAC. Kenya and Uganda are also members of the Common Market for Eastern and Southern Africa (COMESA). Tanzania and Mozambique were members of COMESA but withdrew. They are both members of the Southern African Development Community (SADC). All four West African countries are members of the Economic Community of West African States (ECOWAS). Burkina Faso and Mali are also members of WAEMU.

Results presented in Figure 7 show two different trends for East and West Africa. In both sub-regions we can observe the downward trend in support to production in 2009. This situation of depressed price received by producers appear to have lasted more for producer in eastern Africa than for those of West Africa.

The level of support to the rice sub-sector has been almost neutral on average in West Africa (Burkina Faso, Ghana Mali and Senegal). However, this result masks an important heterogeneity across countries. While producers in Senegal and to a lesser extent Burkina Faso received substantial price incentives on average over the period analysed (+16% and +8%), producers in Mali and even more so in Ghana received rice production disincentives of -1% and -5% respectively.

Figure 7 - Nominal rates of protection for rice, unweighted average by region, 2005-2015



Source: Author calculations based on MAFAP, 2015.

In **Senegal**, the strong production incentives are largely explained by the tariff set at 12.5% and the existence of an indicative producer price adopted by the Government.

The situation of **Burkina Faso** which is also a net importer is largely explained by the effect of the border protection (tariff of 14%) that dissipates partly between the wholesale and farm level due to market imperfections, the imposition of a floor price for rice, both of which are augmented by the natural protection for this landlocked country resulting in very high transportation costs.

For **Mali**, with the exception of 2009 and 2010, the situation of moderate price incentive or disincentives prevails over years. The government adjusts the its policy in support of either producer or consumers depending on the perceived food security situation of the population but the effects of the interventions are partially offset by huge market inefficiencies constraining price transmission.

In **Ghana**, rice imports are subject to an import duty of 20 percent (temporarily removed in 2008 and reinstated during the course of 2009) as well as other taxes and levies. Rice is one of the commodities, purchased by the National Buffer Stock Company (NAFCO), operating since 2010, to stabilize rice prices and build emergency stocks. The main driver of the huge price disincentives appears to be related to the important market failures, including market power exercised by NAFCO, and resulting in very high transport and other market access costs.

For Eastern and Southern Africa, Figure 7 shows that the level of support is generally much higher and could reach level as high as 80% in 2012 on average. However, in this region heterogeneity prevails too. Burundi, Kenya, Tanzania, and Uganda exhibit high levels of price incentives on average with 36%, 23%, 115% and 117% respectively.

In **Burundi**, the rice value chain is characterised by a strong demand that cannot be matched by domestic production and is consistently supplied by imports that represent 40% of the domestic consumption. The policy and market environment made of the external tariff set at 75% by the East Africa Community (EAC) and the high demand for rice explain the level of producer incentives. The fact that the average NRPs is below the tariff is explained by important market failures resulting in very high transportation costs and market power exercise by middle men.

In **Kenya**, this result is due to the market failures affecting wholesale prices and producer prices at least as much as the external tariff. In addition, the Kenya government budgets in 2009 and 2010, for example, included new initiatives to rehabilitate and expand irrigation schemes that are mainly used for rice production.

In **Tanzania**, the Government's objective was to double rice production by 2018. As Tanzania also belongs to the EAC, rice producer benefit from the same high tariff. However, market inefficiencies as well as intervention by local government explain the reduced level of price incentives in Tanzania relative to the case of Kenya. For instance, a district sales tax is charged on grain "exported" from the district to any destination.

In **Uganda**, most of the commodity markets are fully liberalized and the average price incentives observed at farm level of 75% is basically the effect of the tariff adopted by the customs union of the EAC. Mozambique shows less favourable situation for rice producer with respectively - -16% NRPs on average for the period analysed.

In **Mozambique** where rice is also imported to match the demand, the level of price disincentives is largely explained by important market inefficiencies as the consumption region is around Maputo in the south while the production region is located in the north at quite long distance. The high transaction costs and market power exercise by traders explained the low prices received by producers.

3.1.4 Maize

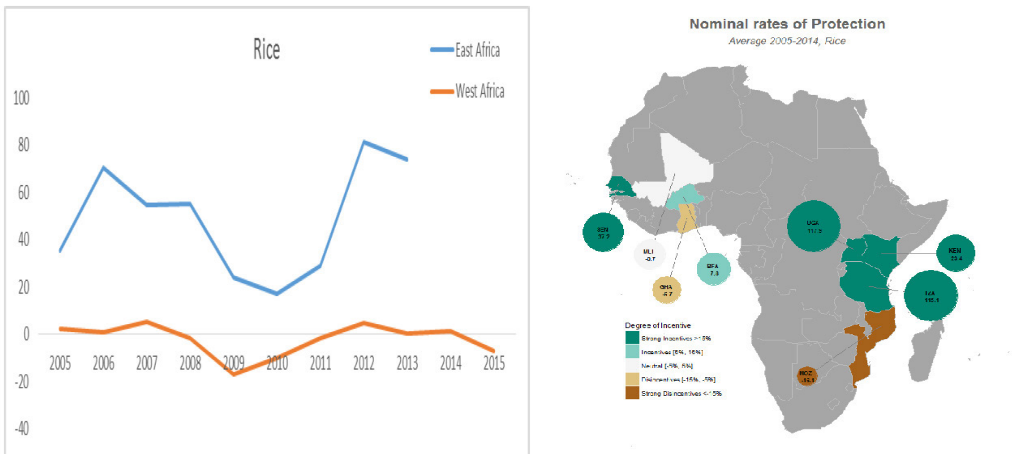
Maize is one of the most important crops in Africa by almost any measure. It is the biggest or nearly the biggest crop in terms of area and volume of production because it can be successfully grown in a wide range of African agro-ecological zones and because it is easy to cook. However maize plays a different role in each of the ten countries studied. In most countries, maize consumers have a strong preference for white maize, while yellow maize is generally regarded as animal feed. Malawi, Tanzania, and Kenya are the top three in terms of the domestic supply of maize in Kg/capita. Malawi for example stands out with 197 kg/capita, more than twice the level of the next largest figure. Uganda and Nigeria at 39 and 47 kg/capita, respectively, rely on a more diverse set of staple foods and have the lowest domestic supply levels with the other countries ranged between these extremes.

Maize is generally thinly marketed and traded. In all countries, there are networks of small traders who buy directly from farmers or in local markets. Maize is sold up the chain through larger market centres to larger wholesalers and ultimately the larger towns and cities and supply other maize deficit regions. Trade volumes are small relative to production and consumption so most of the countries analysed are near self-sufficiency in most years as shown in Table 1. In Malawi for example, which produces twice as much per capita as any other analysed country, only 5 – 10% of the crop produced by smallholders is marketed. Similarly in Kenya, only 32% of smallholder maize producers are net sellers. This is true too in countries like Mali and Burkina Faso where crops like rice, millet and sorghum are relatively more important than maize. Uganda is somewhat different because maize is also seen as an important export crop and, in some districts of Uganda, 75 – 95 percent of maize production is marketed. But even in Uganda, over 60% of maize is consumed within the country which can include informal trade and much of it on the farm. Some countries, like Tanzania, switch back and forth between net exporter and net importer status.

Prices in these countries are frequently both below import parity and above export parity relative to maize benchmark prices such as US Gulf and South African Futures Exchange (SAFEX). Consequently, trade often occurs with bordering countries.

As a result of the relatively small volume of international trade and the low share of production that is marketed internally, marketing channels are generally not well developed. This is also due to the fact that maize was a highly controlled and has often been a politically sensitive commodity in Eastern and Southern Africa, and the disbandment of parastatals has disorganized the marketing channels. There are few facilities for bulk grain handling and shipment that take advantage of economies of scale. It is frequently first transported to a nearby market in a 90 kg bag by the farmer that grew it. The most common form of transportation to large market centres is by 40 tonnes trucks rather than barges or by train in grain hopper cars. The existing marketing systems can cope with normal volumes and respond to small surpluses or shortfalls in production. Larger more widespread shortfalls create a crisis situation as seen in Kenya in 2008 – 2009, requiring atypical imports from world markets and straining logistics capacity.

Figure 9 - Nominal rates of protection for maize, unweighted average by region, 2005-2015



Source: Author calculations based on MAFAP, 2015.

The results for maize are strikingly different for the West Africa and East Africa regions. The aggregated NRPs behaves also symmetrically in opposite direction in the two regions. These very different patterns in the two regions suggest policy interventions moving in opposite directions. Once again, results vary a lot across countries and also within countries over years due to change in policy interventions.

Figure 10 - Nominal Rate of Protection for maize in the MAFAP countries

Source: Author calculations based on MAFAP, 2015.

Farmers in **Burkina Faso** have from price incentives with NRPs set at 20% on average over the period analysed. Burkina Faso is an exporter in all years except 2007 with trade happening with its neighbouring countries at zero tariff in all years. The farm level prices are quite lower than expected in all years given the wholesale prices and estimates of market access costs between the farm gate and wholesale. This result is consistent with inefficiencies affecting the value chain between farmers and wholesale markets. Illegal fees, some taxes often considered inefficient, excessive commercial margins by exporters and wholesalers accounted for a significant shortfall for farmers. This loss, reported in Franc CFA per tonne for the period 2008-2013, is ten times higher than the amount for input subsidies to maize distributed these years.

In **Mali**, Figure 9 indicates that the NRPs at farm level was close to -15 % on average over the period analysed. Producers have received by price disincentives largely explained by the poor connection of small farmers to domestic and regional markets where prices are generally higher than in Mali. Trade levels have been too low for producers to take advantage of potential market opportunities at regional and international levels. The apparent low correlation between domestic and international prices indicates a rather limited capacity of the economy to transmit price signals. Producers and wholesalers seem to have essentially reacted to signals emanating from the domestic market.

For **Ghana**, the right hand panel of Figure 9 shows that overall farmers have been substantially penalized by low prices with a NRPs of -45% on average over the period. Although the NRP at wholesale consistently stands at lower level of penalization both the farm and the wholesale levels have received substantial disincentives. Ghana has had a VAT and other levies amounting to a 17% charge on imports throughout the period analysed. In addition, there was a 20% tariff on maize in 2005-06 and 2009-10 that was reduced to zero in 2007-08. These charges cannot explain the very negative trend observed for the NRP throughout the period analysed. Clearly border protection should have played an important role in the opposite direction keeping domestic prices at wholesale and farm level well above the reference price. The main driver of the important price disincentives observed result from substantial market failure and primarily market power exercise by some agents in the value chain. High transport and handling costs contribute to exacerbate farmers' disconnection with wholesale markets

In **Ethiopia**, farmers have received very pronounced price disincentives at roughly -55% on average over the period analysed. Restrictive trade policy (export bans), overvalued exchange rate, high access costs and high international prices largely explain these disincentives to producers. For instance in 2010 and 2011, when the export ban was lifted and the exchange rate had improved after devaluation in 2011, disincentive declined, whereas in 2012 when the export ban was reinstated and the currency overvalued again and that a record level of domestic production coincided with a context of high international prices, the price disincentive was maximum. The low domestic demand during years of good harvest like in 2012 combined with fairly steady levels of imports between 2005 and 2011 (with the exception of 2012) are factors contributing to the decline in domestic price. Moreover, because Ethiopia is a landlocked country, transaction and transport costs are usually quite high which also contributes to high reference prices.

Uganda is an exporter in all years without export fees or other restrictions on trade. Farmers have benefited from fairly high level of NRPs at nearly 36% on average over the period. Farmers have revived higher incentives than wholesalers. This relatively high levels of incentives to maize producers has been driven by the liberalized policy environment in Uganda where farmers through traders have been able to seize market opportunities arising in the East Africa Community.

In **Tanzania** farmers have received no incentive on average over the reported period. Tanzania changed trade status regularly. It was an exporter in 2005, 2007 and 2009 and an importer in the other years. For the 2005-2013 period, farmers have received either small incentives or disincentives for maize production, but in an erratic and volatile way. Uncertain government policy and erratic interventions in form of export bans, public procurement, price setting, and subsidized distribution of maize is not only regarded as ineffective and destabilizing, but even penalized both farmers and consumers in some years. Careful review of the trade and market environment is required to make maize production more remunerative for farmers and the commodity more accessible to consumers. Substantial value chain inefficiencies are linked to high transport costs and the presence of local taxes, informal fees and rent-seeking practices by value chain agents. These inefficiencies represent a huge cost to the maize sector and should be addressed as a matter of priority if Tanzania is to succeed in its goal of developing a more commercial and export-oriented maize sector.

In **Kenya**, farmers have received moderate price disincentives to produce maize over the period analysed at (-3%). Maize is an import in all years. In normal years, 25-35 percent of total marketed maize is sold directly to the National Cereals and Produce Board (NCPB) by medium and large producers. Smallholder producers sell 96 percent of their maize to private traders/brokers or consuming households. NCPB is used by the government to regulate the market by purchasing maize (mainly from medium and large farms) and selling it below the cost of procurement to incentivize production, while keeping prices low for consumers. The main policy instrument used to affect market prices of maize and consequently the price incentives to producers in Kenya is the trading activities of the NCPB. It does this through purchasing grain and selling it to millers often at a subsidized price. Combined with the short-term adjustment of the tariff to increase imports during years of shortage, the purchase pricing of NCPB manifested itself as a maize price ceiling. Since the NCPB purchase price is not based on import parity of maize, the domestic price of maize in Kenya is isolated to some degree from aligning with world market price.

In **Burundi**, farmers have received quite high price incentives to produce maize at 42% on average over the analysed period. While Burundi is a net maize importer, domestic prices are heavily disconnected from prices on international markets. The majority of maize imports come from Uganda, Tanzania, Rwanda and, to a lesser extent, Zambia. During the study period, these countries were still members of a free trade area with the exception of Tanzania which between 2005 and 2008 was not a member of the Common Market for Eastern and Southern Africa (COMESA) while Burundi was. Since 2009, these two countries are members of the East African Community (EAC). The producer price increased steadily over the period, despite the falls in international prices. In 2010, the international price for maize fell more than 50 percent, but producer prices continued to rise explaining the peak in incentives for that year. These strong production incentives are likely attributable to both the existence of a monopsony on imports which limits the volume of maize flowing in the country to keep high prices in the domestic market and the significant disconnect between the regional market and the Burundian market due different barriers (logistic, administrative , etc.).

In **Malawi**, farmers have received relatively high price incentives to produce maize on average at 32%. Indicators reveal that, over the 2005-13 period, the domestic policy and market environment generated highly volatile price incentives to maize farmers. In a sector dominated by smallholders and subsistence farming practices, this instability represents a major issue, as producers are not able to plan appropriate production and marketing strategies. The inefficiencies between farm-gate and wholesale markets, owing to high marketing costs, have also contributed to penalize maize farmers. On the one hand, price incentives for farmers in several years (205-2007, 2009-2013, 2015) were driven by steady but higher maize prices in Malawi relative to the region. A policy context of limited trade restrictions prevailing before 2007 and in 2010 seems to have allowed for better price transmission and larger protection for maize producers. On the other hand, farm-gate price disincentives in some years (2008 and 2014) were primarily driven by lower producer prices due to bumper harvests and oversupply, coupled with large market inefficiencies between farm gate and wholesale markets generated by poor rural infrastructure and high traders' margins. Furthermore, lack of storage facilities prevent farmers to market their maize later in the season and take advantage of higher prices.

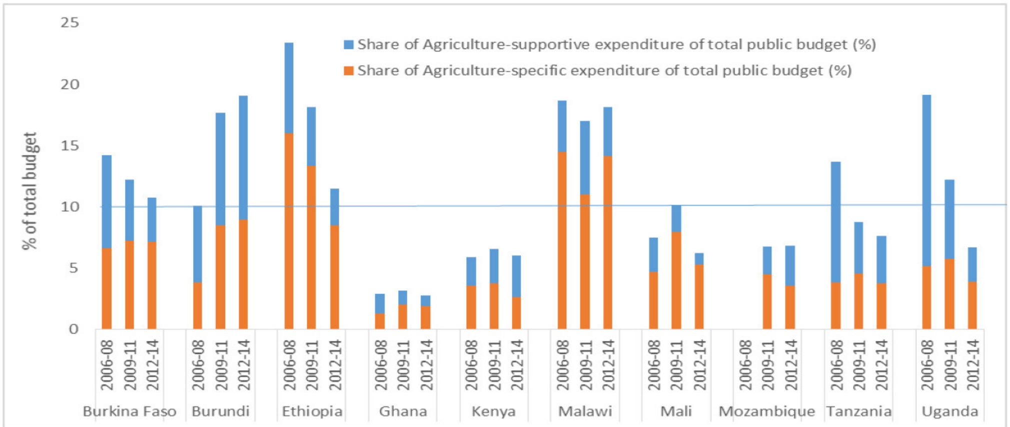
For **Mozambique**, wholesale prices are well above reference prices for all the years analysed, between 20 and 51% except in 2009 where they are only 5% as indicated by the NRPs (see Figure 10). NRPs in the 20 – 30% range at wholesale are consistent with Mozambique's tariff of 2.5% and VAT of 17% applied on imported maize only. The higher rate in 2008 is evidence of exceptional profits that importers could make in that year possibly due to restrictions or other problems of supply including the fact that Mozambique market is not really unified due to enormous transport constraints between the North and South. The 5% NRP in 2009 is consistent with measures to reduce the tariff or VAT in that year. Large scale importers are able to apply for a VAT rebate. Again, border policies appear to provide little incentive for farmers to produce maize. The NRPs at the farm gate should be at least as high as they are at the point of competition (wholesale) if the value chain were transmitting price incentives that exist at the border back to producers. But the NRPs at the farm gate are near zero in all years except 2008. Even in 2008, farmers did not receive the prices they were expected to receive considering the high NRP at wholesale. The wholesale-farm gate price gap suggests that internal market access costs, inclusive of excessive margins and any form of restrictions or exactions on transportation, are well above efficiency levels.

3.2 Public expenditure analysis

To pursue their policy objectives on growth and development, in addition to trade and pricing policy governments often use budgetary allocations in support of agriculture. In such a context, monitoring and analysing public expenditures in support of food and agriculture (PEA) is of the utmost importance for African governments and donors alike.

In July 2003, members of the African Union committed themselves to allocate at least 10% of their national budget to agriculture to achieve 6% growth of the sector. This commitment was renewed in the Malabo declaration of 2014 (AU, 2014). Figure 11 shows the trend in spending for 10 SSA countries. Figure 11 shows that agricultural specific expenditures dominate agricultural budgets. However, the wide variations across countries are also noticeable. While there is a controversy on what should exactly be accounted in the level of spending in reference to the Maputo declaration, most analysts have referred to specific on agriculture excluding spending categories related to rural development at large. According to this interpretation, out of the 10 countries analysed only Malawi exhibits a level of spending above the target. Burundi is quite close with an increasing trend. Ethiopia is also close but shows a declining trend. Even when we account for the agricultural supportive expenditures (i.e. spending on rural health, rural infrastructure, and rural education) only 4 country exhibit level of spending above the 10% threshold for the period 2012-14 (Burkina Faso, Burundi, Ethiopia, and Malawi). Most countries analysed exhibit a declining trend of support to their agricultural and rural sector.

Figure 11 - Share of Agriculture-supportive and Agriculture-Specific Expenditure of Total Public Budget, 2006-2014, three year averages, percent



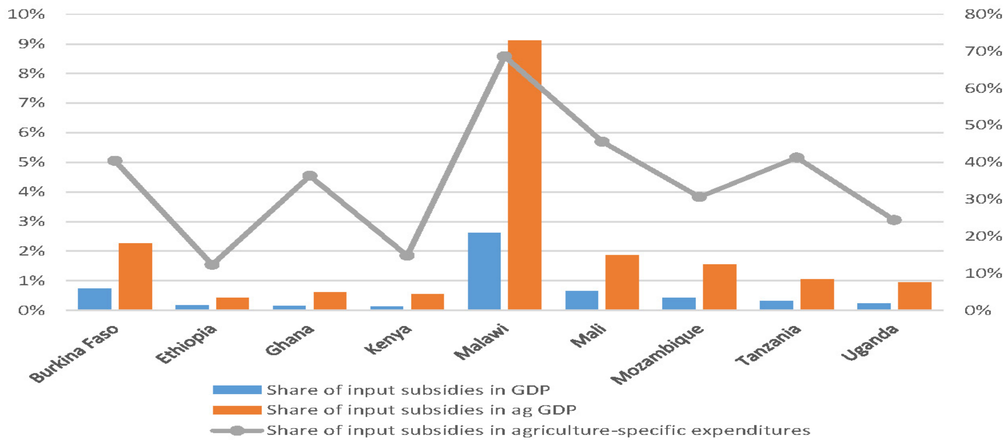
Source: Author calculations based on MAFAP, 2015.

Thanks to a fairly well desegregated MAFAP dataset it is possible to go beyond the level of monitoring public spending to focus on the composition of such expenditures in support of very specific categories such as payment to agents(producers, consumers, traders, ...), general support including agricultural research, technical assistance, extension storage, marketing and others. Payments to producers, for example, can include payments based on outputs, cash transfers, or input subsidies. The merits of spending on input subsidies as opposed to other spending categories such as research or infrastructure has been extensively discussed in the literature (Wiggins and Brooks, 2010). In this paper, we analyse input subsidies in more depth as one example of the type of analysis that can be done out of the MAFAP public expenditure database.

The MAFAP dataset reveals that over the period 2006-13, input subsidies have represented an average 35 % of agriculture-specific expenditures in the countries that were analysed. [6] This average masks three main groupings of countries. Low spenders are Ethiopia, Kenya and Uganda, with respective shares of 12, 15 and 24 %. Average spenders are Burkina Faso, Ghana, Mali, Mozambique and the United Republic of Tanzania (URT), with shares oscillating between 31 and 46 %. Malawi forms its own high-spending group, with a staggering share of 69 % (Figure 12).

The same pattern can be observed when considering the average shares of input subsidies in GDP and agricultural GDP (Figure 12Ghana is a specific case. Although input subsidies do constitute a large proportion of agricultural expenditures, at 36 %, they only account for 0,2 % of the country's GDP and 0,6 % of the agricultural GDP. There is indeed an important imbalance between public spending in the agricultural sector and the value added it produces.

Figure 12 - Share of input subsidies over agriculture-specific expenditures (right axis), agricultural GDP and overall GDP (left axis) in nine African countries, average 2006-13.

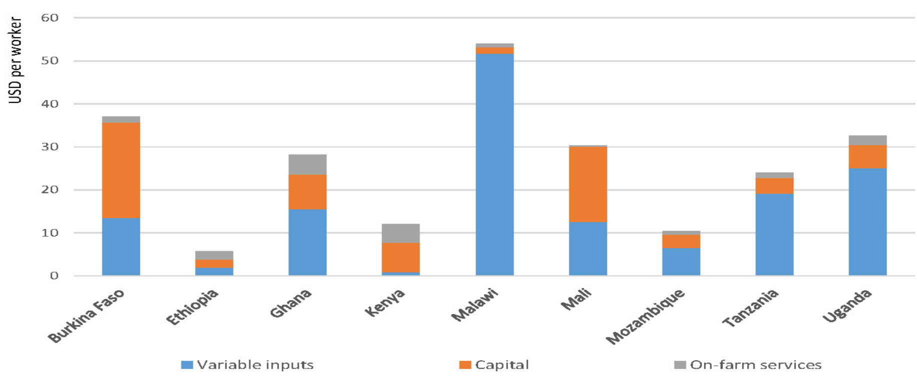


Source: MAFAP, 2016.

These results suggest to see the popular case of Malawi abundantly discussed in the literature (Chisinga, 2012; Jayne et al., 2013; Jayne and Rashid, 2013; Ricker-Gilbert et al., 2013) as an outlier rather than as an example of what is happening on input subsidies in SSA.

The composition of input subsidies is also more diversified than what is usually thought. Input subsidies are often equated to variable input subsidies for fertilizer and seeds. However, subsidized capital (on-farm equipment for instance) and subsidized on-farm services (inspection for instance) also represent a substantial share of the input subsidy category as can been see from. Although variable inputs have accounted for 59 % of input subsidies, capital and on-farm services have benefited, respectively, from 32 and 10 % of them. Burkina Faso and Mali have even subsidized capital, essentially on-farm irrigation, more than seeds and fertilizers (Figure 13). This is due to the geo-climatic characteristics of these countries, where access to water poses an important challenge. Kenya has also invested more in on-farm capital than in variable input subsidies.

Figure 13 - Expenditures in support of on-farm services, capital and variable inputs for nine African countries, average for the 2006-13 period, constant 2011 USD per farm.

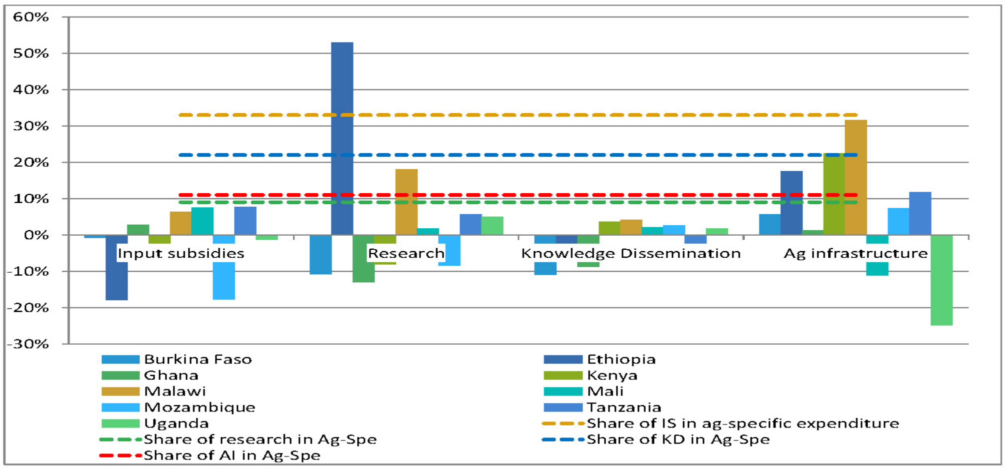


Source: MAFAP, 2016.

[6] The MAFAP methodology considers agriculture-specific and agricultural-supportive expenditures as PEA, which includes rural investments. See "methodology section".

Variable input subsidies have represented 23 % of agriculture specific expenditures on average for the nine countries over the analysed period, and 17 % if Malawi is not included. These results show that subsidies to seeds and fertilizers represent only a moderate fraction of agricultural budgets in all countries with the noticeable exception of Malawi. However, these variables input subsidy represent a substantial share of agricultural expenditures if taken jointly with subsidized capital and on-farm services, the three categories accounted for in the input subsidy category in MAFAP.

Figure 14 - Average exponential growth of the expenditures per farm on input subsidies, research, knowledge dissemination and agricultural infrastructure (in constant 2011 USD) in nine African countries, 2006-13 period, in %.



Source: MAFAP, 2016.

Figure 14 shows that input subsidies account for an average 36 % of agricultural expenditures, in the countries analysed and over the period. Input subsidies per farm, expressed in constant 2011 USD, grew at an average rate of 20.6 % during the period considered and across all countries reviewed. Agricultural research expenditure (ARE) per farm and agricultural infrastructure expenditure (AIE) per farm also grew positively, at about 26 % and 29 % respectively, but they only accounted for ten and 11 % of agricultural budgets respectively (Figure 14). Knowledge dissemination expenditure (KDE) per farm, which is recognized as a crucial area of expenditure to ensure effective uptake of research, increased at an average rate of about 21 %, which is about as much as expenditures on input subsidies per farm. In addition, ARE, AIE or KDE all represented less than 0.5 per cent of overall GDP or 1 per cent of agricultural GDP, on average for the reviewed period, considering all countries. By contrast, expenditures on input subsidies represented 0.6 % of overall GDP and 2.3 % of agricultural GDP, on average in all countries for the period considered here.

Overall, we find that the size and composition of input subsidies in budgets vary widely across countries (average 35%). Variable input subsidies do not always dominate agricultural spending. Other categories appear to be more attractive such as on-farm services, agricultural research/dissemination or agricultural infrastructures.

4 Conclusion

Governments in SSA are supportive of the idea that the agricultural sector in an engine of growth and plays a primary role in poverty reduction and improving food security. They therefore often decide to intervene in this sector through a variety of policy instruments ranging from trade and domestic policies, budgetary transfers or macroeconomic policies, or regulations. However, it also often the case that the governments' stated policy objectives, the policy measures implemented to achieve these objectives and the effects they generate are not in line.

This paper illustrate some of these policy gaps at regional and aggregated level as well as country and commodity disaggregated level.

First of all, while the overall level of price incentives is found to be generally low, the most striking result is the important heterogeneity of the results across countries and commodities analysed.

Second, when important disincentives are observed, the market failures and inefficiencies as captured by the market development gap indicator proposed by MAFAP appear to be playing a substantial if not primary role.

In addition, the problem of developing policy measures to mediate market failures poses difficulties that challenge the most sophisticated governments in developed countries: governments may not be able to accurately estimate costs to regulate prices in a market where one or more agent has excessive market power or evaluate the true value of an externality or public good.

Third, at commodity level based on the analysis of cotton, rice and maize, results also show a huge heterogeneity across countries and over time indicating that the situation is volatile and very much depends on conjectural factors and short term considerations by government leading to ad hoc policy interventions altering market signals and long term incentive structure.

Fourth, recognizing that government also use the budget as a tool to influence farmers' behaviour, MAFAP results indicate that the level of budgetary support to the agricultural sector as a whole for the fiscal year 2013/14 as reported by MAFAP is still below the Maputo target established in 2003. There are also clear signs of declining trends suggesting that the Maputo /Malabo target is not likely to be met in the near future.

Five, taking input subsidies as an example of desegregated result on public expenditure, MAFAP results show that here too heterogeneity prevails. Variable input subsidies for fertilizers and seeds do not always dominate the budget allocated to agriculture or even input subsidies as in some countries subsidies to capital in the form of irrigation or extension services on the use of variable input subsidies represent a non-negligible share of the total.

The Tenure, Ownership, and Transition of Agricultural Land (TOTAL) Survey Conducted by the National Agricultural Statistics Service

H. Hamer, Jr. | National Agricultural Statistics Service United States Department of Agriculture | Washington, DC | USA

DOI: 10.1481/icasVII.2016.c18

ABSTRACT

In 2015, the National Agricultural Statistics Service (NASS) of the United States Department of Agriculture (USDA) in partnership with USDA's Economic Research Service (ERS) conducted the 2014 Tenure, Ownership, and Transition of Agricultural Land (TOTAL) survey, which collected information about farmers and ranchers who rent agricultural land to other farmers and ranchers, as well as about agricultural landlords who do not farm. The TOTAL survey encompasses land ownership income, expense, debt, asset, demographic, and other landlord characteristics to provide detailed information from all agricultural landowners. As the only source of detailed information on agricultural land ownership characteristics and economic data, TOTAL provides important statistics to government, academia, the farming industry, and others who use agricultural land ownership data for planning, policymaking, research, and market analysis. This paper discusses both the major findings from the survey and some of the challenges and successes using this approach, and will highlight major changes in agricultural land ownership identified in the survey results, and lessons learned for future landlord surveys.

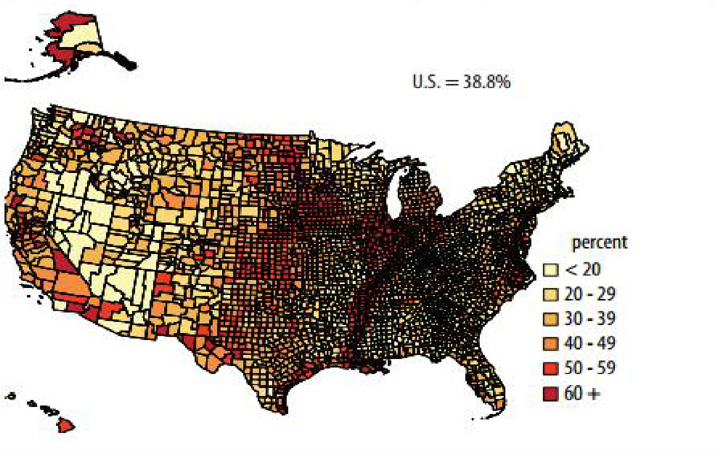
Keywords: Tenure, Ownership, and Transition of Agricultural Land; TOTAL; Land wnership; Landlord; United States Department of Agriculture; USDA; National Agricultural Statistics Service; NASS

PAPER

1. Introduction and Survey Overview

Nearly 40 percent of U.S. farmland is rented or leased from someone else, according to the 2012 United States Census of Agriculture. Moreover, the concentration of rented farmland varies significantly across the country (Figure 1). To learn more about the rented land and who owns it, USDA's National Agricultural Statistics Service (NASS) conducted a special study in cooperation with USDA's Economic Research Service (ERS) as part of the Census of Agriculture program. The 2014 Tenure, Ownership, and Transition of Agricultural Land (TOTAL) survey collected data in the 48 contiguous states about farmers and ranchers who rent agricultural land to others, as well as about agricultural landlords who do not operate a farm or ranch. The survey covers land ownership income, expense, debt, asset, demographic, and other landlord characteristics to provide detailed information from all agricultural landowners. TOTAL was the first landlord study conducted by NASS since 1999.

Figure 1
Percent of U.S. Farmland Rented or Leased, by County, 2012



Source: USDA NASS, 2012 Census of Agriculture.

NASS collected data by mail, personal interviews, and online from over 60,000 landowners across the United States. The agency mailed the forms in December 2014. NASS followed-up by phone with landlord owners who did not respond by mail to maximize response. In some special cases, NASS visited the landowners' operation. Data collection concluded in April 2015, with further analysis and review continuing until the results were published on August 31, 2015.

In order to customize data collection for different types of landlords, NASS used two versions of the TOTAL survey. One version focused on operator landlords (landlords who also farm agricultural land) and the other version focused on the non-operator landlords who are not involved in farming or ranching. The sample was designed to produce national data for the United States, plus state-level data for 25 states with the highest agricultural cash receipts over a three-year period, 2010 through 2012.

2. Landlord Ownership Arrangements

The survey results showed that, in 2014, more than 2 million landowners rented out 353.8 million acres of land for agricultural purposes. This is 39 percent of the 911 million acres of farmland in the surveyed states (and consistent with the 2012 Census findings).

Of these landowners, 13 percent were farmers and ranchers (operator landlords) and 87 percent were landlords who did not operate a farm (non-operator landlords). Non-operator landlords include those who rent out land individually or as participants in a variety of ownership arrangements (such as partnerships, trusts, corporations, municipalities, and limited liability companies or LLCs). A small number rent out land under more than one arrangement.

Table 1

Landlords and Acres Rented Out by Ownership Arrangements, 2014

	Landlord Arrangements[a]		Acres Rented Out	
	(number)	(percent)	(millions)	(percent)
Operator Landlord	**280,044**	**13**	**70.3**	**20**
Non-operator Landlord	**1,851,796**	**87**	**283.4**	**80**
Individual	1,092,551	51	138.2	39
Partnership	361,826	17	52.8	15
Trust	249,632	12	50.6	14
Corporation	91,011	4	31.5	9
Other	56,776	3	10.4	3
Total	**2,131,840**	**100.00**	**353.8**	**100.0**

[a] Landlords who rent out land under more than one arrangement are included in all relevant arrangements.

Numbers in this and other tables may not add due to rounding.

Source: USDA NASS, 2014 Tenure, Ownership, and Transition of Agricultural Land Survey.

Of the acres rented out, 20 percent were rented out by operator landlords, and 80 percent by non-operator landlords (Table 1). A similar survey in 1999, the Agricultural Economics and Land Ownership Survey (AELOS), found that 12 percent were operator landlords and 88 percent were non-operator landlords. Different methodologies between AELOS and TOTAL make direct comparisons difficult, but AELOS found that landlords rented out 394.3 million acres in 1999.

As far as income, in 2014, landlords received $31.2 billion in rent payments. Their expenses were $9.2 billion, and their debt related to the land they rented out was $32.8 billion. The value of the land and buildings they held on their rental acres was $1.1 trillion. Of the acres rented out, 89 percent of acres rented out by operator landlords, and 94 percent of acres rented out by non-operator landlords, were fully paid for.

3. Landlord Demographics

Of the 1.9 million non-operator landlords, 1.4 million can be called "principal landlords." They are either individual owners or the principal in a partnership arrangement.

The average age of principal landlords in 2014 was 66.5 years. Principal landlords are older than principal farm operators, whose average age was 58.3 years in 2012. (The 2012 Census of Agriculture defines a principal operator as the person who makes the day-to-day business decisions for a farming operation.) More than half (57 percent) of principal landlords were 65 years or older in 2014. They account for 67 percent of the rent received, 67 percent of the value of land and buildings, and 32 percent of the debt related to acres rented out. (Table 2)

Most principal landlords have college education; 25 percent have some college, and 38 percent have four or more years.

In terms of race, 97 percent of principal landlords are white. Two percent are Hispanic, regardless of race. Landlords who are white accounted for 98 percent of rent received, expenses, and the value of land and buildings, and 99 percent of debt, in 2014.

Of the principal landlords, 54 percent are not currently in the paid workforce; 41 percent are employed outside of farming. Also, 45 percent have never farmed.

Table 2

Principal Landlords: Income, Expenses, Assets, Debt, by Age
($ billions and percent)

	Number of Principal Landlords[a]	Rent Received	Expenses	Value of Land and Buildings	Debt
		($ billions)			
Total	**1,432,065**	**15.9**	**4.9**	**621.8**	**18.2**

85+ years	9	12	11	12	2
All ages	100	100	100	100	100

[a]Non-operator landlords who are individuals or the principal partner in a partnership.
Source: USDA NASS, 2014 Tenure, Ownership, and Transition of Agricultural Land Survey.

4. Land Uses and Economics

Of the total land rented out by operator and non-operator landlords, 63 percent was for cropland and 34 percent was for pasture. The remaining 3 percent was for other uses such as forest/woodland not pastured, buildings, ponds, ditches, and wasteland. In addition to renting out the land, landowners also lease or sell various rights, including mineral rights, recreational rights, development rights, and wind rights. Non-operator landlords leased oil and gas rights on 31.9 million acres and sold those rights on 4.1 million acres. Out of total farmland in the United States, oil and gas rights were leased on 61.0 million acres and sold on 11.3 million acres. (Table 3)

Table 3

Agricultural Land: Selected Rights Leased and Sold, 2014
(millions of acres)

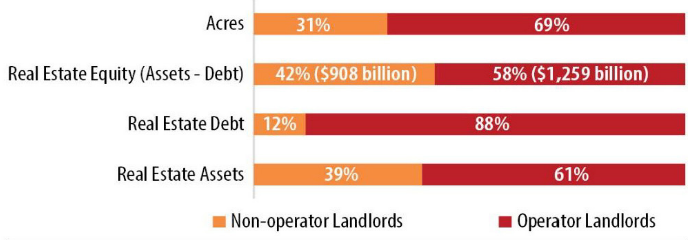
	Land Rented Out by Non-operator Landlord	All Farmland
Oil and gas rights leased	31.9	61.0
Other rights leased	14.9	35.6
Of which: wind rights [a]	3.5	
Oil and gas rights sold	4.1	11.3
Other rights sold	1.0	3.4
Of which: development rights [a]	0.7	

[a] Available for non-operator landlords only.
Source: USDA NASS, 2014 Tenure, Ownership, and Transition of Agricultural Land Survey.

Farm real estate financial statistics varied between non-operator landlords and operator landlords. Operator landlords held 69 percent of the acres, but 88 percent of the farm real estate debt and 61 percent of the farm real estate assets (Figure 2). Operator landlords held 58 percent of the farm real estate equity, or $1.259 trillion; non-operator landlords held 42 percent of the farm real estate equity, or $908 billion.

Figure 2

Farm Real Estate: Real Estate Debt, Assets and Equity



Source: Calculations based on TOTAL and USDA Economic Research Service, Farm Sector Balance Sheets.

5. Land Acquisition and Transition

Operator landlords purchased more than 60 percent of the land they rent out from a non-relative, a relative, or at auction. This is similar to the way all farmers in the United States acquired farmland. Non-operator landlords inherited or received as a gift more than 50 percent of the land they rent out.

The TOTAL survey asked landowners about their plans for transferring ownership in the next five years. Farmers were asked what they plan to do not only with the land they currently rent out for agricultural purposes but with all their land. In the next five years, operator landlords expect to transfer 15 percent, and non-operator landlords 14 percent, of the land they rent out. Operator landlords plan to transfer a larger percentage (70 percent) through trusts than non-operator landlords (40 percent). (Table 4)

In terms of their total land, not just acres rented out, landowners plan to transfer 91.5 million acres or 10 percent of all they own. These data do not included the 57.1 million acres landowners have put or plan to put into wills.

Table 4

Five-year Plan to Transfer Acres Rented Out and All Farmland
(millions of acres and percent)

	Operator Landlord		Non-operator Landlord		All Farmland	
	Acres (mil.)	%	Acres (mil.)	%	Acres (mil.)	%
Put/keep in trust	7.3	70	15.4	40	44.2	48
Sell to non-relative	1.7	17	10.5	27	21.1	23
Gift	0.5	5	8.0	21	12.6	14
Sell to relative	0.9	8	4.2	11	13.2	14

6. Lessons Learned for Future Landlord Surveys

Conducting a new survey after 15 years presented many challenges. Some challenges were not easy to anticipate. Other challenges such as constructing a quality list of landlords to sample were anticipated challenges we addressed throughout the survey cycle. Some other lessons learned related to defining landlords, data collection for sub-leasing arrangements, and comparisons between the location of landlords and the land they rent. These specific challenges are described below.

One of the most significant lessons learned was that the definition of a landlord needed to be specified in more detail. There was no clear definition of who or what is a landlord. Depending on the goal, a landlord could be defined as the entity that is mailed a questionnaire, or it could be defined as all the individuals associated with all landlord arrangements within each entity. While tenants usually pay rent to one entity for each parcel of land, they don't necessarily know all the owners, especially if the landlord is a corporation. Obviously, counting all people with a connection to a corporate landownership arrangement as a landlord would be problematic. However, some measure of size of corporate landlords will become more important as corporate land ownership grows. As far as data collection, identifying the survey respondent for corporate partnerships will be an issue to further address in future surveys. Also, because the questionnaire contained three sections for the landlord arrangements – individual/partner, corporate/trust, and other, counting the entities with multiple arrangements created an issue when combining acreage data to landlord counts.

Sub-leasing arrangements created special data collection challenges. A small percentage (less than 1 percent) of farm operators rented land from others and also subleased at least a portion of the same land to other farmers. In order to be efficient, the questionnaires were used to collect all information for a farmer who is also a landlord. But with a sub-leasing arrangement an even more complex questionnaire would be needed.

Additional data on the location of the landlords would have been useful to data users. The data were summarized by the location of the land, which is appropriate for assigning expenses and land values to corresponding states and regions. However, summarizing the number of landlords by where they reside might produce results that are also valuable for analysis.

7. Conclusion

The TOTAL Survey provides valuable data that were not available in 15 years, and will be used for many years in the future. The data are a comprehensive view of all land, including agricultural land owned by non-operator landlords, as a follow on component of the United States Census of Agriculture program.

NASS conducted the TOTAL survey in collaboration with the USDA Economic Research Service (ERS). Many stakeholders have used these data, and many more will use the data in years to come. As future surveys are planned, the need for landlord data by more and more stakeholders will only continue to grow. There is already a growing list of requests for more detailed data on topics such as future transition to agricultural land, corporate landlord characteristics, and barriers to land ownership by new and beginning farmers. In 2014, the TOTAL survey provided a start into understanding the changes and complexities of land ownership in the United States. More information on the survey, methodology, data collection and results and other products can be found on the USDA NASS website at: www.agcensus.usda.gov/Publications/TOTAL.

ABSTRACT

The lack of reliable and up to date data on land governance is a common issue for countries in developing and developed world. A new approach for generating land data is related to utilization of existing administrative records of government agencies. The case of Ukraine demonstrates how the data from the State Land Cadaster, Registry of Rights, Tax Authority, Court Administration and other agencies can be linked together to produce a comprehensive description of land governance at regionally disaggregated level. A pilot implementation of the Monitoring system was completed in 2015. Results demonstrate a significant diversity in quality of land governance across the sub-national administrative units (rural rayons and cities) and can be used as a base-line for assessment of performance of relevant local authorities and some of the recent reforms in the sector. These differences are unrelated to the common national legislation and are related to factors at the local level such as resource endowment, infrastructure and local government decision making. The results demonstrate that the key challenge to development of land market in Ukraine is related to access to finance, a temporary ban (Moratorium) on sales of agricultural land and non-transparent practices at the local level.

A data set with more than 140 characteristics for the universe of over 600 sub-national administrative units was generated as a result of pilot implementation of the Monitoring system. For most indicators, the data covers period 2014-15 and reported quarterly. This data set is available in public domain and was used to establish a comparative ranking of land governance at the local level. Pilot implementation of the Monitoring in Ukraine faced several challenges including: i) the quality of generated land statistics is conditional on completeness of administrative records (combination of data from different sources helps to assess the gap); ii) most of the authorities do not follow the standards for classification of administrative units, as boundaries of service areas do not always coincide with administrative boundaries; iii) rigidities with data access are related to flexibility of design of the software used for processing and maintenance of administrative records. Development of a comprehensive reporting system allows addressing several practical issues (e.g., assessment of tax gap, mass valuation of land, design and assessment of land reform). To sustain the system, normative acts with reporting requirements and software need to be developed. Land governance monitoring reduces information asymmetry regarding the land use, land availability and performance of local government, and, thus, helps to reduce the moral hazard effect in government decision making.

Keywords: land governance; Ukraine; monitoring; administrative data, transparency, accountability, land reform

PAPER

1. Introduction and motivation

Land is an important factor of production, mean of asset accumulation and development of urban and rural areas. Thus, imperfections in governance of land resources have far-reaching consequences including stagnation of local economic development, poverty trap, low investment attractiveness, low access to capital, conflicts, eviction, land grabbing, etc.

Most of these problems, however, have common roots: information about land rights, land use, land availability and government decision making is asymmetric and protection of land related rights is weak.

[1] Development of the LG Monitoring system in Ukraine and of this paper was funded by the WB IDF Grant "Capacity Development for Evidence-Based Land and Agricultural Policy Making in Ukraine". We greatly appreciate Vladyslava Rutytska, Maksym Martyniuk, Rostyslav Shmanenko, Henz Strubenhoff, David Egiashvili for their support with implementation of the Land Governance Monitoring System in Ukraine and comments to an earlier version of this paper. The authors greatly appreciate research assistantship by Kateryna Ivinska and Vitalia Yaremko.

The overall results of these information imperfections are related to underdeveloped land markets, low transferability of land, low prices for land, inefficient distribution of land resources and imperfections on the interlinked markets (e.g. credit), rent on information (corruption, speculation), lack of productivity growth and technology transfer. The information asymmetry is also a reason for inefficient design of land reforms and lack of their implementation. Thus, reducing this asymmetry would have a profound impact on growth of urban and rural areas and governance of land resources.

Various national and international programs and policies were designed and implemented to reduce the information asymmetry regarding the land rights, their transfer and dispute resolution. Land cadasters and land titling programs in some countries exist for hundreds of years, while in many others they were introduced only recently. Development of the information technologies (including remote sensing) have greatly facilitated this progress. Nevertheless, the causal effect of introducing such systems on improvements in land allocation and investments are yet to be assessed (as many of such innovations were introduced to replace some already existed traditional systems of identification and protection of rights to land).

The issues of non-transparent land use and land allocation remain current for many countries. They are particularly important for governance of state and communal land. But, the same issues are also relevant for private land, where cases of non-formalized land use, violations in zoning and designated use, informal transfers and outdated cadastral records are not uncommon.

As land is an immobile asset, land markets are geographically fragmented and local governments in many countries play an important role in governing land resources. However, information on performance of such local markets and government decisions are not available (with rare exceptions), which provides room for non-transparent practices, opportunistic behavior and sometime market failures.

A response to this challenge belongs to a more general field of efficiency of local governments, institutional arrangements of land market and establishment of information revelation mechanisms and better contract design.

Talking specifically about the governance of land resources, the need for better access to information and use of information for monitoring and evaluation of land policies is clearly recognized by UN as it is stipulated in the Voluntary Guideline for Governance of Tenure (FAO 2012).

Several initiative to address the issue of access to information and transparency of land governance were taken by other international organizations. Starting 2010, The World Bank has developed a diagnostic tool – Land Governance Assessment Framework (LGAF) - for assessment the state of land governance at national level (Deininger et al, 2012). By 2016, this tool was used in more than 45 countries. It helped to reveal the state of land governance and provided recommendations for improvement. One of the common recommendation for these countries was to improve access to information on land governance, to provide regular updates and to reveal the relevant information at subnational level. In some countries (e.g. India, Brazil) LGAF was implemented at sub-national level.

Among other international initiatives are Land Matrix/ Global Observatory (http://www.landmatrix.org/), which collects information about large-scale land acquisitions. LandMark (http://www.landmarkmap.org/) collects and disseminates critical information on the collective land and natural resource rights of Indigenous Peoples and local communities around the world. While providing very important information, these sources are likely to be non-representative and non-comprehensive. Thus, they would have a limited use for design and monitoring of national policies.

There are also international surveys (e.g. Doing Business, Enabling Business for Agriculture), which include some characteristic of land governance as a part of broader investment attractiveness and business climate. While results of these surveys are wildly used as country promotion tools, they are not regionally disaggregated, impossible to scale down and update frequently, and are expensive to collect data.

Finally, there are several local and national pilots for spatial data infrastructure (NSDI) development, which by design should be comprehensive and contain many details. Unfortunately, local pilots are not always scalable as data availability is not universal, have high implementation cost and may be limited to a narrow set of characteristics available to national or local land cadasters.

This brief review points out to a need for a new institutional infrastructure that would reveal information on the state of land governance at the level of local land markets (e.g. districts or provinces) where most land use and land allocation decisions are made.

At least three options for design of such infrastructure are available. Among them are:

- Establishment of a regular survey or reporting system including interviews and focus groups of key informants. While such approach is standard, it also has standard limitations: cost, time, selection and accessibility. As the size of local land market could be anywhere between 50,000 sq. km and 300,000 sq. km (an area within which a buyer, investor or a tenant would consider options if she decides to acquire or rent land in a particular region), establishing characteristics of all local markets using the survey tools becomes difficult for medium and large size countries. A regular updating of characteristics of local markets becomes practically non-feasible;

- Remote sensing becomes a popular and accessible tool for assessment of land use, changes in land use and several other physical characteristics. However, this tool cannot provide information on social characteristics such as ownership, conflicts, taxation, values.

- Administrative records of government authorities dealing with different functional areas of land governance become a new alternative source of information as most of such records become available in electronic form. For example, tax declarations, cadastral records, court cases, - they all cover the universe of all relevant transactions or characteristics that belong to the formal side of land governance. Such individual records can be used as a source for regionally disaggregated statistics and can be updated regularly at almost no cost. It is not clear, however, if such approach is feasible and what institutional arrangement is necessary to sustain land governance monitoring system based on administrative records.

In this paper we describe the design of Land Governance Monitoring System – an infrastructure that helps to reduce asymmetry of information regarding the state of land governance at local and national level, ...- and demonstrate the case of Ukraine where the biggest progress up to date is made in establishing of such system. Ukrainian system is relies on administrative data from six different government authorities. This case demonstrates some feasible institutional arrangements, issues with linking administrative data across government institutions and options for dissemination and use of information on land governance for decision making by private and public sector at local and national levels. It also presents tools that can be used to overcome a moral hazard problem with local government decision making.

The rest of this paper is structured as follows. Section 2 presents the concept of Land Governance Monitoring System, its goals structure and stakeholders and relates it to moral hazard problem in local government decision making. Section 3 describes the case of establishment of monitoring system in Ukraine, example of institutional arrangement, monitoring results and describes implementation issues. Section 4 demonstrates how the monitoring data can be used analysis of the state of land governance by employing ranking and benchmarking of local land governance. In conclusions, we compare the case of Ukraine with several other examples and draw recommendations for other countries and development of land governance from a broader perspective.

2. Land Governance Monitoring as an infrastructure for information revelation

Regionally disaggregated Land Governance Monitoring System is considered as an institution to reveal the information on the actual state of formal land governance based on administrative data. It includes normative acts, institutional arrangement, methodology and software for collecting, processing and disseminating data on key indicators that describe the state of land governance at local land markets. The fundamental principal of the system is that it reports on the spatial/administrative units that coincide with geographic boundaries for local decision-making authorities in different functional areas of land governance (e.g. courts, tax authorities).

The institutional arrangement of the local land governance that currently exists in many countries can be described in a framework of standard principal-agent problem. Local government authority is appointed or elected to perform functions related to governance of land resources (e.g. to provide for registration of land parcels and related rights, manage state or communal land, collect taxes, resolve conflicts). In terms of outcomes and efforts of performing these functions, we face a dual problem with asymmetric information. First, the outcome for each local authority is not perfectly observable as the performance is often reported at aggregated national level (e.g. number of registered parcels or collected land tax) or at a level of individual parcel (a common situation with several cadastral or tax reporting systems). Second, the effort level of local authority is not perfectly observable as the outcomes depend on factors not observable to outsiders (e.g. number of applicants, quality of applications). The optimal behavior of the local government authority in such a setup is also standard – the authority would exert a minimal effort and extract a maximum rent on private information (including use of public resources for individual benefits).

This model for socially optimal land governance can be formalized in the following way. Consider a universe of N land parcels (with individual parcels $i \in N$) with some characteristics x_i. Such characteristics could include a state of formal registration, status of land tax payment, pending dispute, land investment etc. For simplicity x_i takes is binary (tax is paid or not, parcel is registered in the cadaster or not). Each such parcel locates in one of the local areas j ($j \in J$) where the land governance function is performed by a local authority.

Assume that a social utility function for land governance is $U = \sum_{i=1}^{N} x_i$ and local authorities are employed to maximize it (or minimize in case of conflicts) within the boundaries of a local area j. Thus, $U = \sum_{j=1}^{J} u_j$. The probability that a given parcel has desired properties $x_i=1$ (e.g. is registered) is affected by several parcel specific (k_i) (e.g. availability of historical records on ownership, owner's attitude or preference) and regional (r_j) (e.g. demand for land) factors. One of such regional factors is an effort level of local authority (e_j), which is not observable to outsiders. For simplification, we assume that the market transaction cost (e.g. for registration or dispute resolution) is an inverse of the efforts.

$$(1)\ P(x_i=1)=P(k_i, r_j, e_j)$$

It is a common situation that the reward of local government officials (l_j) for performing their functions (e.g. registration of land rights) is a fixed wage and is not dependent on the outcome (moreover on unobservable effort). It could be region specific to adjust for the local cost of labor or could be the same nationwide. The utility of local government officials that performs a specific governance function (e.g. registration) can be expressed in the most general form as $v_j=V(l_j, e_j)$, which is increasing in l_j and decreasing in e_j. As l_j is independent of e_j we face a standard moral hazard problem with an optimal outcome $e_j=0$ (and, thus, the registration transaction cost taken the maximum possible value and U becomes sub-optimal).

As the above principal-agent (PA) problem is structured in a standard way, the solutions to this problem would be also standard: to establish either a franchise contract with local government authorities or to make the reword (l_j) being conditional on the observed regional outcome $\sum_{i=1}^{N_J} x_{ij}$. The problem becomes interesting when one starts considering feasible implementation strategies for such contracts.

Franchising contracts makes the respective government authorities a residual claimant of the better land governance. There are two possible implementations of such contract:

i) *Decentralization* of land governance function (as currently considered in Ukraine), which means that local government receives authority to manage all state and communal land within the respective boundaries of their geographical area, collect land tax and stamp fees and other land transaction revenues as well as other benefits of better land market and better investment climate. While such contract allows resolving the PA problem in relationships between the central and local government authorities, the PA problem persists in the relationships between the local government and the individual government officers. Thus, there is a chance for preserving the lower equilibrium with ej=0 when the individual benefits from corrupted or low quality service provision remain higher than the benefits from the onset behavior. Unavoidably, the contracts of local government officials responsible for land would require modification that makes the reward conditional on the service outcomes (either in a form of bonuses or penalties) lj=L(xj).

ii) *Self sustainable services for land governance* is yet another option for franchising contracts with a functional government authorities. An example of such arrangement was practiced in Georgia between 2010 and 2014. With such arrangement, the functional authority (e.g. registration) becomes a residual claimant for all land transaction and registration fees or other service revenue as well as services provided to other government authorities (e.g. tax administration). Such arrangement provides incentives to the authority to establish performance based contracts with individual officers and to monitor their performance, which makes the operations of government authority similar to business operations.

An important issue that needs to be considered while designing the above contracts is the relative degree of risk averseness of local governments or the functional authority vs. central government.

The performance based contract becomes unavoidable whether we talk about local governments or individual government officers responsible for land governance decision making. Such contract would condition the reward on the observed outcomes for a given area xj (e.g. completeness or currency of registration). Establishment of such contracts would require knowledge of distribution of xij conditional on ej and, thus, access to reliable information on xij, ki, rj, and a proxy for ej is necessary for implementation.

A performance based contract for local authorities may take many different forms. One of them, with a moderate information requirements would be a benchmarking contract, where the benchmark would be either an individual past performance or the performance of "similar" (peer) government authorities or the combination of the two. The peer group may include either the authorities in a close proximity or authorities with similar characteristics of land resources (rj,) (e.g. structure of land ownership and land use, conditions of related markets).

Thus, overcoming the PA problem in land governance unavoidably would require access to regionally disaggregated information on land governance outcomes xij, conditions of land resources and related markets rj, and on distribution of individual characteristics of land owners and land users ki.

Establishment of Land Governance Monitoring System with regular reporting on key indicators at the level of local government authorities can change the contract arrangement in two ways. First, it would allow associating the outcomes for specific local area with activities of specific local authority. In many cases, such performance indicators could come from the sources independent of a particular authority. For example, quality and completeness of cadastral registration (area of responsibility of registration authority) could be characterized with a number of boundary disputes (recorded by a court authority). Second, data on the performance indicators can establish a benchmarking system for performance evaluation for local authorities. Such benchmarks could include previous period outcomes for the same authorities and/or performance of neighboring or similar authorities for the same period. For example, land tax revenue in one district could be comparable to the revenue in the previous period for the same authority or for a similar authority (normalized in per hectare terms).

It is expected, that introduction of the monitoring system and enforcement of new contracts based on performance outcomes could improve the quality of land governance at local and national levels, and increase effectiveness of use of public and private land resources. However, like in many theoretical models, the main question is what would be a feasible design and implementation arrangement for such monitoring system and how to sustain it.

2.1. Design of Land Governance Monitoring System

The primary goal of the monitoring system is to improve transparency and accountability of decision-making at local and national level. It also allows supporting evidence based policy making and keeping track of progress with reform implementation and their evaluation. Besides, better information on the state of local land markets provides for decision making in private sector, improves business climate and investment attractiveness, stimulates effective use of land resources and economic development at local and national levels.

The monitoring system includes a set of indicators that describe key functional areas of land governance (Figure 1). Among such functional areas are:

1. Formal registration of land parcels and related rights;

2. Formal land transactions of different types (sales, rent, inheritance, exchange, mortgage, etc);

3. Land tax;

4. Expropriation and privatization;

5. Land-related conflicts;

6. Equality of land related rights and their exercising by women, men, legal entities, national and ethnic minorities, and other potentially vulnerable groups of land owners and users.

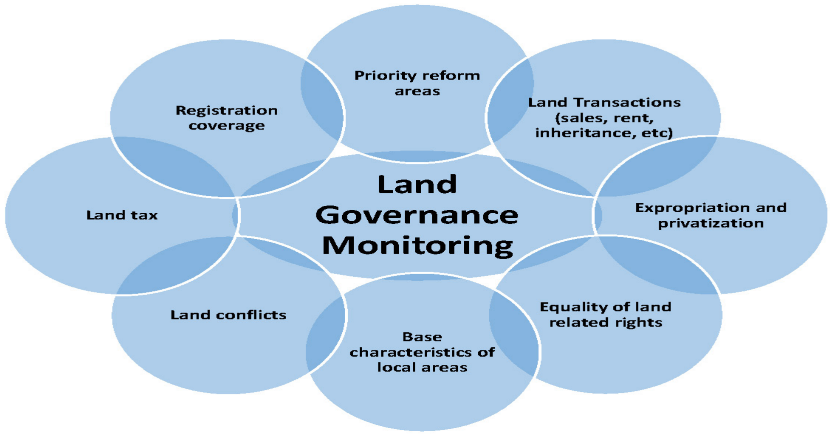
Besides the functional areas, the monitoring system may include two additional groups of key indicators:

7. Country priority reform areas (country specific);

8. Base characteristics of local areas (total land area, total number of land parcels, population, distribution of land ownership and land use).

The monitoring indicators for each of the functional areas could be further disaggregated by type of land use (e.g. agricultural/ non-agricultural) and form of property (state, private, communal, collective/ group).

Figure 1 - Structure of land governance monitoring indicators



The motivation and examples of specific indicators for each of the above groups are the following:

1. The formal registration of land parcels and related rights

Proportions of land resources of different ownership types are qualitative characteristics that determine the resource base for economic development and investment attractiveness. In contrast, the share of land that is formally registered by state is a measure of security of property rights and a factor that influences market activity and productivity of land use. Often, communal land without clear demarcation is highly vulnerable to encroachment by powerful outsiders leading to major conflicts. These indicators highlight the importance of land inventory and registration for state/community/public lands and related assets, which in turn is crucial for effective land management.

Indicators included to this group are: the number and area of land parcels (total and by use type and form of ownership), which are formally registered according to the national legislation in the Land Cadaster and/or Registry vs. total area of a relevant local area. The number of primary registrations is an indicator that shows the currency of the cadastral records and refers to previously unregistered parcels, merged and split parcels. Share of formally registered land is both a measure of completeness of administrative records and a quality of formal protection of rights.

Two *Data sources* are required for these indicators. First are the Land Cadaster or Registry data bases on registered parcels, which are used to generate the number of parcels and area of land formally registered for each local district by land use and form of property. Second, as a base for comparison several sources of data can be used. Among them could be results of inventory or a survey (e.g. in Georgia), statistical surveys or reports (e.g. in Ukraine) or results of remote sensing (e.g. in Vietnam). In some countries (e.g. Croatia) completeness of the Cadaster is not an issue, however accessibility of the records and their currency are. For cases like this, other indicators may be more informative. For example, the share of records that were updated during the last 5 years, the share of records entered into the electronic data base or accessible by a central authority, records that are entered into European systems (e.g. ARKOD - System for Registration of Agricultural Parcels).

Reporting Frequency depends on the stage of development and completeness of the cadaster in a particular country. In established and complete systems, annual updates may be sufficient, while in cases where some active reform of land governance is in progress, some more frequent updates may be necessary.

Use for decision making would vary depending on the country priorities and context. Among the examples are the need assessment for inventory and registration of state and communal land, identification of target areas for interventions related to formal registration, assessment of tax base, assessment of risks of investments in local area, assessment of potential costs of investments, etc.

2. Formal land transactions of different types

The information on transactions indicates how the market reacts to micro- and macroeconomic factors, government programs, etc. These indicators also reveal the market capacity and flexibility, and they are the most sensitive to changes to the quality of land governance. Comparisons by transaction types, land use categories, types of ownership and regions helps to reveal market imperfections that should become a subject to public regulation/ de-regulations or administrative actions. The completeness of public registry affects the quality of such conclusions to a great extent.

Reporting indicators include the quantity of registered market transactions for land (sales, bequests, gifts, mortgages, rentals, exchange) – total number, area, prices and payments (including rental) per ha. The indicators are disaggregated by land use category. Comparison of transactions across geographic areas requires normalization in per hectare or per capita terms.

Data sources include administrative records of State Registrars, Cadasters, Courts, notaries or other authorities responsible for keeping track of land transactions. Accessibility of these records, ability to link them to cadastral records and reliability of information (particularly on price) is one of the biggest challenges in the countries we worked with over the last 3 years. On the other hand, resolving this issues and publishing information on prices makes the biggest breakthrough in terms of transparency of land markets.

Reporting Frequency depends on the frequency of transactions. Monthly reporting would serve the purpose in most of the cases. There are, however, examples when the data on individual transactions is published and could be updated in the real time or quarterly.

Use for decision making would include assessment of market capacity, mass valuation (appraisal) of property, identification of market imperfections and sources of inequality.

3. Land Tax

Taxes on land and other real estate objects, as well as related fees are among the few sources of revenue available to local governments. As actual receipts depend on coverage, assessed values, tax rates and collection efficiency, among other factors, comparison across local areas could provide for a better design of land tax system. Land and property taxes may play an important role in stimulating the productive utilization of resources and sustainable development of rural areas. Such taxes can also foster investment in infrastructure, improvement of land quality and real estate as well as to prevent a non-effective use of land parcels (brownfields and idle property).

Reporting indicators include the number of tax payers, declared area, the revenue and a number of tax exemptions for the different categories of land and land tax.

Data sources for these indicators include relevant administrative records of tax authorities or municipalities. An ability to access the records (including local tax rates) from the central level and institutional capacity to link the tax and cadastral records (e.g. consistent use of cadastral and tax numbers) is a target for institutional development of tax system on its own right.

Reporting Frequency depends on frequency of tax declaration and payment. In most cases annual or semi-annual reporting is sufficient.

Use for decision making would include assessment of the tax gap, design and evaluation of changes in tax system, assessment of elasticities of tax revenue to various intervention, identification of target area for policy and administrative interventions.

4. Expropriation and Privatization

Privatization and expropriation can play both positive and negative role in stimulating economic development. Land acquisition for public purposes with fair compensation is unavoidable to provide public services (e.g. infrastructure) effectively. However, low levels or failure to pay compensation and use of excessive administrative power to acquire land can easily undermine good governance and the respect for due process. In contrast, transparent procedures (e.g. auction), divestiture of public land (e.g. brownfields in urban areas) can be a driver of private sector development and revenue generation for the public sector. Therefore, information about these transactions is an important indicator of the quality of land resource management, it can also indicate possible directions for improvements of the system.

Reporting indicators include the number, area of land parcels by use type that were expropriated (taken, purchased) for public needs and value of compensation paid, and the number and area of land parcels by use type transferred to private ownership (privatized) (separately via auction and free of charge) and relevant revenue.

Data source for these indicators may represent a challenge. While the records on privatization can be maintained by a state land authority, local municipalities, state agency for privatization, records on expropriation may be identified only partially in some contexts. In most cases authorities responsible for decisions on expropriation are well defined (e.g. courts, central government authorities, President of a country). However, many decisions on alienation of private land for the public purposes are made in amicable way via buyouts by municipalities or infrastructure development companies (e.g. rail roads or transportation authorities, project implementation authorities). Thus, identification of sources of information would require some additional investigation in a context of a specific country.

Reporting Frequency depends greatly on data accessibility. In most cases annual reporting is the only option.

Use for decision making would include assessment of risk of expropriation and fairness of payments.

5. The Number of Land-Related Conflicts

A large number of cases in court points to either drawbacks in regulatory and legal environment, or an under-developed conflict resolution system. In both cases reduction in the number of conflicts should coincide with an increase in number of formally registered land plots. Thus, this indicator can be used not only to track changes in the legal and regulatory environment, but also to justify further improvements of the system of State land cadaster and land inventory. It could also indicate the quality of decision-making by local authorities regarding land allocation and other land governance and land management issues.

Reporting indicators include the number of cases, for which there are court disputes filed or pending. The cases could be disaggregated by court authority (administrative, commercial or civil) and type of disputes (boundary, misuse, encroachment, registration of property rights, distribution of land, valuation, payments, etc.) between different categories of participants (individuals, legal entities, government bodies) by state of cases in the dispute process (filed, resolved: granted/declined) and length of the process.

Data sources depend on the specific institutional setting and could include State Court Administration, Ministry of Justice or individual courts.

Reporting Frequency is annual as the number of formal disputes is relatively low in most cases when disaggregated regionally.

Use for decision making would include assessment of reforms and changes in other areas of land governance and targeting local areas. Analysis of frequency of different types of disputes and length of disputes helps to identify the areas where legal and procedural changes are needed. Frequency of disputes is yet another measure of security of rights and quality their protection.

6. Share of land and real estate registered in the State Land Cadastre in women's, men's name or as a joint property and in legal entities' ownership

Although the legislation of most countries has no gender-related limitations for acquisition or use of land parcels (or other assets), the practice of exercising these rights may reveal certain evidences of discrimination. It may be related to some traditional practices of intra-household distribution of rights. Such inequalities may also happen when women or minorities have less negotiation power, access to information (e.g. in native language) or means to protect their rights, which can influence the rental and sale pricing, the number of conflicts, etc. The discrimination may also take place at the stage of divorce or bequest. Therefore, consideration of gender and minority status in land relations and prevention of possible discrimination can have a significant positive impact on the quality of land governance, economic development and human rights protection. Moreover, FAO Voluntary Guidelines, Global Land Indicators Initiative (GLII) and Global Development Goals focus on guarantying equal rights of men and women and other land users.

Reporting indicators include the number of private land plots, total area and prices by use type registered on women's name, men's name or as a joint property, in property of legal entities or minorities.

Identification of the data sources often represent a challenge as too often it is not recorded on the titles or in other records. However, gender indicator may be added as a mandatory field to the registration forms as it was recently done in Georgia or India. As an alternative, a name comparison against the male and female name dictionary can be performed for the registered property. Finally, the registration data may be merged with tax registry or civil status records where gender and nationality is recorded.

Reporting Frequency is annual as this indicator is not likely to change fast.

Use for decision making would include identification of inequalities, design and implementation of legal changes and programs to protect vulnerable groups of land owners or land users.

7. State of Land Reforms

This group of indicators reflects on key reform priorities in each specific country and helps to assess the scope of reforms and keep track of their implementation. As priorities differ from country to country, the following examples are just for illustration. In case of Georgia, Eastern European countries, such indicators include the number and are of land parcels owned by foreigners. In case of Ukraine, they include the number and prices for renal rights sold via auctions and the number of errors corrected in the State Land Cadaster. Other countries may focus on large-scale land acquisition, land conversion, etc.

The data sources, indicators and reporting frequency would also be country specific.

8. Base characteristics of local areas.

Comparison of the data for reporting units (local areas) of different size requires normalization (e.g., per unit area, per capita) or statistical weighting by size of administrative units.

Reported indicators included into this group are the area and the number of plots (total and by land use and ownership types), population, number of business entities.

Data sources are the State Statistics or National Census authorities (data on population and business entities as well as on land ownership and use). Land inventory, cartographical base (with identification of boundaries) could serve as a source of data on land area and types.

Reporting frequency is annual. However, less frequent updates would also fit the purpose.

2.2. Administrative data

The use of administrative records from government authorities involved with land governance is considered as a feasible strategy for providing regular regionally disaggregated data for the purpose of Monitoring. However, administrative data has some specifics that has to be taken into account at the stage of interpretation of the Monitoring results and features, which can contribute to sustainability of the Monitoring system.

First, completeness and currency of administrative data determines the quality and reliability of the resulted monitoring indicators. For example, if the land cadastre covers only a relatively small share of land, it could not provide a reliable information on land use, distribution of ownership and other characteristics of land. Thus, other sources for such characteristics have to be considered. On the other hand, completeness of the cadaster is an important characteristic of land governance on its own rights and is included as an indicator of quality of protection of land related rights.

Second, the use of administrative data from multiple sources creates mutual benefits to all the agencies involved. It allows assessing gaps and technical errors across the data sets, which cannot be revealed otherwise. For example, joint use of cadastral and tax records helps to verify the currency of information in the cadaster. The cadaster records can improve the tax base. Thus, participation in the monitoring helps authorities to improve the quality of their administrative records and, thus, the quality of their service. However, to fully benefit from such data exchange, the relevant authorities need to upgrade their internal data sharing and error correction procedures. Too often, the government agencies may know about errors but do not have rights, a functional responsibility or procedures to correct them. For example, the area of land parcel recorded during a transaction may not coincide with cadastral records. But, verification and correction may be initiated only by the owner.

Third, administrative data have several important benefits in comparison to alternative sources of information that can be used to create the indicators and sustain the monitoring system. Among them are:

- *Low cost of data collection* – government authorities collect and store the administrative records as a part of their regular operations. Thus, only some small initial investments are needed to develop a reporting software that would generate the reporting indicators out of records with a pre-designed frequency or on demand.
- Promptness – administrative data requires minimum processing, allows construction and publication of monitoring indicators on a regular base with virtually no delay after the reporting period;
- *Regular update of information* – as the reporting software were developed, the reporting can be done with any frequency. The option for generation of retrospective values is also feasible;
- *Accuracy of information* – the authorities keep records on the universe of formal transactions, land parcels and other relevant objects. Thus, selection is not an issue for producing characteristics of formal side of the land governance. Also, the authorities are interested in and have responsibilities for having their records accurate and they employ different quality control and back up practices; they should be interested to address any known gaps in data as well.

Fourth, there are some common challenges of working with administrative data that need to be anticipated and addresses with normative acts and procedures. Among them are the rigidity of current software (property and access rights, formally approved procedures, etc.) which does not have functionality for generating necessary statistics out of data and does not provide access to the raw data. Another challenge is the lack of common standards among the authorities in terms of definition of land use and land cover types, boundaries of reporting areas, etc. Finally, some administrative data (or a part of it) are yet stored in hard copies only (or in form of scanned copies). Resolving these issues is often time consuming and require solutions tailored to each specific case. However, the solutions do provide for not only the monitoring function, but they also help to improve the overall quality of government services in the field of land governance.

2.3. Motivation for implementation of Land Governance Monitoring

Besides the theoretical and strategic benefits of more transparent and more efficient governance of land resources, establishment of the monitoring system can bring several short-term tangible benefits to different groups of stakeholders. Central government authorities and policy makers can use the information on monitoring indicators as an evidence base for their decision making, policy design, monitoring and evaluation of reforms, programs and policies, need assessment for public intervention. Authorities responsible for delivering public services receive a tool that helps to reveal errors, improve coverage, assess the gaps in delivering of the relevant services. They also can monitor and assess performance of various local branches and service centers to identify the best practices and targets for improvements. Private sector receives a source of information necessary for risk assessment, valuation and planning in all industries where land is used as an important production factor. Finally, land owners, public activists and media can rely on publicly available monitoring results to understand the impact of various government decisions on wellbeing, to assess the performance of elected local authorities or to set agenda for improvements on local level.

There are also groups of stakeholders that would face losses because of better availability of information on land, and, thus, would oppose the introduction of monitoring. To this group would belong the local and central authorities involved in non-transparent management of state and communal land. The land users, which currently enjoy a monopolistic market power on the local markets and producers that use land informally would likely to oppose the introduction of the monitoring too as better information and higher competition will likely to reduce their rent on non-transparent use of land.

However, the most important motivation and factor of success for the monitoring system is the support from top government authorities, which coordinate land reform activities among different functional areas of land governance. Three factors may play a role in supporting the introduction of land Governance monitoring. These are political agenda (if transparent land governance is already a part of priorities), legal requirements (if monitoring is stipulated by law as for example in Columbia and Vietnam), and development projects by various international donors (for example, the World Bank supports pre-project or relevant implementation activities in Georgia, Ukraine, India, Croatia, Peru, Philippines, Rwanda).

The motivation of various stakeholder groups is taken into account when institutional and implementation arrangement is developed for introduction of the monitoring system.

2.4. Dissemination mechanisms

The degree to which the benefits of the Monitoring system can be realized by different stakeholder groups depends on the dissemination channels for the monitoring results. Online publications of the regionally disaggregated data would fit this purpose only partially. In addition to that, supplementary products such as regional rankings, benchmarking, policy briefs on the selected topics would help to communicate the results to the relevant audience. However, one of the most important dissemination tool would be the distribution of the local area profiles, which would make the results of the local authorities' practices perfectly observable and comparable with other peers and over time. The local landowners and land users should be aware of such profile and monitor the performance of the local authorities.

2.5. Institutional arrangement

As it follows from the motivation of different interest groups, a successful implementation of the monitoring system requires arrangements at three different levels: policy, coordination and technical implementation.

Policy level includes establishing a policy agenda where increasing transparency of land governance is included as a priority. The key players in this process could be the reform-oriented government or political parties representing interests of landowners. International organizations and donors could be instrumental in this process by providing financial support for initial investments and methodological help. However, without political support and political leader, the process of improving transparency of land governance and implementation of the monitoring is not feasible.

Coordination of development and implementation activities among the key government authorities involved with the land governance is an important factor of success. Such coordination could be done in form of a land reform steering committee or other body, which includes top decision makers from the relevant government authorities (e.g. Land Cadaster, Ministry of Justice, Tax Authority, Ministry of Agriculture, Ministry of Regional Development, Ministry of Land and Natural resources). The primary task of such coordination body is to agree on the need for the joint work to establish the monitoring system in order to achieve a political goal or a legal requirement for better transparency of land governance. The members of this coordination body would also authorize the relevant departments to engaged into development and implementation work, and to authorize the information sharing for the purpose of monitoring.

Technical implementation or a working group would include technical experts from the relevant government institutions that are in charge for management of administrative records. The tasks of this group include organization and implementation of data exchange and data processing, development and testing relevant procedures and methodology. At the implementation stage, the experts from this group would also organize and supervise development of software that generates monitoring indicators out of administrative records.

In terms of institutional arrangement, there is also a need for a task force, which would actually do all the day-to-day development and coordination work across the institutional levels and among the government authorities.

The effective institutional arrangement is a key element of successful implementation of the monitoring system. The case of Ukraine demonstrates an example of such arrangement and illustrates some first implementation results.

3. Case of Ukraine: indicators, sources and results

Different elements of the land governance monitoring can be found in many countries and are implemented by several authorities as a part of their regular duties. For example, most of the land cadasters publish regular information on the total number of registrations, extracts or complaints. Similarly, information on land transaction and prices are often available to the public at regional level and at a level of individual transactions. The case of Ukraine, however, is informative as it represents an example of successful institutional arrangement for a comprehensive monitoring system based on administrative records from six different government authorities and where synergy effect from linking the data from different sources is observed. This system produces all monitoring indicators consistently for all rayons (districts) and cities of Ukraine. So far, Ukraine represents the first case where such comprehensive system is established and where the benefits of improved transparency can be expected in a near term.

3.1. Timeline and institutional arrangement

Development of the Land Governance Monitoring System in Ukraine started in 2015 with a coincidence of several events. After the Parliamentary election in the fall of 2014, a new pro-reform government was formed, and land reform was included as one of the reform priorities. It followed by a development of Comprehensive Strategy for Agricultural Development 2015-20 by the Ministry of Agrarian Policy and Food of Ukraine (MoA) and experts from private sector and professional associations. This strategy has established a clear set of priorities for land reform and was supported by the National Reform Council. Monitoring of land governance was included to this strategy as a necessary condition for transparency and accountability of the land reform.

At the same time, the World Bank has established a new project to support the government and to upgrade the government's capacity for evidence-based policy making in area of agriculture and governance of land resources. The project has provided methodology and implementation support for establishment of the Monitoring system. To coordinate the Project's efforts, the MoA has established a Steering Committee, which includes representatives of six central government authorities at a level of Deputy Ministers, Members of Parliament, representatives of professional associations and international organizations. The Steering Committee supervised the progress with development of the Monitoring system and made some key decisions regarding the distribution of functional responsibilities among the government authorities with respect to Monitoring. Its functions also include a review of normative acts related to the land governance monitoring that were proposed to the Cabinet of Ministers and other central government authorities.

The MoA has also established a Monitoring Working Group, which included technical experts from the government authorities involved with land governance and maintenance of administrative records. The responsibilities of the working group include organization of data supply, development of methodology, coordination of joint implementation work, liaison with corresponding government authority, interpretation of the monitoring results, feedback and administrative actions.

Establishment of the working group marked a start for the pilot implementation of Land Governance Monitoring system in Ukraine. The pilot implementation took about eight months, from April to December of 2015, and included development of monitoring indicators, identification of the data sources, sample data collection, data cleaning and construction of the sample monitoring indicators for the period 2013-2015. The pilot implementation has also identified gaps in existing administrative data in terms of data quality, availability and data collection procedures, and suggest approaches for bridging some of these gaps. The pilot implementation resulted in the following outputs:

- The first set of monitoring indicators for 2013-2015 at rayon (district) level were published online on the Project web site (land.kse.org.ua). This data establishes a base-line for designing and monitoring further land reform and for development of the monitoring system;

- A yearbook "Land Governance Monitoring 2014-2015" was presented to the stakeholders and published online. It provided a description of the monitoring result to the expert community and policy makers;

- Normative acts for establishing the Monitoring system and methodology ware drafted as well as the terms of reference for monitoring software.

Currently, a permanent automated system of land governance monitoring is at a stage of development and implementation. It is expected that the fully operational system can be established within six months after adopting the necessary normative acts. Besides the above outputs, the system would also generate maps and charts, local area profiles, and a list of detected errors in administrative data.

3.2. Sources of data

During the pilot implementation, the administrative data on land parcels, related rights, land tax and other functional areas of land governance was provided by the following state authorities at the level of rayons and cities of Ukraine:

- State Service of Ukraine for Geodesy, Cartography and Cadastre (2014-2015);
- Ministry of Justice of Ukraine (provided by the "National Information Systems" State Company) (2013-2015);
- State Fiscal Service of Ukraine (2015);
- State Court Administration of Ukraine (2013-2014);
- State Statistics Service of Ukraine (2011-2015); and
- State Water Resources Agency of Ukraine (2014).

Based on these data sources, more than 140 indicators for land governance performance were constructed. However, some areas and time periods were not covered as the data was unavailable during the pilot implementation. In particular, the gender of landowners and data on expropriation remained non-accessible. Some examples of the monitoring results are provided below.

3.3. Pilot results

Administrative structure

The territory of Ukraine is 60.3 mln ha and includes 27 primary administrative units (of national subordination): 24 regions (oblast), the Autonomous Republic of Crimea, cities of Kyiv and Sevastopol[2]. These units are further subdivided into the secondary administrative units: rural rayons (districts) and cities of regional subordination. There are 490 rayons and 182 cities, which are the units of reporting for the Monitoring system. These units have elected local governments (councils), and most of the public (government) cervices have local branches (service delivery units) at this level (e.g. Fiscal Service, State Geocadastre, Courts). Thus, most of the decisions on governance of land resources are made at this level and the administrative reports (besides those generated from a parcel level data bases) are available at rayon/city level and higher levels. The average size of rayon is 119,530 ha (ranging from 30,874 ha to 361,615 ha) while the cities occupy on average 10,000 ha (ranging from 202 ha to 86,400 ha). The average population of rayon is 41,226 and of city is 143,333 people. As basic characteristics, land prices, land use and quality of land governance are different between rural rayons and cities, most of the descriptive analysis of the monitoring results is presented separately for cities and rayons.

There are also administrative units below rayon/city level. These are village councils and urban rayon councils. There are 10,798 of such units. There are also 29,772 settlements (villages, towns, cities) in Ukraine. As one of the monitoring indicators, the System reports on the number of village councils and settlements with clearly established and formally registered boundaries. The monitoring reports that only 50 such units have registered boundaries as of 2015. Undefined formal boundaries was a reason for boundary conflicts in several areas. The unclear situation with boundaries and the fact that Ukraine is currently going through an administrative reform (village councils are aggregated into larger units) were the reasons for selection of rayons and cities as the primary reporting units for the Monitoring system.

Main characteristics of rayons and cities of Ukraine

The Monitoring system includes both, the indicators on the functional areas of land governance and some basic characteristics of the reporting units. Table 1 present some of these characteristics to illustrate the diversity of property distribution and land use structure.

---

[2] Since March 2014, the City of Sevastopol and Crimea Autonomous Republic are temporary occupied by Russian Federation and several districts of Donetsk and Lugansk region are regulated by regime of anti-terrorist operation and information on these regions may be unavailable.

Table 1 - Main characteristics of rayons and cities of Ukraine, 2014

	Total	West	East	North	South	West	East	North	South
		Rayon				City			
Population per ha[a]	**0.7**	0.5	0.3	0.3	0.3	16.6	23.3	21.0	17.1
Agricultural land[b], %	**68.7**	58.6	78.5	70.6	77.4	26.1	39.8	27.0	26.0

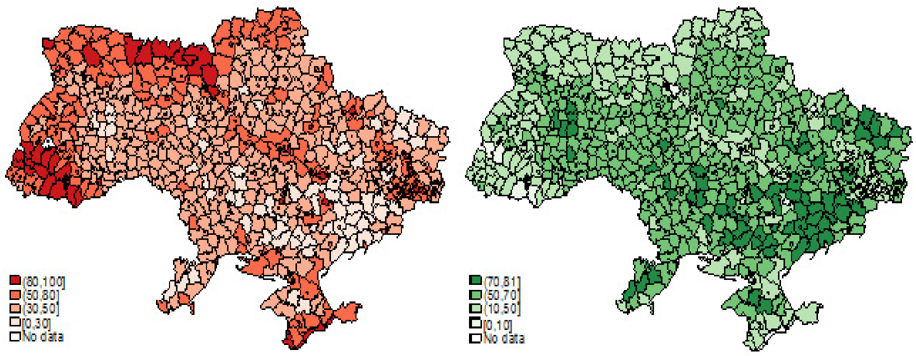
Data: a) State Statistics Service; b) State Service of Ukraine for Geodesy, Cartography and Cadastre

The primary land use in rural rayons is agriculture, which occupies about 70% of total rayon area with some regional variation. Less agricultural land is available in Western part of Ukraine as about 30% of rayons in this part of the country are covered with forests. The largest share of land used for agriculture is in the Eastern part. Cities have on average 32% of land used for agriculture as many cities include into their administrative boundaries also adjacent villages and village councils. About 35% of the territory of cities is developed and the rest of city territory is covered with water and forests. Only 3.3% of rural rayons territory is developed. A small share of territory is classified as mountainous areas (Crimean and Carpathian mountains), desert (in Kherson oblast) or swamps (in Northern part).

About 52% of land in Ukraine is privately owned with private ownership being lower in urban area (19% on average). State owns 47.87% of the land (of them 10 mln ha is agricultural land). The rest of land is in communal property. The share of state property in rural rayons ranges from 94.7% (primarily in mountainous and forested areas) to 19.6% (see Map 1). In cities, this range is from 99.1% to 36.9. The management of state land is a responsibility of various state enterprises and ministries. Most of agricultural land is managed by the State Service for Geodesy, Cartography and Cadaster. It has to be mentioned, that Ukraine started a process of transferring land within the boundaries of settlements from state to the communal property. However, the formal registration of this new communal property is incomplete. The monitoring will be able to show the progress with this process. Also, a reform related to state ownership of agricultural land is in a process of design and is likely to start in 2017. It is anticipated that a part of state agricultural land will be transferred to communal property while another part will be privatized via auctions. The monitoring system will help to keep track of implementation of this reform and to evaluate its effect on productivity, prices and investments.

Map 1 - The share of land area of the state (left) and private (right) form of ownership by rayons, 2014



Ukraine is a large agricultural producer and exporter. There are 52,543 agricultural producers (State Statistics 2015). Of them, 44,968 commercial producers are involved with cultivation of land (total area of cultivated land is 21.5 mln ha in 2014). The rest of private agricultural land is cultivated by individual owners. The average size of a commercial farm in Ukraine is 481.7 ha. The farms are larger on average in Eastern and Northern parts of the country (643.5 ha and 706.2 ha respectively).

A specific of Ukrainian farmland market is that a ban to sale agricultural land (Moratorium) was established in 2001. As a result, rent is the primary mode for transferring use rights and more than 4.6 mln rental agreements for about 16.6 mln ha of private land are signed as of 2015. Such a large number of rental agreement is a result of land distribution during the privatization of 1990s. During this process, 27.72 mln ha of agricultural land of former collective enterprises was equally distributed among 6.91 mln of employees of these enterprises. As a result, an average enterprise has to sign and maintain about 130 (primarily short term) rental agreements which imposes a significant transaction cost and puts a downward pressure on the size of rental payments.

Lifting the Moratorium is considered as one of the top priorities for the land reform in Ukraine. Land Governance Monitoring System will help to demonstrate the progress with opening up of the sales market and its impact on land consolidation, number and prices of rental agreements as well as other characteristics of land governance.

The quality of land governance is also associated with a cost of land transactions and security of land related rights and is the primary focus area of the monitoring.

4. State of land governance in Ukraine, 2014-2015

As it was mentioned above, access to information on the state of land governance at the level of decision making is a necessary condition for overcoming the moral hazard problem in relationships between central and local government and between the individual bureaucrats and government authorities. To address this issue, the monitoring system includes a large number of indicators on six functional areas of land governance. Each of these areas contains one or two aggregated indicators, which are presented in Table 2.

Table 2 - State of Land Governance, 2014-2015

		West	East	North	South	West	East	North	South
	Total	Rayon				City			
Registered in the Land Cadaster - private, %	**70.9**	64.5	72.7	73.3	74.2	81.1	74.3	81.9	85.9
Registered in the Land Cadaster - state, %	**24.0**	18.8	31.4	23.5	25.9	15.5	28.1	11.6	26.0
Number of rental agreements per 000 landowners	**40.8**	41.3	37.2	56.1	30.7	1.3	2.8	1.2	0.4
Number of non-rental transactions per 000 landowners	**1.2**	1.1	0.5	2.0	1.2	0.5	0.3	0.9	1.0

State of land governance, average rank	-	**289.8**	**372.1**	**200.6**	**310.2**	**251.5**	**243.7**	**226.7**	**167.3**

4.1. Completeness of formal registration

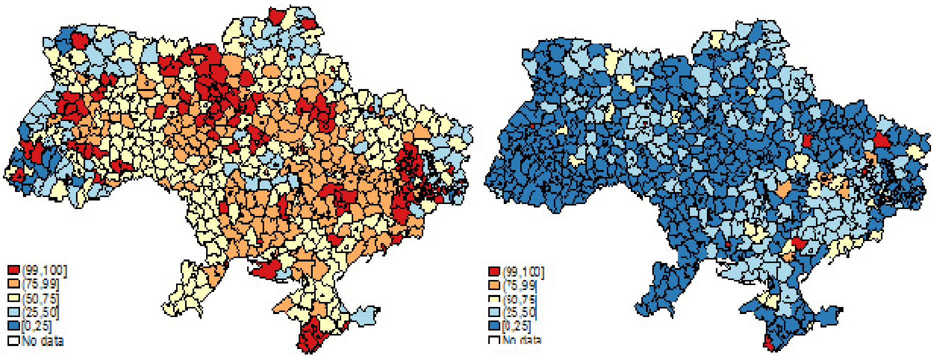
Formal state registration of land plots and related rights is an important institution for protecting rights of owners, users and other stakeholders. There are two institutions in Ukraine performing the registration function. The State Service of Ukraine for Geodesy, Cartography and Cadastre is responsible for management of State Land Cadaster, which contain records of physical characteristics of land plots (geographic coordinates of boundaries, area, designated land use, etc.). All rights and encumbrances, related to these parcels, are registered by the State Registry of Rights for Immobile Property administered by the Ministry of Justice of Ukraine. Completeness and currency of the Land Cadastre and Registry is a characteristics of quality of protection of land rights.

As of December 1, 2015, there were 16,661,051 plots registered in the State Land Cadastre with a total area of 41,812,127.76 hectares, representing 69% of Ukraine's territory. However, the completeness of registration is different across the forms of property and geography. There was only 24.0% of state-owned land registered in the Cadaster, while the completeness of registration of private property is 70.9% (Table 2). The level of registration of private property is higher in cities (average for cities is 79.9% vs 70.6% for rayons). The completeness of registration of private property for rural rayons ranges from 7.8% to 98.7%. For cities, this range is from 21.0% to 99.6% (Map 2, left panel). For state property these ranges are from 0.03% to 95.2% and from 0.35% to 88.8% correspondingly (Map 2, right panel). In several rayons, the area of registered land turned out to be above the total area of land of corresponding form of property. Such cases were reported to the administrators of relevant data sets and were top coded for further analysis.

The difference in the level of registration between the state and private land points to a significantly lower level of protection of ownership rights of state, which provides opportunities for land grabbing and other forms for poor land management. Better contractual arrangements (e.g. benchmarking) for land registration and governance of state land can bring significant benefits to Ukraine.

The total number of registrations of land rights in the State Register as of September 2015 is 3,485,630, which corresponds to 20.9% of the land plots registered in the Cadaster with significant regional variation in terms of coverage.

Map 2 - Share of land registered in the State Cadaster in private (left) and state (right) property.



The observed spatial variation in formal registration coverage demonstrates that despite the common legal environment, rayon specific factors play a significant role in determining the level of protection of property rights. Among such factors could be professional skills and motivation of the registration personal, awareness of land owners, level of corruption, commitment of the local government to improve the governance of land resources, value of land. Most of these factors are non-observable to central government and local landowners. Thus, publication of the monitoring indicators on cadastral and registry registrations would provide the information for comparison across time periods and with neighboring or similar communities. Such information can be used by central government authorities to assess the performance of local personnel and by local activists, media and politicians and makes the local registration authorities accountable for their performance.

Improvements in registration coverage bring several important benefits to local governments, landowners, and land users. It is safer, faster and easier to transact (including renting) the parcels, which are already registered. With lower transaction costs, local markets become more active, which increases sales and rental price for land. As the registered parcels establish a tax base for land tax and single tax for agricultural producers, local governments are the direct beneficiaries of more complete tax base.

4.2. Transactions

The total number of transactions with the change of the owner or user of land that are formally registered by the State Registry varies between 2,167 in the first quarter to 2013 to 208,735 in the fourth 2014 (Figure 2).

Figure 2 - Total number of transactions with the change of land ownership\user in Ukraine, 2013 - 3rd quarter 2015

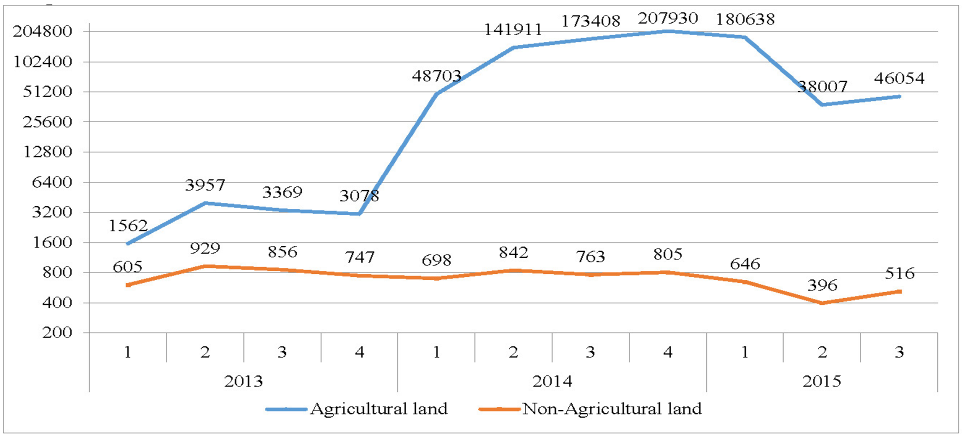


Figure 3 - Number of transactions of different types for agricultural (left panel) and non-agricultural (right panel) land in Ukraine, 2013 - 3rd quarter 2015

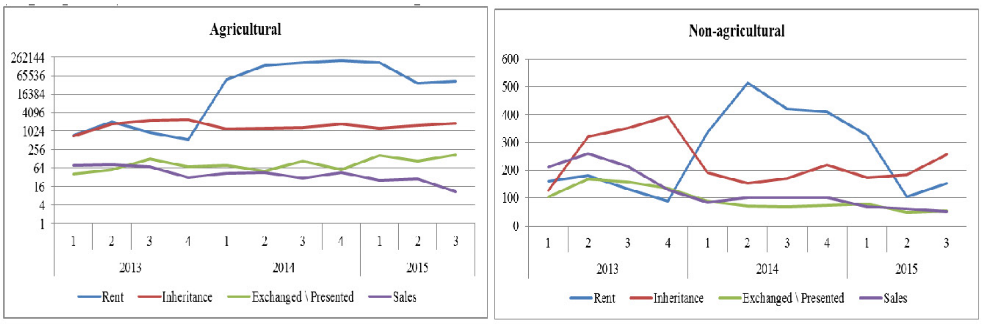
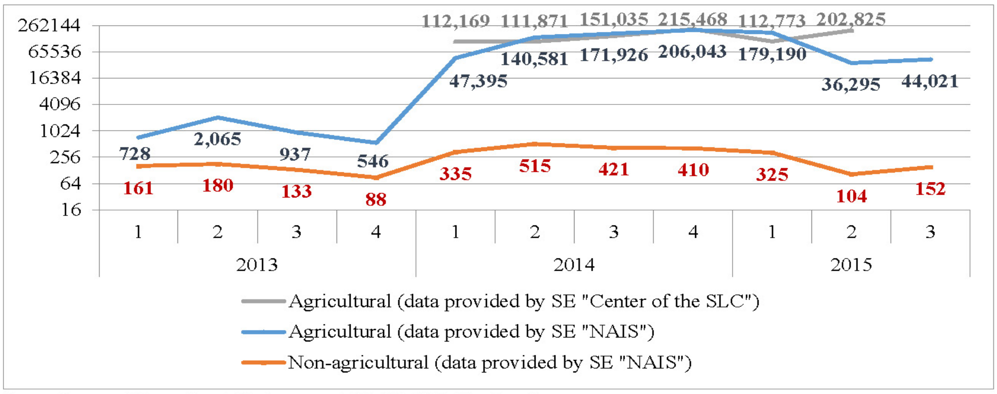


Most of these transactions are the rent of agricultural land (Figure 3). The second type of transactions in terms of frequency is inheritance. There were 1,077 land sales in 2013, 560 in 2014, and 262 during the first three quarters of 2015 with corresponding total area of 2,943.49 ha, 177.38 ha and 3,094.89 ha. The very small number of sales (total area of private land is 31.4 mln ha) points to significant barriers on the sales market for land. While for agricultural land the main barrier is Moratorium for sales, for non-agricultural land the reason is different. Comparison of the number of sales with the number of mortgages indicates that mortgages almost not used in Ukraine, which may be the primary reason for slow development of the land sales market in the country. In 2013, there were 19 mortgages for total area of 7.69 ha; in 2014, these were 58 mortgages for 42.03 ha; there were 14 mortgages for 3.24 ha during the first three quarters of 2015. In other countries the number of sales ranges from 0.5% to 3% of the number of property per year and mortgages are the main source of funding.

In the absence of sales market for agricultural land in Ukraine, rent became the primary type of land transfers. As of 01.07.2015, about 4,671.5 thousand rental contracts for private agricultural land (shares of privatized state farms) were signed in Ukraine for the total area of 16,597.0 thousand hectares (43% of privately owned land). During 2013-2015, transfer of use (rental) rights were registered for 832,551 land plots with total area of 3.5 mln ha (about 16% of land under rental

agreements) (Figure 4). The average rent payment was 786 UAH/ha per year in 2015. Also, 56,053 rental contracts for state-owned land were established with an average rental payment of 1351.6 UAH/ha per year with a significant difference in rental price across the regions.

Figure 4 - Number of registered rental agreements



Data: Center of State Land Cadastre and SE "NAIS" (Registry)

The variation in the number of formal transactions across time periods is related to several policy changes and, thus, the monitoring results can be used for evaluation of such policy effects on various land governance characteristics. For example, in the first quarter of 2015, new restriction on the minimum term of rental contracts for agricultural land was imposed, which coincides with a drop of formal registration of rental agreements from 179 thousand cases in the 1st quarter of 2015 to only 36 thousand in the 2nd quarter 2015. This change is unrelated to seasonality (as no such change was observed before).

For comparison across regions, the number of transactions is weighted by the number of landowners. Table 2 demonstrates that except for rental agreements, number of transactions is distributed relatively universally across the regions. However, if compared across rayons some outliers can be identifies. Such outliers would require a closer analysis and targeted inspection as they may reflect technical errors, cases of best practice or wrongdoing.

4.3. Land tax

The land tax in Ukraine is a local tax paid by land owners and land users (individual and corporate). Starting 2015, the rate of tax and tax exemptions are determined by local councils based on normative value of land. The total amount of land tax collected in 2015 was 3,651 mln. UAH, of which 86% were paid by corporate tax payers. About 70% of land tax revenue was collected in cities (reflecting difference in value of land). For some rural rayons, however, land tax constitute more than 80% of local budget revenue. Thus, improvements in administration of land tax would make a significant contribution to self-sufficiency and independence of local governments.

In 2015, the were 7,826,787 land tax payers, among them 98.5% were individuals (the rest are corporate). This number represents 46% of the total number of landowners, registered by the State Land Cadastre, which points to some significant tax gap.

This statistic does not reflect the payments of single agricultural tax (which includes land tax payment) as the data was not available.

Example of land tax is a good illustration of how closely different areas of land governance are interlinked and how the monitoring results can be used for analysis of land tax. Table 3 presents the regression results for relationship between the tax revenue per hectare of private land, and completeness of cadastral registration controlling for characteristics of local land resources (distribution of land use, forms of property and oblast fixed effect – for more details see Annex 1). The results show that an increase in registration coverage of private land by 10 percentage points would correspond to about 1% increase in average tax revenue per hectare in cities for both individual and corporate tax payers corresponding respectively to 15 and 243 additional UAH per hectare of private land. These benefit outweigh the registration cost many times meaning that local government would have a net gain if they invest in better registration of private land. Expectedly, the registration of state land does not affect land tax. Thus, a privatization of state land via open and transparent auctions may benefit local communities in a short (via sales revenue) and long run (via tax revenue).

Table 3 - Link between the formal land registration and land tax revenue

	Tax per ha of private land paid by			
	Corporate		Individuals	
	In cities	In rayons	In cities	In rayons

Robust standard errors in parentheses; *** p<0.01, ** p<0.05, * p<0.1; oblast FE are controlled for. Details in Annex 1.

4.4. Other indicators

The Monitoring system includes indicators on other areas of land governance. Some of them are presented as examples in Table 2 (disputes, privatization). The diversity of indicators opens opportunity for detailed analysis of land governance and for development of policy recommendations to improve security of land rights and land transferability. More importantly, availability of detailed regionally disaggregated information provides an opportunity for design of better contractual arrangements with local authorities for delivery of land governance functions. The monitoring indicators could serve as a measure of performance as well as benchmarks in such contracts.

4.5. Ranking of Land Governance

By its nature, land governance includes activities and decisions that target multiple objectives. Thus, assessment of land governance should incorporate all these different objectives and have tool for a simple instrument for comparison of the quality of land governance across the administrative units.

There is a large literature on operational research and in several other field that provide various tools for multi-objective assessment. Ranking is one of the simplest tools that allows aggregate performance along multiple dimensions into a simple index. Below, we demonstrate how the monitoring results can be used for comparison of quality of land governance across administrative units. Such comparison is necessary when performance of neighboring communities or other peer groups is used as a benchmark for assessment the quality of land governance in a given administrative unit.

Ranking represents a position (rank) of a specific city or rayon in comparison to the rest of administrative units in a range from the first (the best value of a specific indicator) to the last with the lowest value for a particular indicator of land governance (e.g. tax revenue per hectare). Ranking for each individual indicator can be combined into an aggregate ranking of land governance. Such ranking is proposed to assess the quality of land governance for each rayon and city of Ukraine. It is based on monitoring results for 2013-2015. One or two indicators were selected to represent each functional area of land governance. A rank of rayon/city was calculated for all of the indicators separately. To assess the total rank, an average across all functional areas was taken. This approach effectively provides equal weight for each functional area as there is no theoretical ground to set priorities among the functional areas differently. In case two sub-indicators represented a functional area (e.g. share of registered state and private land), an average of the two ranks was used to represent the functional area in the final computation. The distribution of weights among the sub-indicators can potentially be adjusted to the share of the sub-components in the total (e.g. share of private vs state land). However, such adjustment may unnecessary complicate the practical implementation of the ranking. The following indicators are used for five functional areas:

1. Share of land registered in the State Land Cadaster (50% of weight is given for registration of private and 50% for registration of state land);
2. Number of transactions per thousand landowners (50% - rental agreements (change of land user) and 50% - other transactions with change of ownership: sales, inheritance, exchange);
3. Land Tax paid per ha of private land;
4. Share of individuals, who claimed their privatization rights for land;

5. Number of court cases related to land per thousand landowners (50% - in Administrative courts and 50% - in Civil courts).

The ranking was performed for all sub-regional administrative units of Ukraine, Map 2. In case several administrative units have the same value of indicator, they receive the same rank, that correspond the highest rank in the group (standard competition ranking). The presentation of results, however, is done separately for cities and rayons (Table 2). The Autonomous Republic of Crimea, Donetsk and Lukhansk regions are excluded from ranking as mentioned above, thus, the lowest rank is 557, which corresponds to the number of cities and rayons used for establishing the ranking.

For example, Barskiy rayon of Vinnitsa oblast has 12.46% of state land registered in the Land Cadaster and 70.56% of registered private land. It is ranked respectively 354 and 294 among cities and rayons participated in ranking (Table 4). As Indicator 1 "Share of land registered in the State Land Cadaster" includes two sub-indicators, the average of them is 324 and is included in computation of the overall ranking. Ranking for other functional areas of land governance are performed similarly and their total equals to 1363. As the sum of ranks gets larger, the overall position of rayon or city in terms of quality of land governance is getting lower. The overall rank for Barskiy rayon is 293. Dubenskiy rayon of Rivne oblast is in the first palace.

Table 4 - Calculation of ranking for state of land governance: case of Barskiy rayon of Vinnitsa oblast, 2015

Monitoring indicator	Sub-indicator	Value of indicator	Rank
1.Share of land registered in the State Land Cadaster, %	State	12.46	354
	Private	70.56	294
2. Number of transactions per thousand landowners	Rental (change of user)	43.89	201
	Change of owner	0.07	367
3. Land Tax paid per ha of private land, UAH/ha	-	43.02	179
4. Share of individuals, who claimed their privatization rights for land, %	-	91.03	337
5. Number of court cases related to land per thousand landowners	Civil	0.22	218
	Administrative	0.04	260
Sum of ranks			***1363***
Overall rank of land governance			***293***

There are also 8 administrative units with missing data for one or more indicators used for ranking. One of such units is the city of Prypiat', which is de-populated after Chernobyl nuclear disaster. This observation is excluded from ranking. The rest of missing data was replaced with average values for respective oblast rayon/city clusters.

Comparison between the cities and rayons shows that there is a statistically significant difference in terms of the ranking and across the regions. The oblasts with the highest average rank is Zaporizhzha (average rank across rayons and cities is 88), Rivne (103) and Poltava (average rank is 104). The lowest rank is in Kharkiv (466), Zakarpatska (461) and Odessa (447) and oblasts. The lowest and highest ranks for individual cities and rayons is presented in Table 5.

Map 3 - Rank of land governance at local level

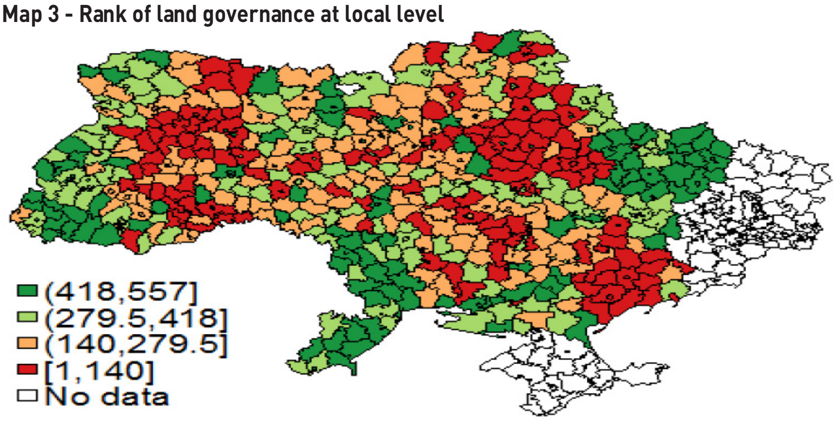

Table 5 - Ranking of land governance for selected rayons and cities

	Top ranking	Lowest ranking
Cities	(12) Znamianka, Kirovograd oblast (17,5) Kalush, Ivano-Frankivsk oblast (23) Polrava, Poltava oblast	(555) Bucha, Kyiv oblast (556) Kotovsk, Odessa oblast (557) Bilgorod-Dnistrovskiy, Odessa oblast
Rayons	(1) Dubenetskiy, Rivne oblast (2) Grebinkivskiy, Poltava oblast (3) Karlivskiy, Poltava oblast	(547) Irshavskiy, Zakarpatska oblast (549) Velykolepetyskiy, Kherson oblast (553) Dvorichanskiy, Kharkivska oblast

As demonstrated, the ranking provides a simple measure of relative position of the land governance at the local level and can show if improvements takes place over time. The potential users of the ranking results include policy makers, government administrators, land owners, land users, journalists and general public.

4.6. Benchmarking

The ranking, presented above, can be a useful tool for the overall comparison. However, for practical recommendations how to improve the ranking and for establishing contracts with local governments, the ranking can be complimented with clear benchmarks for overall performance and for each component and sub-component as presented below.

Figure 5 presents a graphical comparison of ranking for Barskiy rayon (Vinnitsa oblast) along each of the ranking sub-indicators with average performance of two peer groups for this rayon: its immediate neighbors and all rayons and cities in Vinnitsa oblast. We can see that Barskiy rayon outperforms its neighbors in terms of registration of private land and land tax revenue. In terms of registration of state land and the number of transactions with change of ownership, the rayon is significantly below its peers. Thus, efforts for improvements in land governance in Barskiy rayon should target better registration of state land (e.g. by allocating the budget for land registration, bringing state land to the auctions with registration of land parcels as a part of auction preparation procedure). In terms of establishing the performance indicator, Barskiy rayon should target an increase in registration of state land from current 12.46% to 22%, which is an average for Vinnitsa oblast (Table 6). The improvements in number of land transactions can be achieved via improvements in registration practices (e.g., improving performance of registration personnel, increasing their qualification), improving access to finance and improving awareness of population regarding the procedures for land transaction registration. The reasons for the relatively low number of transactions should be investigated further and the reviled barriers should be target with specific administrative actions.

Figure 5 - Benchmarking results for Barskiy rayon of Vinnitsa oblast, 2015

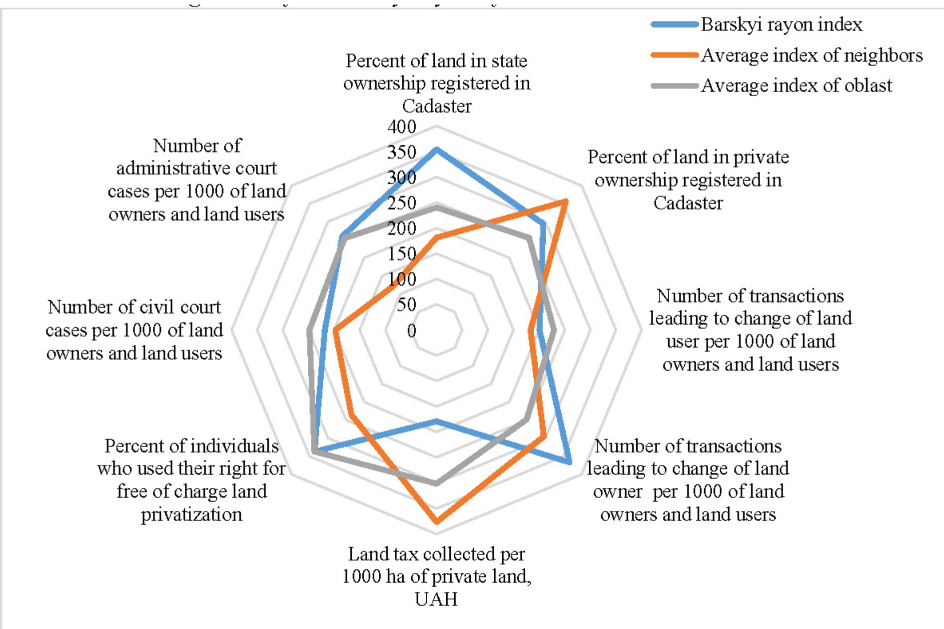

Table 6 - Comparison of ranking results with peer groups.

		Percent of in state land registered in the Cadaster	Percent of private land registered in Cadaster	Number of transactions leading to change of land user per 1000 of land owners and land users	Number of transactions leading to change of land owner per 1000 of land owners and land users	Land tax collected per 1000 ha of private land, UAH	Percent of individuals who used their right for free of charge land privatization	Number of civil court cases per 1000 of land owners and land users	Number of administrative court cases per 1000 of land owners and land users
Barskyi rayon	Rank	354	294	201	367	179	337	218	260
	Value	12.46	70.56	43.89	0.07	0.04	91.03	0.22	0.04
Neighbors	Average Rank	181.0	356.5	183.3	295.5	376.5	235.0	197.8	120.8
	Value	26.32	64.48	51.75	1.82	0.02	92.88	0.32	0.02
Vinnytsia oblast	Average Rank	240.1	255.5	228.9	248.3	301.4	337.0	248.2	254.4
	Value	22.06	74.88	51.61	3.18	1.18	91.03	0.34	0.06

As demonstrated, land governance monitoring helps to address the issue with unobservable performance of local government authorities and establish clear targets for improvements in land governance functions.

4.7. Difficulties with practical implementation

One of the results of the pilot implementation of Land Governance Monitoring in Ukraine is identification of issues, which require normative changes or development of procedures in order to implement a full scale automated monitoring. First, there were issues with delays in data supply and lack of common structure for reporting. Besides, there are cases when data important for policy making is not recorded and/or is not provided in the form of regular reports (e.g. number and characteristics of the land plots that were expropriated for public use, gender of land owners, prices for rental and sales transactions, etc.). Overcoming these issues requires adoption of new regulations.

Second, several government agencies have corresponding service areas that do not match the administrative territorial structure of Ukraine. Most common case is that one local office serves several administrative units (e.g. city and an adjacent rural rayon). As a temporary solution, the reporting statistics was distributed among the administrative units proportionally to population. A permanent solution would be a requirement to report separately for each administrative unit.

Third, there are inconsistencies in standards used by authorities for land use categories and other characteristics of land governance. Thus, establishment of common standards would improve the performance of land governance functions by providing for better data exchange among the government authorities.

Fourth, several errors were detected in administrative records. A clear procedure is yet to be established for errors correction for each relevant agency. Among the solutions would be an establishment of procedures for automated control at data entry, linking the administrative data at parcel level and eliminating the duplication of information across the government authorities, and simplifying procedures for error correction.

Fifth, several authorities use licensed and certified software for management of administrative data which does not have functionality for producing regular, regionally disaggregated reporting on a selected set of indicators. Thus, development and certification of reporting software is required. This also implies that terms of reference for development of new software in different areas of land governance should, by default, include the reporting function.

Finally, data exchange procedures across the government authorities need to be improved. It requires adoption of normative acts that stipulate requirements for regular reporting and data exchange.

5. Implications and Conclusions

Introduction of the monitoring system allows testing several hypothesis regarding the state of local governance of land resources and its impact on growth and development. For example, effect of better protection of property rights for land on investments and productivity growth. It also provides information for design of policy intervention, monitoring their introduction and evaluation of impact. Moreover, monitoring provides for transparency and accountability of local government decision making, which to a large degree would decries the room for moral hazard in local government decision making.

The case of Ukraine demonstrates only some core features and possible extensions of Land governance monitoring. Examples of overlaying spatial data (including remote sensing of satellite images) can provide additional functionality to the monitoring system. Among additional tools that would extend the functionality of the monitoring system could be mass valuation of land and real estate, modelling and assessment changes in land tax, etc. The monitoring can also be extended to monitoring of forestry, water, urban land and real estate.

Monitoring provides evidence regarding the actual state of land governance at national and local levels and allows to reduce information asymmetry regarding the administration of land resources. It helps to reduce political speculation regarding land and enhances practice of evidence based policy making. Moreover, by improving one of the key resource market it improves the investment attractiveness of agriculture and rural areas.

The results of Monitoring point to a significant difference in the characteristics of land resources and land governance at the local level. Therefore, the land reform must take into account the diversity of local conditions and capacity for implementation of reforms at the local level and provides input to various international rankings.

Case of Ukraine demonstrates an example of successful institutional arrangements for implementation of the land governance monitoring. Comparison with monitoring experience of several other countries demonstrates the importance of establishing a working group within government at the level of decision makers and the need for normative regulation of the monitoring function. Also, the comparison of the presented case with examples of parcel level pilots in selected regions demonstrate that the presented approach of establishing the national system with reporting at the level of local governments can solve a significant problem with asymmetric information and can be extended if necessary in terms of additional indicators and reporting scale. On the other hand, very detailed pilots in most cases lack capacity for extension to the national level.

ABSTRACT

This paper provides an example of application of massive farm-level panel data for agricultural economic studies. We used a panel data of 1,008,310 farms from the V and VI Italian agricultural censuses and we described the adjustment in land use at farm level, in order to observe the changes in the economic and production behavior at individual level.

Changes in market structure, such as the consolidation of downstream and upstream industries, global sourcing, price volatility, increase in reservation wage of family labor increase the socio-economic pressure on farmers and call for adjustment in strategies and operation (Russo, Sabbatini 2010).

The most evident consequence of the severe challenge was the sharp decrease in the number of farms (-32.4% between 2000 and 2010) and the decline of utilized area (-2.5%). The combined result of these trends determined a relevant increase the average size of a farm: from 5.5 to 7.9 hectares. These aggregate data were interpreted at first as a consolidation of the farm system: the selection operated by the competitive pressure made the surviving farms larger and somehow more competitive.

We use our panel data to provide a more in-depth analysis. In particular, we test the hypothesis that larger farms are more likely to survive the competitive pressure.

Keywords: Resilience, Agriculture, Performance

PAPER

1. Introduction

In the decade 2000-2010 Italian (and European) agriculture underwent a process of consolidation (i.e., the growth of farm size aiming at exploiting economies of scale). Census data registered a remarkable decrease in the number of farms and, simultaneously, an increase in the average farm size.

The consolidation process is the result of dramatic changes in farmers' social and economic environment (Sabbatini 2011). A mix of social and economic factors (such as increasing competition, decreasing public intervention, demographic changes, technology, etc.) resulted in a non-negligible 'squeeze' on farming profit margins (van der Ploeg 2006). Facing the increasing pressure, farmers implement a set of strategies defining new paths in rural development (van der Ploeg et al. 2002). Consolidation is often considered the mainstream approach to competitiveness (van der Ploeg et al. 2016), although it is not the only one. The rationale of consolidation is straightforward: given the declining per-unit margins and the increasing fixed costs, farmers must achieve much higher production in order to break-even. A minimum scale is considered a prerequisite for profitable capital investments, and even multi-functional oriented investments are assumed to be fully justified only if the farm is 'large enough' (van der Ploeg et al. 2016).

In this paper, we test if larger farms are more resilient than smaller ones. The study question is relevant because agricultural policy supports farm consolidation and cooperation in order to foster competitiveness and ensure surviving of farm businesses. If farm size proved to be inconsequential, then such policy measures should be reconsidered.

In our study, we measure the farm size with arable land and we use econometric models to link the initial endowment of utilized land (year 2000) to the probability that a farm is still active at the end of the period (year 2010).

In our analysis, we build a panel dataset to identify the surviving farms (i.e., firms from the 2000 Census that are in the 2010 Census). A Logit regression is used to calculate the conditional probability of belonging to the subset of surviving firms. We found a significant and positive impact of farm size on such probability.

2. The dataset

The Database used for this study was obtained combining three independent data sources via statistical matching: the V and VI General Agricultural Censuses and Integrated Administration and Control System (IACS).

The General Agricultural Censuses (Reg. EC 1166/2008) provide complete information based on the structure of the agricultural and livestock system on a national, regional and local level. The dataset of the V Census refers to the year 2000 with 2,396,274 farms and dataset of the VI Census refers to the year 2010 with 1,620,884 farms.

IACS (Reg. EC 73/2009) is the most important system for the management and control of payments to farmers made by the Member States in application of the Common Agricultural Policy.

IACS consists of a number of computerized and interconnected databases that are used to receive and process subsidy applications and respective data. In this study is considered the year 2013 reporting 1,915,560 farms.

We linked the datasets and matched the units having the same person as head of operations from year 2000.,. This approach underestimates the number of surviving farms because units with a passage of an inheritance or a change in legal form have been excluded from the dataset.

In order to integrate the three datasets we applied statistical matching model (also known as data fusion, data merging or synthetic matching) that is a model-based approach for providing joint statistical information based on variables and indicators collected through two or more sources (Leulescu A., Agafitei M., 2013).

Statistical matching relies on certain pre-requisites of harmonization and coherence of data sources to be matched, in particular the choice of matching keys.

For the linkage of the two Censuses three variable which identify the farms are chosen:

1. Unique Code Farm (UCF).
2. Address of the headquarter.
3. Name of the farm.

UCF is represented by the personal code in the individual companies and the Value Added Tax (VAT) in the companies, it is a stable variable along the time and allows a deterministic linkage of the two universes. In both censuses, this variable was not subject to control procedures, so it was applied a standardization procedure before the linking activities.

Related to the addresses a fundamental issue is related to the existence of multiple ways to express the location qualifiers, (e.g. Piazza and P.zza) or parts of the proper name of the street (such as Santa, or S. or S or S.ta). To validate the addresses was used a software to validate the addresses and standardize them to the official format (www.egon.com).

The farm name or the holder name (depend on the UCF) is the variable potentially wrong for the presence of transcription errors and for the possibility that during the period each farm might changed its name.

The first step of the matching model selected for the linkage was linking the Unique Code applying a deterministic model of equality, combining the frame of V and VI agricultural censuses. In this way has been obtained a panel of 816,319 farms existing at 2000 Census and still active at 2010 Agricultural Census. We excluded approximately 20,000 farms existent in the lists of both censuses, because they result inactive in 2010 year.

804,565 farms detected at VI census and 1,579,955 farms of 2000 census result un-matched. A comparison function1 is used to compute the distance between records on the values of the chosen matching variables, name and address. It is requested to choose a threshold, between 0 and 1. The higher distance for two strings is, the more similar the strings are. The threshold chosen is 0.69 for both variables. The distance function was used combined with a deterministic merge.

With the deterministic merge with variable name 130,455 farms have coupled. According to the threshold of distance function applied on the address of these farms, just 783 have similar addresses.

The same procedure was applied on residuals, making a deterministic match on the variable address combining to the comparison function on the variable name. 47,657 have the same address, but only 6,669 also the same name.

The result was a panel of 823,771 farms that are present in the censuses of 2000 and 2010.

We checked the residual 2000 census farms with IACS. It was done a deterministic linkage between IACS database and 2000 census residual farms using the Unique Code as merge key. In this way it was been identify other 184,539 of 2000 Census still "alive" based on IACS source.

Totally we can considered 1,008,310 farms detected at V General Agricultural Censuses still-existing after 10 years.

[1] The function distance calculated is $d(\delta, \theta) = \begin{cases} 1 & se\ \delta = \theta \\ 0 & or \end{cases}$

3. Farmland distribution a comparison between 2000 and 2010 Censuses

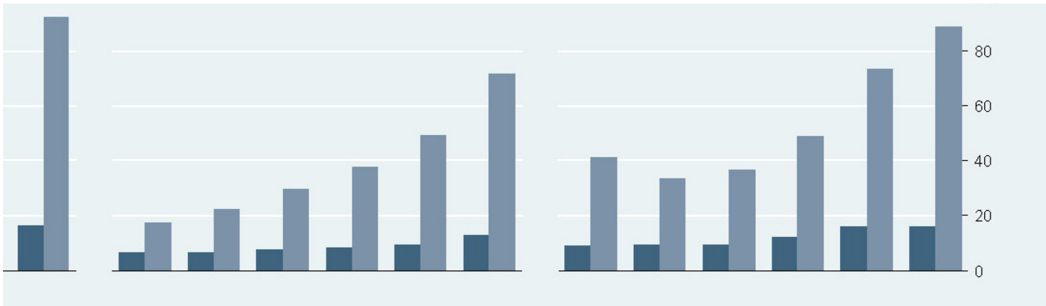
Aggregate descriptive statistics from the two Censuses show that, the agricultural sector has been characterized by a deep restructuring due to competitive pressure (Spinelli, Fanfani 2012; Sotte, Arzeni 2013). Between 2000 and 2010 the number of farms declined by 32.4% while the average tillable area increased by 30.4%. More than half of the farms in the panel is located in the hills, about a third in the plains and the rest in the mountain. In terms of Utilized Agricultural Area (UAA) the farms in the panel registered an increase of 22%, but they have values slightly higher than the total number of farms in 2010, with an average UAA of 8.9 hectares against 7.9 hectares of the total, and an average Total Agricultural Area (TAA) of 12 hectares against 10.5. However the distribution and the increase in the UAA varies across regions, indeed the average values vary from less than 2.5 hectares of Liguria to more than 20 hectares in Lombardy and Sardinia. Almost all regions recorded an increase in the area, the highest value is recorded in the Province of Trento (+70%), followed by Abruzzo (+42%) and Lazio (+33%), the lowest values in Molise and Liguria (+12% and +10%, respectively), the only region that recorded a decrease is the Valle d'Aosta (-11%). Average size varies with altitude. The value reaches 12.4 hectares in mountainous areas, generally characterized by the presence of large area of pasture and meadows, 9.3 hectares in the plains and 7.6 hectares in hilly areas. Also the change in UAA is affected by altitude. Censuses registers an increase of the UAA in the mountainous part of the country (+34.2%) followed by about 20% in the plain area while in the hilly the rise were smaller (+17.3%).

At national level the most common form of land tenure is still the property, with 66% of the UAA, although it is down compared to 2000 (70%), while the rented area slightly increases (from 25% to 27%) and even more the area used for free, that is almost doubled, although it remains marginal (from 4.6 to 7.2%). This situation varies across Regions, in fact, even if the property remains the most prevalent form of tenures, the percentages vary from region to region.

4. Farm size and resilience

The panel data described in section 2 can be used to address the first study question: are larger farms more resilient? The question has theoretical implications. The hypothesis that larger farms are more resilient implies that the incentive to selling out operation decreases with farm size. The Figure 1 summarizes the problem. From an economic standpoint, a farmer should sell his/her farm if the present value of future cash flows (the thick line in Figure 1.) is lower than the sum of the sale price of land (and operations) plus the value of any alternative revenue (e.g., a reservation salary).

Figure 1 - Farm size and the decision of selling operations out



The Figure 1 presents two illustrative examples of the comparison between the Present value of future cash flows (PVFC) and sale price plus outside option (SPOO). In the graph, we depicted two SPOO lines: one refers to the outside option (reservation salary) for the farmer, the other refers to the outside option for the family member who can take charge of operation after the farmer's retirement (for example, a son or daughter), which has been assumed to be greater than farmers' one (for example, because of more education, etc.). The graph identifies three areas: when PVFC is lower than farmer's SPOO, the rational behavior is Competitive pressure and structural change in agriculture. Are larger farms more resilient? An analysis of Italian Census data to sell operation immediately. If PVFC is lower than family's SPOO but higher than farmer's SPOO, the rational decision is to sell after the farmer's retirement. Finally if PVFC is greater than any SPOO, the optimal behavior is to keep farming and the family member should take over at farmer's retirement.

The two panels in Figure 1 depict opposite cases. In case a) small farms are more likely to be sold; in case b) large farmers are more likely to be sold. The difference between the two panels is in the curvature of the PVFC curve. If the PVFC increases faster than SPOO, then large farms are more likely to survive. In this case, our simple framework suggests that the price of land is not able to capture the increase in PVFC. Such result might be due to scale economies: the marginal value product of land changes depending the amount of factor. Vice-versa, case b) suggests the presence of declining marginal value product of land (scale diseconomies).

In order to test the hypothesis, we developed an econometric model assessing if farm size (measured as hectares of utilized agricultural area) is a statistically significant variable affecting the probability of surviving in the competitive agro-food sector. The test is structured as a logit regression estimating the probability that a farmer detected in the 2000 census is still active in 2010. We built a binary variable yr that is equal to 1 if a given farmer belongs to the panel of 1,008,310 surviving farms (described in section 2) and it is equal to zero otherwise. The logit regression of yr on a set of explanatory variables, including farm size, can provide an answer to the study question.

The independent variable yr is subject to measurement error due to the construction of the panel data. The linkage procedure is designed to minimize the probability of including non-surviving firms in the panel (type I error). Yet among the set of excluded firms might still include surviving firms that for several reasons (data collection errors, changes in management or in address, etc.) have not been identified in the 2010 census (type II error). The low power of the linkage procedure might introduce a bias in the estimation of significant variables affecting the surviving probability, because the control group (i.e., the non-surviving firms) might include unidentified surviving firms. We run our analysis under the assumption that misidentification of surviving firms depends on non-systematic, random factors so that model still provides unbiased estimates.

In order to assess the statistical significance of farmland size on the surviving probability of a farm, we regressed yr on a set of variables describing the structural characteristics of the farm, the social and demographic characteristics of the farmer and his/her family, and the marketing approach. This reduced model approach is based on the assumption that the surviving probability is somehow affected by four drivers: the resource endowment (measured in terms of land, livestock, and machinery), the working effort of the farming family (measured in terms of farmer's age, working days, number of family members working on farm), human capital (measured by farmer's education) and market opportunities (measured in terms of share of self-consumed products, presence of value-added productions, differentiation and horizontal coordination). In theory, we expect a positive pairwise-correlation between each driver and the probability of surviving. Table 1 reports the regression results. The odds ratio in the logistic regression output summarizes the relationship between the explanatory and the dependent variables: an odds value ratio greater than 1 means that an increase in the explanatory variable is associated with an increase in the probability that the observation belongs to the panel of surviving farms, holding everything else constant (i.e., the regression coefficient is positive). A lower-than-1 odds ratio indicates a negative association (i.e., the regression coefficient is negative). The z-score and the p-value of a t-test on the statistical significance of the regression coefficients are also investigated.

The sign of the regression coefficients is consistent with expectations. Market access, participation to associations (such as cooperatives or producer associations), and processing activities are associated with higher probability of belonging to the surviving panel. The variables are associated with higher PVFC, while have a weak link with SPOO. Consequently, we expect that the probability of selling the operations is smaller.

The share of rented land has a positive impact (although the confidence level is only 10%). Land rental is profitable only if the farming activities are profitable enough to pay the rent. Therefore, we expect that land rental is a proxy of high PVFC. The association with SPOO is weak, because the value of rented land usually is not captured in the sale value of operations.

Multi-functional activities, measured with the presence of agri-tourism and the location in a natural park, are not statistically significant. However, the complexity of multifunctional agriculture is hardly captured by the available variables and measurement errors might reduce the efficiency of estimates.

The personal characteristics of the farmer are expected to affect both the PVFC (because of higher farming profits) and the SPOO value (because of better outside working opportunities). The regression results support the conclusion that better human capital increases the probability of being in the panel of surviving firms. Such conclusions are consistent with a wide literature about human capital in agriculture (e.g., Idda and Pulina 2011). Young, educated and full-time farmers have higher probability of being in the panel of surviving farms than otherwise. Noticeably, female gender is positively associated with yr. This result might be explained by the lower value of the outside option for women in agriculture (e.g., Sabbatini et al. 2011).

The role of family members is ambiguous. On one hand, the presence of 'family members working on farm' increases the probability of being in the surviving panel. The presence of family workers is associated to the ability to sustain the family with farm profits. Both factors are associated to higher PVCF. Furthermore, family members are assumed to be working on farm because the value of outside options is low, depressing the SPOO value. The combined effect of the two drivers results in higher probability of yr =1.

On the other hand, when an additional variable discriminating the presence of full time family members, a negative effect emerges. The interaction of the two variables results in a negative and statistically significant coefficient (the 2(2) test statistic is 65,443, which allows us to reject the null hypothesis of no joint significance at 1% confidence level). The result might be explained considering that a full time position by a family member might be associated to a planned turnover in management (e.g., Cardillo et al. 2010). In this case, the full-time member might act as apprentice, learning specific skills, with the objective of taking over.

The farm's factor endowment is associated with a negative impact on the probability of belonging in the surviving panel. Capital investments in irrigation, machinery and livestock present negative coefficients (although significance is at 10% confidence level). In part, this result might be due to the crisis of cattle farming that struck Italy after the 2003 dairy quota reform. Nevertheless, the data suggest that markets are efficient in capturing the value of investments in the sale price of the farm.

Finally, land size shows a positive and statistically significant coefficient. Data support the conclusion that larger farms have higher probability of being in the surviving panel. Yet, the quadratic term in the regression shows that the relationship is not linear and the impact of land increase is decreasing. This conclusion might explain why empirical studies have reached mixed conclusion when looking at the relationship between land size and farm surviving.

6. Conclusions

In this paper we tested the hypothesis that larger farms are more successful in surviving the increasing competitive pressure. This assumption is the rationale for agricultural policies fostering consolidation in the agricultural sector as a key driver for competitiveness. Yet, academic literature has not reached a consensus about the link between size and resilience.

We contributed to the debate using a unique dataset composed of observation from two censuses (2000 and 2010). The comparison between the two censuses allowed us to identify the subset of farms that are in both surveys. We considered this set as the group of 'surviving farms'. A Competitive pressure and structural change in agriculture. Are larger farms more resilient? An analysis of Italian Census data simple logit regression allowed us to establish that larger farms have higher probability of being in the surviving group. We conclude that large farm, holding everything else constant, are more likely to survive the competitive pressure.

ABSTRACT

In rural societies of low- and middle-income countries land is a major measure of wealth, a critical input in agricultural production, and a key variable for assessing agricultural performance and productivity. In the absence of cadastral information to refer to, measures of land plots have historically been taken with one of two approaches: traversing (accurate, but cumbersome), and farmers" self-report (cheap, but marred by measurement error). Recently, the advent of cheap handheld GPS devices has held promise of balancing cost and precision.Guided by purposely collected primary data from Ethiopia, Nigeria, and Tanzania (Zanzibar), and with consideration for practical household survey implementation, the paper assesses the nature and magnitude of measurement error under different measurement methods and proposes a set of recommendations for plot area measurement. Results largely point to the support of GPS measurement, with simultaneous collection of farmer self-reported areas.

Keywords: Land, Agriculture, Measurement, Surveys.

PAPER

1. Introduction

Land is a key measure of absolute and relative farmer wealth, a critical input in production, and a key variable for normalizing agricultural input use and output measures. Although easily overlooked by analysts, the quality of land area measurement can have non-trivial implications for agricultural statistics, economics, and policy analysis. The methodological menu for collecting land area measurements is diverse and selection of the appropriate method depends on several factors. This paper focuses on the methods that hold relevance for agricultural and household surveys. For the analysis of household level processes and outcomes it is vital that the land area being measured can then be linked to other variables concerning the agricultural production, or welfare outcomes, or other variables of interest for the same household or holding. The main types of surveys for which these measurements are relevant are agricultural sample surveys, agricultural censuses, multi-topic surveys that cover agriculture (such as most Living Standard Measurement Study (LSMS) surveys), and smaller scale household surveys carried out for research purposes. This paper aims to provide some elements to inform the selection of measurement methods, based on empirical evidence gathered by the Living Standard Measurement Study – Integrated Surveys on Agriculture (LSMS-ISA) team of the World Bank in Ethiopia, Tanzania, and Nigeria during methodological fieldwork aimed at understanding the relationship between the three primary methodological options: farmer estimate, GPS measurement, and the traditional compass and rope method.

2. Methods

The first step in analyzing the different methods is comparing the measurements obtained. To that end we construct two measures of deviation between the GPS and CR measures, defined as follows:

$$Bias = GPS - CR$$

$$Relative\ Bias = \frac{GPS - CR}{CR} * 100$$

The bias is the simple difference between the GPS measure and the CR measure, expressed in acres. The relative bias is the simple difference between the GPS measure and the CR measure, in acres, divided by the CR measure, expressed in percentage terms. The absolute value of both measures is also used in the analysis. Although the main focus on what follows will be on the deviation of the GPS from the CR measure, we will occasionally employ measures of deviation of the self-reported (SR) from the CR measure, employing a terminology analogous to the one just described for the deviation of GPS from CR measures.

The analysis will be based initially on a bivariate comparison of the means of the above variables for particular portions of the sample cross-tabulated with a broad range of variables of interest. The second part of the analysis will explore the determinants of the different measures of bias. We will estimate two main regression models. The first model is an OLS regression specified as:

$$(1) \qquad Y_i = L_i + C_i + S_i + SAT_i + T_i + W_i + e_i$$

Where *Y* is one of the four measures of bias defined above, L is the measure of the plot taken using CR, *C* is the closing error of the CR measure, *S* is a vector of proxies for the shape of the plot (including the number of corners and the ratio of the perimeter/area, *SAT* is the number of satellites the GPS device was fixed on at the time of measurement, *T* is a vector of dummy variables related to tree canopy cover (the reference being no canopy cover), *W* is a vector of dummy variables related to weather conditions at the time of the measurement (the reference being clear or partly cloudy sky), and e is a random error with the usual desirable characteristics.

To focus specifically on plots for which large deviations are observed between GPS and CR we then estimate a probit model to capture the factors likely to increase the probability that a plot be measured with arelative bias larger than ten percent (in absolute value). The model is specified as follows:

$$(2) \Pr(Y_i = 1|X_i) = \Phi(X_i\beta)$$

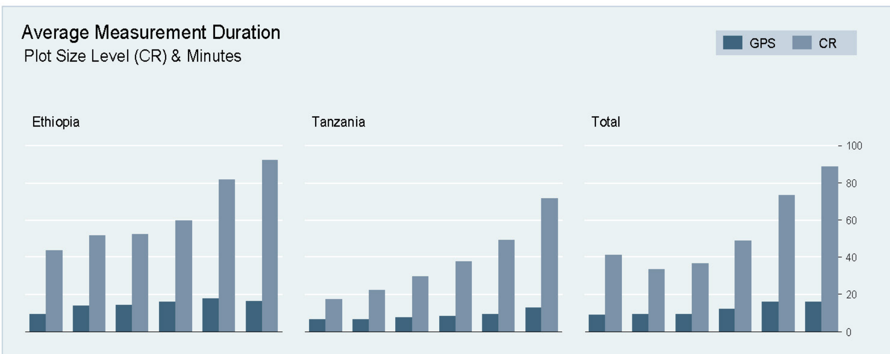
where $X_i = (C_i, s_i, SAT, T, W_i)$ and Φ is the standard cumulative distribution function. In equation (2), Y_i is one of three outcomes: a plot having absolute relative bias greater than 10%; a plot having relative bias greater than 10%; a plot having relative bias smaller than -10%.

3. Results

From the perspective of survey practitioners and national statistical offices, considerations about accuracy need to be accompanied by considerations related to time (and hence cost) of each methods implementation.The reason why the choice of method should matter for survey practitioners is compellingly conveyed by Figure 1, which shows the measurement time for GPS and compass and rope measurements by plot size classes, moving from small plots on the left to large plots on the right. Compass and rope requires significantly more time than GPS with time increasing exponentially with plot size, while the additional time required for GPS measurement for plots of the size included in these studies is negligible. In Ethiopia, GPS required 13.9 minutes on average, while the compass and rope measurement on the same plots required an average of 57 minutes. In Tanzania, the duration averages were 7.4 minutes and 29.3 minutes for GPS and compass and rope respectively. These findings are consistent with previous studies such as Schoning et al.(2005) and Keita and Carfagna (2009) who find that compass and rope takes approximately 3.5 times as long as GPS on average.

To put the time considerations into context, given the sample size and average measurement urations in Ethiopia, the field teams spent a total of 416 hours measuring plots with GPS (1797 plots * 13.89 minutes) and 1,707 hours measuring with compass and rope. Using GPS instead of compass and rope, therefore, saved 1,291 hours of labor – over 160 person/days (at 8 hours per day).

Figure 1 - Time taken for GPS and CR measurement



A. Comparison of competing measurements

1.Compass and Rope vs. GPS

In the literature, the main reservation regarding the use of GPS measurement in surveys is its performance on small plots. Table 1 presents descriptive statistics on the GPS and compass and rope area measurements completed as part of the methodological studies. Mean plot size is small in all countries, ranging from 0.38 acres in Ethiopia to 1.30 acres in Nigeria. The mean difference between compass and rope and GPS measurement is very small. The sample mean bias in all three countries is plus or minus 0.01 acre, which translates in a 1 to 3 percent difference when expressed in relative terms (note that the values are not expressed in absolute value and as such negative and positive figures are averaged). Notably, GPS and CR measurements on the smallest plots (level 1) are not found to be significantly different in Ethiopia, Tanzania or the pooled data. While some literature suggests that plots smaller than 0.5 hectares (1.24 acres) have significantly different GPS and compass and rope measurementswith much lower correlation (Schoning et al., 2005), results from the methodological validation experiments suggest otherwise. In the pooled data, the difference between the average GPS measurement and average compass and rope measurement for plots ranging from 0.05 – 0.15 acreswas less than 0.001 acres or 3% of the average compass and rope area. Even for the smallest plots, those less than 0.05 acres (202.3 square meters or 0.02 hectares), the average measurements are extremely consistent. In Ethiopia, the average GPS measurement of 390 plots in this size range is 0.0216 while the average compass and rope measurement for the same plots is 0.0215 acres.

The differences that are recorded do not appear to bear any clear trend with plot size. In Tanzania, the smallest and largest plot classes have the smallest and largest average relative bias, but the figures are not large, and the number of observations in these two classes fairly small. The correlation coefficients between GPS and CR are in excess of 0.99 in all three studies, and 0.87 or larger in all classes with n larger than 50.

Table 1 - GPS vs Compass and Rope (CR) measures, by plot size classes

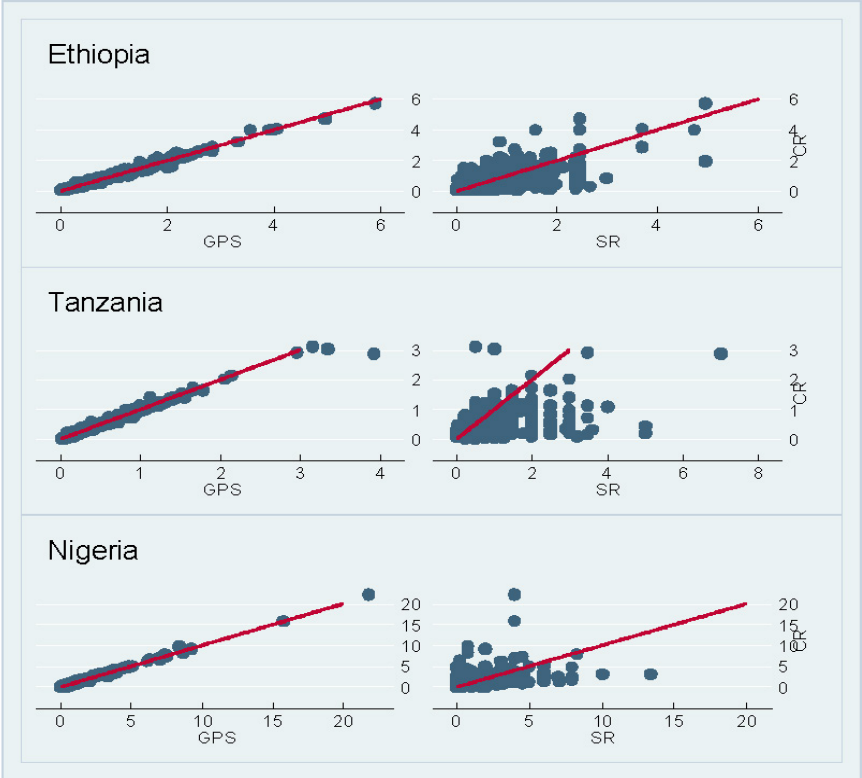
The results presented here suggest that average GPS measures are not much different from compass and rope even for very small plots, and even from a fairly small n, and that is despite the difference in enumerator skill levels and plot characteristics of the different studies. This is confirmed by an inspection of the scatter plots in the left side of Figure 2, where GPS measures are plotted against compass and rope with measures tightly clustered around the equality line. This alllends support to the argument that GPS is an acceptable substitute of compass and rope measures across the range of plot sizes in our samples, at least if the goal is that of estimating average plot size for groups with sufficient numerosity.

Figure 2 - Scatter plots of Compass and Rope vs GPS (left) and Self-Reported (right) land area measures, acres

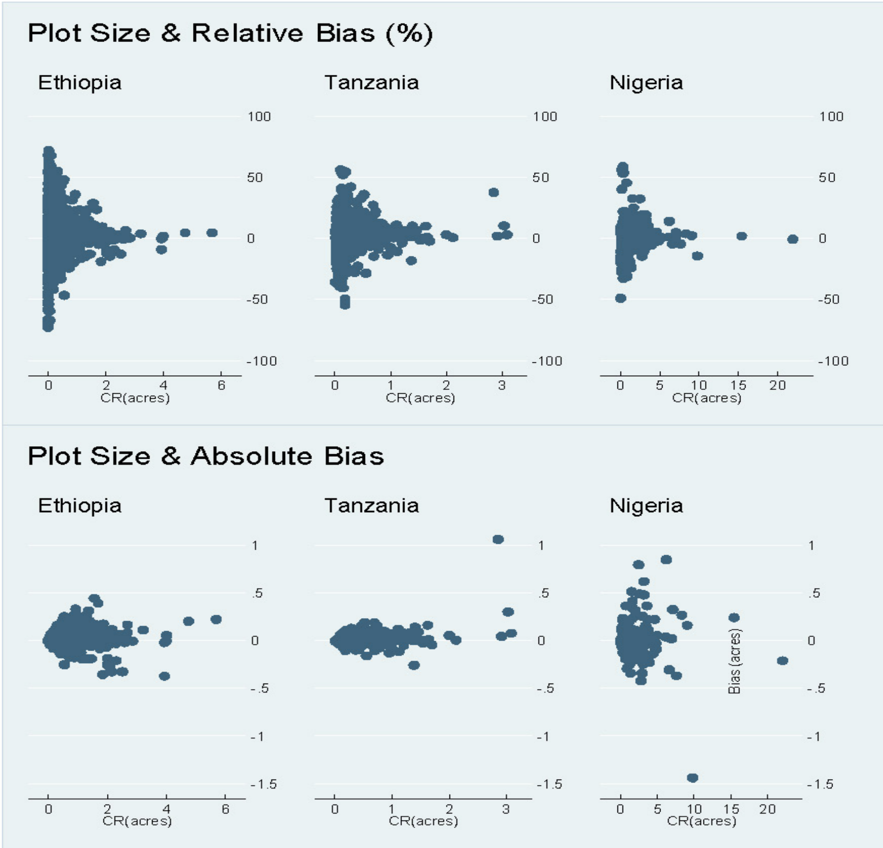


2.GPS measures: Exploring deviations from the gold-standard

Previous studies have also raised the issue of how factors other than plot size may affect the quality of GPS measures. None of the studies have provided compelling, conclusive evidence on the impact of these factors on measurement quality. Some have explicitly called for further research to systematically investigate this matter. Our data allow for analysis on a number of factors including plot shape, slope, and tree cover, weather conditions, and number of GPS satellites acquired at the time of measurement, via a comparison of the GPS measurement to the „gold standard" of CR measurement.

The global navigation system requires, at a minimum, the acquisition of four satellites to triangulate the 3D position of the GPS receiver. Descriptive statistics suggest that the difference between GPS and CR measurement tends to decline the higher the number of satellites, but average difference remain small across all the distribution of plot areas. In Ethiopia, the difference between measurements is 1.6% (but not statistically significant) on the plots with less than 16 satellites and 1.2% on plots with the 20 or more satellites, though the trend is not linear as the middle category has an average of 1.8% bias. In Tanzania, the differences are 2.9% and 2.6%, respectively.Dense canopy cover and weather conditions at the time of measurement have been found or argued to impair the precision of the GPS measurement. Contrary to expectations, descriptive analysis reveals that the relative difference between the GPS and CR measurements was slightly higher on plots with no tree cover, with the level of bias decreasing with increasing canopy density. In Ethiopia and Nigeria, there was no statistically significant difference in measurements found on plots reported with partial or heavy tree cover.The lack of statistical significance in the groups with canopy cover is also likely linked to the smaller sample size for these groupings.This could also be attributable to plot size, enumerator characteristics or other factors, which are not controlled for in these simple descriptive statistics. The sections below will further explore the influence of tree cover on measurement.No clear trend emerges in terms of systematic association of the differences between the two measures and weather conditions.
Having ascertained that the average difference between GPS and CR is small does not rule out that for individual measurements, there may be observations with errors of significant magnitude. To investigate this aspect we plot the percentage and absolute differences between GPS and CR measures over plot area (Figure 3). A number of considerations emerge from a visual analysis of these graphs. First, the GPS measurement error in percentage terms is often far from negligible, in some instances larger than plus or minus 50 percent. Second, large percentage errors appear to be roughly equally distributed above or below the zero line, which explains why we do not observe differences in the means for the two measures.Thirdly, the magnitude of the percentage errors is much larger for the small size classes, and decreases rapidly as plot size increase. Those trends are clearly mirrored by the graphs with the absolute bias, which show no clear correlation with plot size and fairly constant dispersion both sides of the zero line, with most values within the plus/minus 0.5 acres range. That seems to suggest that it is the inherent imprecision of GPS devices that causes percentage error to matter much more for very small plots. We therefore turn to investigating more in depth the extent and nature of the errors for observation with an arbitrary set value of plus or minus 10 percent.

Figure 3 - Scatter plots of relative (%) and absolute (acres) bias over plot size (acres)



3. Compass and Rope vs. Self-Reported Estimations

With an understanding of the comparability of GPS and compass and rope objective measurements, we now explore the difference in subjective (self-reported) and objective (CR) measurement. While the mean plot areas as measured by GPS and compass and rope differ by only as much as 3% on average, the mean self-reported and compass and rope measurements differ by as much as 143% on average (Tanzania). The mean difference is smaller in Ethiopia and Nigeria, at 23% and 5% respectively, but still considerably larger than the divergence observed between the objective measurements. Self-reported measures result not only in higher average deviations, but in dramatic systematic error as the size of small plots is overestimated by anywhere from 30% (Nigeria) up to a factor of six (Tanzania), with the over-estimation declining almost monotonically as plot size increases and eventually results in under-estimation in the larger plot size classes in Nigeria and Ethiopia. The scatter plots on the right side of Figure 2 convey the same message in graphic form.

B. Regression analysis of the differences between competing measures

1. Comparison of CR and GPS

The results in Table 2include four specifications(only pooled model shown), the difference among them being the dependent variable, which is: (i) bias (GPS – CR), (ii) absolute value of bias, (iii) relative bias (bias as a percentage of the CR area), and (iv) absolute value of relative bias. Recall from the descriptive statistics that the observed error is generally small, and little evidence of systematic variation with many of the factors that are a priori expected to influence GPS measurement precision was found. It is therefore not surprising that the explanatory power of these regressions (as captured by their R2 values) is low, and that the majority of the estimated coefficients are not statistically significant.

The main variables of interest are the set of terms (levels, quadratic, cubic) related to the plot size itself, as measured by CR. In the first specification, there appears to be a relationship between plot size and measurement error in Ethiopia, where the shape of the relationship is that of an inverted U, with the predicted bias being positive on very small plots, peaking at about 0.7 acres, and becoming negative for plots larger than about 1.7 acres. The coefficients are small, so that the predicted error is in the plus/minus 0.02 acres range.In Tanzania, a linear relationship is exhibited in which larger plot size results in larger bias (in terms of acres). In Nigeria there is no statistically significant relationship between bias and plot size, and in the pooled data there is very little, controlling for other factors.

Of the covariates reflecting physical characteristics that are expected to affect the quality of GPS measures (cloud and canopy cover, plot slope) hardly any are consistently significant across country.

Table 2 - Determinants of Bias (GPS – CR)

OLS Regression
Bias = GPS - CR (acres)

	Pooled			
Dependent Variable:	Bias	|Bias|	{Bias/CR} * 100	{|Bias|/CR} * 100
CR Area (acres)	0.011	0.050***	-1.898***	-3.344***
CR Area^2	-0.001***	-0.002***	0.352**	0.507***

Per : Area Ratio (GPS)	-0.006	0.001	-13.442***	11.534***
Number of Satellites	-	-	-	-
Slope (clinometer)	-	-	-	-
Treecover:				
Partial	-0.001	0.001	-0.217	0.692**
Heavy	-0.002	0.004	-0.870	2.170***
Weather:				
Mostly Cloudy - Rainy	-0.004	0.003	0.219	0.772**
Constant	-0.002	-0.008*	3.979***	5.731***
Includes Country Dummies	Yes	Yes	Yes	Yes
N	4158	4158	4158	4158
R2	0.026	0.316	0.095	0.162

*p<.1; ** p<.05; *** p<.01

What appears to matter most are closing error and the perimeter/area ratio. The former reflects inaccuracy in the CR measure, while the latter is a proxy for the complexity of the plot shape which is likely to affect the accuracy of GPS measures, but can in principle also be capturing noise in the CR measure besides what is captured by the closing error. An unsystematic comparison of plot outlines computed from the CR method and collected in the GPS also suggests that it may often be the case that enumerators may tend to simplify the shape of the plot more when collecting CR than GPS data.

2. Comparison of SR and Objective Measurements

The models run above for the comparison of objective measures are ran again in an attempt to explain the difference between self-reported estimates and compass and rope measurements. The claim of plot area affecting the direction and degree of error associated with self-reported area estimates is supported by the regression results. In the first specification (on bias) the coefficient on plot area is negative quadratic and positive in the cubic term in Ethiopia, Nigeria and the pooled data. In the second specification (on absolute value of bias), the coefficients on plot area are positive suggesting that as plot size increases the degree of farmer over-reporting shrinks while at the same time the absolute value of the bias increases. In this second specification, the Tanzania data exhibits a negative quadratic term and positive cubic term. When looking at the relative bias and absolute value of relative bias, the linear term is negative and the quadratic term positive in each country but at very different magnitudes, potentially driven by the difference in average plot size observed across the countries. The distance from the plot to the dwelling holds significant explanatory power in the Ethiopia data, but not in Tanzania. The results from Ethiopia suggest that self-reported estimates of area diverge more from compass and rope measurements on those plots that are further from the household. Consistent with Carletto et al. (2015), the existence of property rights (proxied here by the possession of a title or certificate of ownership or the ability to sell or use the plot as collateral) has a significant, negative relationship with the relative bias in Ethiopia and the pooled data, suggesting that on plots where the household has some form of property rights they are better able to estimate the area. Household characteristics such as the gender, age, and education of the household head play out differently across countries.

4. Conclusions

Several important findings emerge forcefully from this analysis, which translate into clear implications for future survey design and implementation. The first result is that our experimental data confirm what we already knew about the presence of large, systematic measurement error in farmers self-reported estimates of land area, and on its direction, correlates and determinants (which include land area itself, introducing potentially large biases at the data analysis stage). An important finding of the study is that on average GPS measures return very accurate estimates of plot size, even for very small plots, and even for reasonably small samples.We also do not detect any evidence that GPS systematically under-reports land size, as is the case in earlier studies. That should suffice to make GPS an attractive method for land area data collection for most household survey practitioners.

ABSTRACT

Food consumption patterns in West Africa have changed over the past few decades, with a higher proportion in the food basket of animal products, fats, sugars and certain cereals such as rice and wheat. These trends, their causes and implications for food security and households have been widely studied but their meaning for agricultural production and farmers remain a more open field of investigation. Have farmers changed their production patterns in reaction to changing diets of increasingly urbanized consumers? Has agricultural production in West Africa diversified or has it concentrated on a smaller number of highly demanded commodities? What are the implications on the value of the farmers' production and their exposure to risks? The aim of this article is to provide statistical evidence on the economic implications for West African farmers of structural changes in the agricultural sector, such as the impact of the shift towards more diverse, calorie-intensive and often more expensive diets. After a presentation of the data and analytical framework, this article compares long-term food consumption and production trends of West African countries. Then, by combining two international datasets on food balance sheets and agricultural producer prices, the implications of these structural changes on the value of agricultural production and the uncertainties associated with the farmers' activities are assessed.

Keywords: Food balance sheets, structural changes, food trends

PAPER

1. Introduction

The comparison of today's food diets with what they were in the 1960s shows that food consumption patterns in West Africa have changed significantly, with a higher proportion in the food basket of animal products, fats, sugars and certain cereals such as rice and wheat (Vincent C., 2015). A number of megatrends are usually invoked as explanatory factors: rapid increase in urbanization rates, from 7.5% in 1950 to 31% in 2000 (OECD, 2011), a rate that has continued to increase since then; a deepening of globalization, facilitating the import of commodities which, until recently, were not considered as staple food items in West Africa such as rice, wheat or sugar; more recently, rising per capita incomes have also contributed to the evolution in diets, both in terms of calorific intake and composition.

The implications of these trends on food security have been widely studied[2] but their meaning for agricultural production and farmers remain a more open field of investigation. This imbalance in the analysis is first explained by the fact that the change in diets directly affects households and consumers and only indirectly farmers and agricultural production. It can also be explained to some extent by the existence of household surveys or population censuses that allow for a detailed analysis of consumption patterns. Many efforts at national and international level have been and are being made to improve household data, with initiatives such as the LSMS (Living Standards Measurement Study).

The stress that has been put on household statistics is due in part to its importance as a major data source for economic and social statistics: data on household expenses is needed to measure poverty and to construct many of the Millennium Development Goal (MDG, now SDG) indicators, in addition to being the main data source for the weights of the Consumer Price Indices (CPI); household survey data is widely used by national accounting departments to measure and calibrate household consumption, a major component of the supply and use equation in national accounts.

1 At the time this article was written and submitted.
2 Recent references include Vicent (2015), Bricas (2015a and 2015b) and Worku (2015).

Comparatively, fewer resources have been directed towards the measurement of agricultural production and farm-specific data: agricultural censuses and farm structural surveys are infrequent in West Africa, leading to data that lack in timeliness, quality, and level of detail and to the absence of proper sampling frames.

The poor measurement of agricultural production at farm level also has to do with the fact that agricultural statistical services are usually separated from national statistical institutes. Farm-level studies made by non-governmental organizations or the private sector often rely on their own data sources and data collection vehicles instead of using national surveys, which are often lacking or considered of insufficient quality. As a result, many of the analysis of the agricultural sector that can be found in the literature generally lack statistical representativity and is restricted in terms of geographical or commodity coverage. In addition, given the cost of carrying-out statistically representative surveys, these are often one-time exercises, impeding the construction and analysis of time-series. Notwithstanding the limitations attached to data on West African agriculture, international datasets compiling nation-wide data on agriculture do exist, allowing the analysis and comparison of macro-level trends on agricultural production and supply. The Food Balance Sheets (FBS), disseminated and updated on a regular basis by the FAOSTAT platform, is in this respect a unique data source which remains under-exploited.

The purpose of this study is to provide statistical evidence on the long-term trends (1960 - present) affecting the supply and demand of agricultural commodities in West African countries[3], based on aggregated sources of information such as the FBS. Through the construction and analysis of appropriate statistical indicators, this study seeks to identify the major trends of the farming sector in West Africa, in a context of changing food diets, and respond to questions such as: have farmers changed their production patterns in reaction to changing diets of increasingly urbanized consumers? Has agricultural production in West Africa diversified or has it concentrated on a smaller number of highly demanded commodities? What are the implications on the value of the farmers' production and their exposure to risks?

After a presentation of the data and analytical framework, this article compares food demand and production trends in West African countries since the beginning of the 1960s. Then, the implications of these structural changes on the value of agricultural production and the uncertainties associated with the farmers' activities are assessed. These analyses are based on two international datasets on food balance sheets and agricultural producer prices. The last Section concludes and identifies further lines of research.

2. Data and analytical framework

The statistical indicators constructed in this article are mainly based on the Food Balance Sheets (FBS) and agricultural producer prices compiled by FAO's Statistics Division and disseminated through its on-line data dissemination platform, FAOSTAT[4]. The data, its underlying compilation framework, and the main statistical indicators used in this study are presented in the remaining of this section.

2.1 Supply and use equation: the framework for Food Balance Sheets

The supply and use equation states that at any point in time there has to be a balance between the supply of an agricultural commodity and its different uses, for a country or any other geographical grouping, as illustrated by equation (1) (FAOSTAT, 2015):

$$\underbrace{Q_i + M_i}_{\text{Supply}} = \underbrace{C_i + NC_i + F_i + Sd_i + X_i + L_i + \Delta S_i}_{\text{Use}}$$

Where:

Q_i : Quantity produced of commodity i

M_i : Quantity imported

C_i : Quantity available for human consumption

NC_i : Quantity available for industrial or other non-food uses

F_i : Quantity used as feed for livestock

Sd_i : Quantity used as seed

X_i : Quantity exported

L_i : Quantity lost during transportation and storage at farm and wholesale levels

ΔS_i : Change in stocks between two periods

This analytical framework, generally referred to as Food (or Commodity) Balance Sheets (FBS), is analogous to the concept of supply and use equilibrium in national economic accounts.

---

[3] According to the United Nations classification, West Africa is composed of the following countries: Benin, Burkina Faso, Cabo Verde, Côte d'Ivoire, Gambia, Ghana, Guinea, Guinea-Bissau, Liberia, Mali, Mauritania, Niger, Nigeria, Senegal, Sierra Leone and Togo.

[4] http://faostat3.fao.org

It is useful in that it provides a complete picture of the sources of supply and use for a given commodity and a quantification of the associated flows. The common unit used is the raw commodity equivalent, such as kg of wheat, paddy rice, etc., which allows a standardization of the flows associated with different degrees of processing of the commodity. For example, humans or animals generally consume products that are based on some degree of processing of one or more commodities (wheat flour, pasta, bread, feed meals, etc.), whereas exports or imports may include both the commodity in its raw or processed form (cocoa beans and chocolate, for example).

To allow a proper aggregation of flows, processed products are therefore converted back to their raw commodity equivalents using appropriate technical conversion factors (also referred to as extraction factors)[5].

2.2 Statistical indicators

For the purposes of this study, several statistical indicators have been constructed using data from FAOSTAT (FBS, agricultural producer prices) and World Bank's World Development Indicators (agricultural GDP). The indicators are defined below.

2.2.1 Food production and consumption

Production (Q) is one of the variables of the supply-use equation of the FBS. It measures the total amount of the commodity produced for a given time period and country (or any other geographical grouping). C, the amount of the commodity available for human consumption, is given in the FBS framework by the difference between total supply and all the uses other than C. It does not mean that C is the amount actually consumed: losses occur in the transportation, storage and distribution process at the retail level; and a share of food is wasted by households after the actual purchase or production. Nevertheless, this indicator provides a measure of the domestic demand for the commodity in question and can therefore be considered as a proxy for potential consumption[6].

From equation (1), we consider the ratio $r = Q/C$ as the measure of the capacity of domestic production to satisfy domestic food demand. In this article, r is used as an indicator of the extent to which farmers in West Africa have adapted their production mix to the changes in domestic food demand.

2.2.2 Diversity of food production and consumption

Empirical evidence tends to suggest that there is a positive correlation between income per capita and diversity in diets. Doan D. (2014) has estimated that in the case of China income effect on food diversity is significant and positive, but diminishes along the income distribution and overtime. It is interesting to test if these results also hold for a region such as West Africa, which has seen income per capita rise in most of its countries, even if this rise has been relatively recent. In line with the objective of this study, it is also relevant to understand if agricultural production has diversified or not, in other terms if farmers have responded to changing diets by broadening their product mix or by specializing on a smaller number of commodities. To respond to these questions, a measure of diversity is constructed: is the Herfindahl-Hirschman index for C and n the number of commodities. To respond to these questions, a measure of diversity is constructed:

$$div = 1 - \left({[HHI - {}^{1}/_{n}]} \Big/ {1 - \frac{1}{n}} \right)$$

Where:

$$HHI = \sum_{i=1}^{n} \left({}^{C_i} \Big/ {\sum_{i=1}^{n} C_i} \right)^2$$

div is the complement of the normalized Herfindahl-Hirschman index: as the latter measures market concentration, the complement (one minus the normalized *HHI*) measures diversity. The diversity index for food production is computed exactly in the same way, replacing C by Q. As *HHI* varies between1 / n and 1, div varies between 0 (minimum diversity) and 1 (maximum diversity).

2.2.3 Agricultural value of production

Changes in the production mix of farmers impacts the average value of their production. The amount produced valued at farm-gate prices gives the value of production: v = Q.P, where Q is the production of the commodity and P its farm-gate price. A decomposition of changes in can help determine if farmers have benefited from the changing structure of their production, by isolating the share of the change in

---

[5] For example, it is estimated that 100g of raw wheat are needed to produce 80g of wheat flour. To convert wheat flour to its raw wheat equivalent, wheat flour quantities are multiplied by 1/80%, the reciprocal of the extraction factor (80%).

[6] In this study, we will refer to indiscriminately as consumption, demand or potential consumption.

v that is due to a structural effect such as, for example, a change in the production mix towards higher-priced commodities. This is done by decomposing the growth rate of the average value of production in a price, quantity and structural (or weighting) effect, as described in Annex 1.

2.2.4 Agricultural prices and margins

The deflator of agricultural production measures changes in the average prices in the agricultural sector: defl = V/Q. It is generally presented in the form of an index: indeed, as it aggregates all kinds of products, its direct interpretation in value per quantity unit has little meaning.

Comparing defl to indicators such as the deflator of the Gross Domestic Product (GDP), an economy-wide measure of inflation, provides a gross indication on the evolution of producer margins. Comparing defl to the food Consumer Price Index (food CPI) provides an indication of the evolution of producer margins with respect to those of other actors of the food chain, such as wholesalers, retailers, transporters or importers. For example, a persistently higher inflation in food consumer prices respective to agricultural producer prices is an indication that average margins of farmers are decreasing relative to wholesalers and retailers margins.

2.2.5 Risks

Farmers operate in an uncertain environment and are exposed to a wide array of risks. The impacts of some of these risks, such as natural catastrophes, are to a large extent independent from the nature of the activities of the farm. Similarly, as farmers are generally price-takers, they face an uncertainty in the prices that they will receive for their product. Farmers can to some extent insure themselves against the impact of some of these risks, through the purchase of hedging instruments such as weather derivatives or futures contracts. However, most of these tools are still out of the reach of farmers in developing countries. Instead, farming practices and commodity specialization can and are used by some as a risk management tool. Indeed, the revenue of a farm in monoculture is more exposed to production risks (a pest, for example) and to price risks (if the price of this commodity plunges, so does the farm revenues) than for a multi-output farm which can spread these risks across different commodities. Therefore, the question of the extent to which structural changes in the production mix affect the exposure of farmers to uncertainties and risks on their revenues is a relevant one. The benefits for farmers of a change in production structure towards higher-priced products may be mitigated by a higher exposure to price and/or production-related risks. This means that, when taking into account the probability distribution of yields and farm-gate prices, the expectancy of earnings may in reality be lower than for a production structure composed of lowerpriced but less risky commodities.

Risk is often approximated through a measure of historical variability. In this study, the coefficient of variation[7] will be used to measure variability in quantities (production risk) and average prices (price risks). We will also provide a measure of the exposure to price risks, based on a decomposition of the variance in average prices. Refer to Annex 2 for details on this decomposition.

The data sources on which these indicators are based and the different operations that had to be done to standardize and fill data gaps are presented in the remainder of this section.

2.2 Food Balance Sheets

A Food Balance Sheet (FBS) presents a comprehensive picture of a country's food supply and utilization during a specified reference period, a calendar year in the case of FAO's FBS data. The FBS shows for each food item (each primary commodity) the availability for human consumption that corresponds to the sources of supply and its utilization (FAOSTAT, 2015). FBS bring together the larger part of the food and agricultural data in each country, as it compiles country information on production, trade and utilization produced at national level. It is therefore a derived statistics and its statistical reliability depends on the accuracy and quality of the underlying data produced by the countries, which is known to be highly variable. In fact, the food available for human consumption (C) is often not measured in the FBS but calculated as a residual. Knowing that there are many gaps particularly in the statistics of utilization for non-food purposes, such as feed, seed and manufacture, as well as in those of farm, commercial and even government stocks, C has to be used with caution. In spite of all these imperfections, FAO's FBS are one of the few database (if not the only one) that compiles annual data for such a large set of countries with more than 50 years of history. Moreover, these imperfections can be partly mitigated by considering the trends and not the absolute values, as done in this study. This is possible thanks to the availability of long time-series (the FBS data in FAOSTAT starts in 1961) and the full coverage of West African countries. Furthermore, this study focuses on the analysis of regional trends, limiting country comparisons that may be hampered by differences in the way the data is compiled.

[7] The coefficient of variation is defined as the standard deviation divided by the mean of the distribution.

2.3 Agricultural producer prices

FAO's agricultural producer price data set is the other source of information used in this study. It provides data on farm-gate prices for more than 130 countries and 200 commodities. Its level of commodity detail, country coverage and data history[8] makes it a unique source of information for the investigation of long-term trends in producer prices. Information on prices is collected annually from the countries, compiled, harmonized and disseminated in July-August of each year. The quality of FAO's producer prices data set depends largely on the quality of the underlying country data.

While a country will generally adequately report data for its major commodities, data availability and quality is lower for minor commodities, or for highly volatile and seasonal items such as fruits and vegetables. Adding noise to the data is the uneven adherence of the reported prices to the farm-gate concept: while some countries report the price of the commodities when they leave the farm, others provide the price at the first point of sale, at wholesale markets or even at retail stores or markets. African countries in particular tend to report wholesale or retail prices, especially for fruits and vegetables.

Focusing on the trends instead of the absolute values cancels out some of these biases, to the extent that these do not vary in time and that the series are exempt from breaks.

2.4 Matching categories of the food balance sheets and agricultural producer price datasets

To compute the value of production, producer prices have to be available for each of the items produced. The commodity classifications used for the FBS and the producer prices differ slightly: the former is a hybrid classification that incorporates most of the raw commodities (for example, wheat and wheat products) but also some processed items (butter, sweeteners, olive oil, etc.). The producer price dataset uses a classification solely based on raw commodities (milk, sugar cane, olives etc.). A procedure to associate the appropriate price to the corresponding item of the FBS data set has therefore been implemented:

- If an item is common to the two datasets, the price of the item is taken and attributed to the corresponding item of the FBS classification without any further modification (except unit transformations);
- If an item of the FBS classification is more highly aggregated than in the price classification, the prices of the corresponding items of the latter are averaged and applied to the FBS item. For example, the price of the item sesame seed and sesame seed oil of the FBS classification is equal to the unweighted average of the price of sesame seed and sesame seed oil, which constitute two different items in the price classification;
- In the opposite case where the item of the price classification corresponds to more than one item of the FBS classification, the price of the former is applied to all the items of the latter. For example, the price of the single item oranges and mandarins from the price list is applied individually to oranges and mandarins, that form two distinct commodities in the FBS list;
- The price of processed products such as butter or vegetable oils is computed based on the price of the raw commodity from which they originate[9], by multiplying the price of the processed item by the reciprocal of the extraction rate. For example, if the price of one litre of cow milk in Mauritania is 0.392 USD (FAOSTAT, 2015) and if the extraction rate of butter to cow milk is 4.2% (4.2g of butter can be produced from 100g of cow milk), the price of one kg of butter will be equal to 0.392*(1/(4.2%))=9.3 USD. This procedure assumes that the price of a processed product is only a function of the price of the raw commodity from which it is produced and implicitly considers that transformation margins are equal to zero. This necessary assumption undermines the plausibility of the absolute prices constructed in this way. However, given the relative stability of transformation margins over time, the analysis of trends may adequately reflect changes in producer prices. This matching procedure and transformation in prices can be summarized in correspondence matrices, an example of which is given in Annex 3.

2.5 Estimation of missing data

The data reported on producer prices is generally incomplete, especially for minor or highly seasonal or volatile items. To ensure that the value of production is computed for all countries over the same set of commodities, missing item prices are estimated. The method is straightforward:

- The missing price for an item is estimated by the average price of the item group to which it belongs. For example, if the price of maize is missing, it is estimated by the average price of cereals;
- If the data is too scarce to compute item group averages, the missing price is imputed by the average regional price for the same item. For example, the missing price for maize is estimated using the average maize price in the West Africa region.

---

[8] The data goes back to 1961, although due to a temporary halt in the FAO's data collection activities the data series before and after 1991 have been split into two not necessarily compatible datasets. This article uses only the most recent dataset, from 1991 onwards.

[9] In this classification a processed product originates from only one raw commodity, which simplifies the computations. The computation procedure as described in Annex 3 can in theory accommodate products based on several raw commodities.

This Section has presented the information sources, the main transformations operated to the raw data and defined the different indicators used in this study. We will now analyze and compare the trends in food diets and production in West Africa.

3. Have West African farmers adjusted their production to changing diets?

3.1. Food diets are getting richer

Statistical evidence suggests that West African diets tend to converge towards "western" standards, characterized by a larger share of animal products, fats and sugars in food consumption. Urbanization and economic growth, which contribute to the emergence of a new middle class, are among the main drivers of this structural change (Vincent C., 2015).

The data compiled here for West Africa shows that the share of items such as sugars and vegetable fats in the per capita kilocalories available has risen from an average of 3.7% in 1961-1979 to 5.0% in 2000-2011 for sugars and from 12.8% to 14.6% for vegetable fats and oil crops. In contrast, the share of traditional food staples has declined: for roots and tubers, for example, it has fallen from 17.1% to 14.3%. For other food categories, the changes are less significant: cereals still represent more than half of the calories available, with little change compared to the 1961-1979 average. The weight of meat and animal products has also remained stable over the period of analysis, just under 8.0%. The data also confirms that overall food supply per capita (excluding alcoholic beverages) has increased at a steady pace, from an average of 1957 in 1961-1979 calories per day to 2434 for the period 2000-2011. Changes in food consumption habits become more apparent when looking within the aggregated categories. For instance, the share of wheat and rice relative to traditional cereal crops such as sorghum and millet has increased significantly (Figure 2). The rise in the share of rice is a common and defining characteristic of the evolution in West African food diets. Several studies, such as Me-Nsope and Staatz (2013), have indicated that there is a positive correlation between on the one hand income per capita and urbanization rates, and on the other hand the share of rice in food diets. For meat and animal products, the share of poultry meat has increased markedly (from 2% in 1961-1979 to 6% in 2000-2011). It has also been the case, but to a lesser extent, of eggs, pork meat and pelagic fish. In contrast, bovine and mutton meat have lost ground (from 14% to 10% for beef and from 7% to 6% for mutton). Milk (excluding butter) remains by far the largest item consumed within this category, with a stable share in diets oscillating around 35%. Among the excitants, cocoa has gained significant ground to the expense of coffee and, to a lower extent, tea: its share in the consumption of excitants averaged 68% over the period 2000-2011, against 40% in 1961-1979.

One of the characteristics of the change in food diets is their greater calorific content: the average number of kilocalories by kilogram of food available for consumption has increased from just above 1860 kcal/kg in 1961 to around 2000 kcal/kg in the recent years, after reaching a peak during the mid-80s at 2050 kcal/kg (Figure 3). This is the result of a greater reliance on commodities with a higher calorific content, a change that occurred both within item categories (wheat and rice, for example, have a higher calorific content than millet and sorghum) and between them (higher proportion of fats and sugars in food diets compared to other items, for example). Cereals and oils and oil crops have seen their energetic content rise at a steady and sustained pace: rice and wheat drove the increase for cereals; for oil crops, the rise is due to the higher availability of calorie-rich soybeans and derived products such as soybean oil. Conversely, the average calorie content for meat and animal products has slightly decreased, reflecting the increase in share of less calorie-rich poultry meat and products.

This article will now investigate if the changing composition of food consumption evidenced above has been accompanied by an increase in the diversity of food diets and agricultural production, or if new products have simply replaced old ones.

3.2. More diverse food diets

Recent analysis of consumption behaviors of households or individuals in West Africa have concluded that food diets are becoming more diverse, with significant intra-category substitutions, in a broad context of rising demand for items with higher calorific, fat and sugar content. It has become apparent that lifestyle changes that accompany increases in income are correlated with diversification in food types and with the consumption of products with high added value, animal products and fruits (Bricas et al., 2015). However, most of these studies have concentrated on urban and peri-urban dwellings, leaving out rural households, which, in spite of their declining weight, still represent around three quarters of the population in West Africa[10]. Can the results for urban or peri-urban households be extrapolated to the population as a whole? The analysis of FBS data, which includes by construction all food items produced domestically or imported in the country, can help answer this question.

---

The measure of diversity used in this study is the complement of the normalized Herfindahl-Hirschman index, the latter being widely used to measure market concentration (refer to the second section of this article for details). According to this indicator, the diversity in the food available for consumption has increased over the last 50 years for a large majority of Western African countries (Figure 4). This measure also shows that the dispersion among these countries with respect to food diversity has decreased. This indicates the existence of a common trend underpinning the change in food diets in the region, characterized by a re-balancing of the consumption in cereals (with wheat and rice increasing in share) and meat (white meat in complement to red meat). Interestingly, the group of countries that was significantly behind in terms of food diversity (Niger, Liberia, Sierra Leone and Benin) has progressively caught-up with the rest of the countries. This is a sign of improving production conditions and/or an increased capacity of these countries to satisfy food demand through imports.

Contrary to food diets, the diversity of agricultural production has not increased (Figure 4). The diversity indicator also shows that the dispersion among Western African countries with respect to production diversity has widened. This may reflect different food and agricultural strategies, with some countries preferring to widen their production scope while others tend to specialize on a reduced number of crops. The dispersion among countries also highlights their different endowments and capacity to import. The fall in the production diversity of countries such as Nigeria and Sierra Leone, for example, reflects the tendency of commodity-rich countries to neglect domestic agricultural production, a phenomenon that has been exacerbated by the commodity super-cycle of the 2000s[11]. Additionally, the increased demand for cocoa has clearly been one of the drivers of the concentration of agricultural production in the two main cocoa-producing countries of the region, Ivory Coast and Ghana. These findings suggest that farmers in West African countries have responded in different ways to changing and more diversified diets.

To understand if domestic production is now better able to satisfy food demand or, on the contrary, if it has lost ground with respect to foreign providers, food demand has to be compared with production. This is done below.

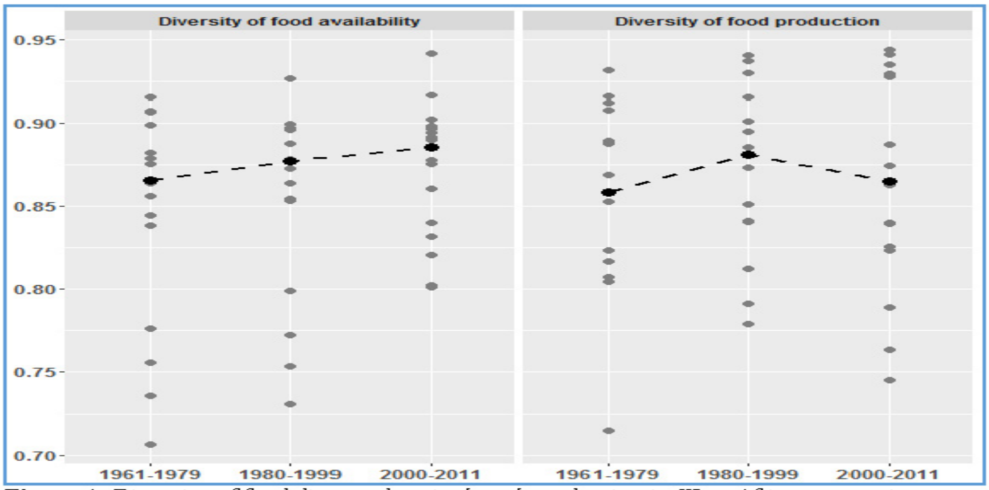

Figure 4: *Diversity of food diets and agricultural production in West African countries*
Source: FAOSTAT 2015, author's calculations.
Note: the dots correspond to individual country data. The median is represented by the connected dots in black.

3.3. Food demand versus. food production

Overall, production-to-demand ratios have not improved nor deteriorated significantly (Figure 5). In a context of increasing food demand and changing food diets, this suggests that producers have scaled-up their production for emerging commodities and/or generated additional surpluses for their major commodities. A stable ratio may be the reflection of an increase in the production of commodities that are largely exported and not meant to be sold on the domestic market (such as cocoa) and not necessarily an indicator of self-sufficiency. A commodity-level analysis is better adapted to draw conclusions that are more meaningful on the capacity of domestic producers to satisfy internal demand. For cereals, the ratio of production to demand has remained stable slightly above one, meaning that West Africa produces enough of the commodity to satisfy internal demand.

Looking at this ratio for the different cereal crops reveals that output of both traditional and emerging crops has increased in volume, but the demand for the latter has outpaced its output. For example, the production of rice has doubled since the beginning of the 1960s to reach 20kg or above per capita in the region but is still insufficient to cover the demand, which has tripled to reach more than 30 kg per capita in 2013. Regarding wheat, because agro-climatic conditions in West Africa are not favorable to the production of this cereal, the increase in demand has directly translated into a higher import dependency. On the contrary, surpluses of maize, a traditional crop, have significantly increased, generating additional export capacity.The statistical evidence provided in this section confirms a structural change in food demand: it has increased in quantity, is more energy-intensive and diverse. In response to these changing preferences, the agricultural sector has partially adjusted its production, by scaling-up its output for emerging food staples such as rice but also by increasing its output for certain traditional commodities, some of them with a good export potential (cacao, maize, sorghum, for example). This has generated revenues that can in turn be used by countries to import the commodities for which they are in greater deficit, such as wheat and, to a lesser extent, rice and certain processed products such as sugar. The next section will delve more deeply into the economic implications for the agricultural sector of the change in the composition of its production mix: has it translated into a higher average remuneration for its products? Is the agricultural sector more exposed now to production and price shocks?

[11] The 2000s commodities boom or the commodities super cycle was the rise in many physical commodity prices (such as those of food stuffs, oil, metals, chemicals, fuels and the like) which occurred during the decade of the 2000s (2000–2009), following the Great Commodities Depression of the 1980s and 1990s. The boom was largely due to the rising demand from emerging markets such as the BRICS countries, as well as the result of concerns over long-term supply availability.

4. Changing food diets and production patterns: economic implications for farmers

4.1. Agricultural value of production: a price-driven increase

The value of agricultural production has risen relatively steadily in West Africa since the beginning of the 1990s, at an average annual rate of 8.5% (Figure 7). This increase has been determined largely by fluctuations in prices (for details on the decomposition procedure, see Annex 1). Fluctuations in quantities have had a smaller influence on value of production, although it has become more significant during the past 10 years. The effect of structural changes (structural or weighting effect due to a change in the production mix) appears minor compared to price and quantity effects. Weighting effects reflect longer-term changes in the specialization of production which, when looked at on an annual basis, are necessarily lower than those resulting from more volatile components such as price and quantities. That said, the average structural effect over the period of analysis, at +0.04%, is negligible compared to the average price and quantity effects (respectively +5.1% and +3.4%). This suggests that the product-specialization of the agricultural sector in West Africa has not been made towards products with a structurally higher remuneration potential. While this is true on average for West Africa, it is not necessarily the case for all individual countries within this region. Indeed, section 3 has revealed different specialization patterns in West Africa, with some countries that diversified their production to satisfy changing consumer preferences while some others tended to specialize into a smaller number of commodities with a higher revenue potential (cacao, etc.).

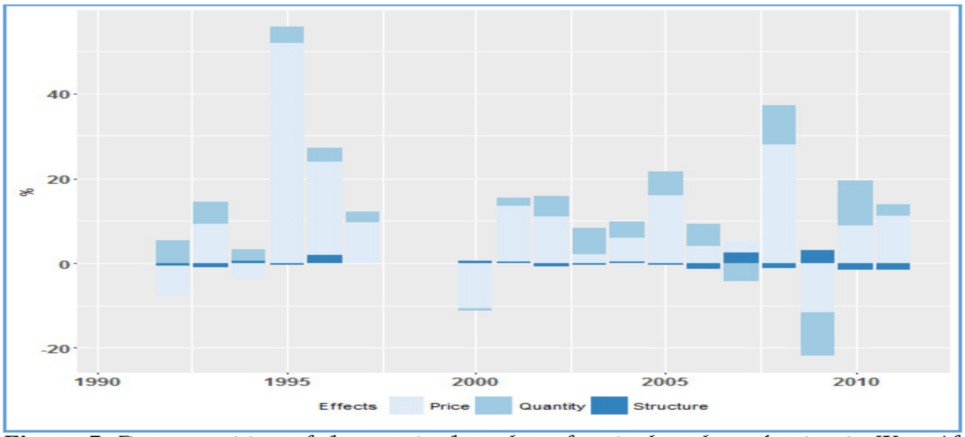

Figure 7: *Decomposition of changes in the value of agricultural production in West Africa.*
Source: FAOSTAT 2015, author's calculations.
Note: 1998 and 1999 have been omitted because of the distortion created by the devaluation of the Naira in 1998.

4.2. Agricultural prices and margins in West Africa have not evolved to the benefit of farmers

Put aside the correction in prices after the end of the 2007-2008 food price crises[12], average agricultural prices in West Africa rose at a steady and sustained pace: the deflator of agricultural production has been multiplied by 2.4 from 2000 to 2012. This does not necessarily mean that producer margins have risen, because the price of agricultural inputs has probably risen in parallel. In fact, taking the GDP deflator as a proxy for the price of inputs, no clear-cut conclusion can be made on the evolution in agricultural margins: the two deflators have evolved at similar rates from 2000 to 2009 (Figure 8). Since then, the GDP deflator has been increasing faster, pointing to deterioration in producer margins. More data points are needed to conclude if this trend is persistent, transitory or if it is due to a statistical artefact. The fact that food consumer prices have increased at a higher pace than agricultural producer prices indicates that farmers have probably seen their margins reduced to the expense of intermediaries (wholesalers and retailers). The widening gap between consumer and producer prices may also reflect structural changes in West African food markets, echoing changes in food diets: food chains are becoming wider and more sophisticated with the emergence of new actors in the agro-industrial complex, lessening the link and widening the gap between prices at both ends of the chain.

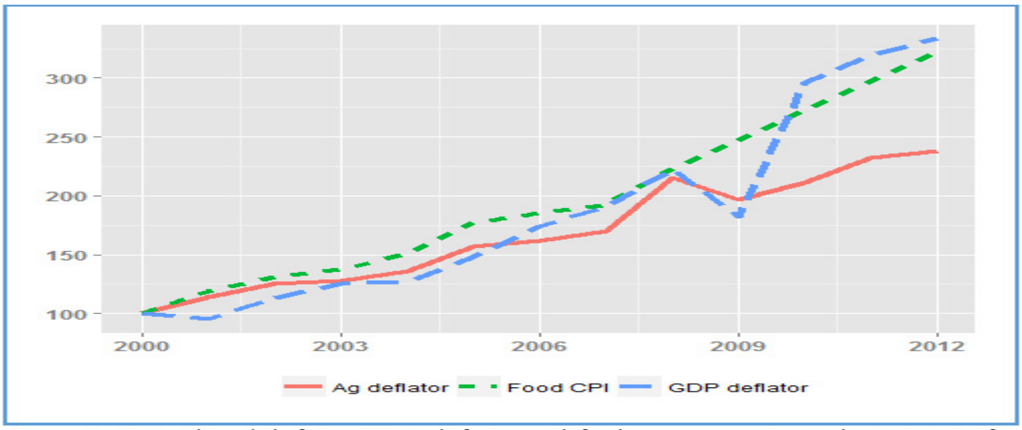

Figure 8: *Agricultural deflator, GDP deflator and food consumer price index in West Afric (100=2000)*
Source: FAOSTAT 2015, World Development Indicators (The World Bank), author's calculations.

The level of uncertainty in the price paid to farmers and, by consequence, in their revenues is a key determinant of production decisions as well as, to some extent, private investment in agriculture. We will know delve into the analysis of the risks to which West African agriculture is exposed, especially price-related risks.

4.3. Decreasing price variability but higher exposure to price-risks

Risks of different nature are faced by farmers: uncertainties affecting yields are mainly exogenous, as most of them are climate-related. Yet, as crops and agricultural activities are diversely exposed to climate-related risks, the composition of the farmer's agricultural production and, by extension, the production specialization of an entire country or region has an impact on the overall exposure to production risks.

[12] World food prices increased dramatically in 2007 and the 1st and 2nd quarter of 2008 creating a global crisis and causing political and economical instability and social unrest in both poor and developed nations. This series of events is usually referred to as the 2007-2008 food price crises.

Farming practices also have a role: for a given crop, specific varieties may be more tolerant or resistant to droughts; cultural practices such as crop rotations may improve water use efficiency[13]; an appropriate use of inputs may also mitigate the impact on yields of adverse climate-related events. An agricultural sector highly specialized in the production of a small number of commodities, with a low level of infrastructure and input use will be highly dependent on weather conditions and therefore over-exposed to adverse climate-related events: yields, production and revenues will, as result, be more volatile and uncertain.

Another class of risks is that affecting the farmer's selling prices. When considering individual crops or agricultural activities, these risks can be considered as largely independent from the farmer's practices: except in exceptional cases, farmers are price-takers and the price received reflects local, national or international market conditions. The price trends, seasonality and volatility are highly dependent on the nature of agricultural products: perishable and non-storable commodities tend to be more volatile than non-perishable and storable ones. The price of some commodities such as rice, wheat or maize is mainly determined on international markets while for others prices mainly reflect local market conditions: the price variability (or uncertainty) of different groups of agricultural commodities tends to some degree to be independent from one another. As a result, the overall price risk faced by a farmer is to some extent dependant on the set of commodities that are produced. His exposure to price risks can be mitigated by choosing commodities with less correlated prices, much similarly to a financial investor who would construct a portfolio of stocks from companies with different activities in order to diversify its risks. By extension, the overall exposure to price risks of a country or region's agricultural sector is dependent on its commodity specialization. The contribution of the product specialization to price risks, defined mathematically in Annex 2, measures the exposure of farmers to these risks.

The results, illustrated by Figure 9, indicate that the variability in price has been declining since the beginning of the 90s: the coefficient of variation has declined from close to 120% at the beginning of the period to just under 80% in 2012. The 2007-2008 food price crises, which was characterized by surging and volatile prices on international agricultural markets, have little impacted agricultural prices in West Africa: the price variability did increase during this period, but by a limited amount (the coefficient of variation rose to 93%, slightly above the pre-crisis levels).

This may be explained by the composition of food production in West Africa: the commodities that saw their price increase the most, wheat and soybeans, are not the region's main crops. Furthermore, as most of the agricultural output in West Africa is either consumed by the farmers themselves or destined to local markets, prices of agricultural commodities respond rather to local market fundamentals than to international market shocks, at least on the short to medium-term. If the impact of the 2007-2008 food crises on agricultural producer price variability has been mild in West Africa, the same is not necessarily true for consumers: their diets, especially of those living in urban centers, relies more heavily on imported commodities and therefore make them more vulnerable to international price shocks. That said, recent econometric evidence suggest that the overall impact on food consumer prices in the region was limited: for example, Cachia (2014) estimates that only 10% of the initial shock in international commodity prices is transmitted to food prices after 4 months, 20% after 8 months.

Figure 9 also indicates that the decrease in variability of average agricultural prices has not been accompanied by a reduction in the exposure to price risks, quite the contrary. The contribution of the commodity production structure to the average price variability, what we named exposure to price risks, has in fact been increasing since the beginning of the 90s (Figure 9, right-hand side graph).

This means that a shock in commodity prices would probably have a higher impact on average prices now compared to the beginning of the 90s: farmers are more exposed to price shocks, either positive or negative. As the final formula of Annex 2 clearly shows, a greater exposure to price shocks can be the result of two effects, which can potentially be combined:

- A structural increase in the correlation between commodity prices. Theoretical and empirical evidence suggests that the integration of commodity markets and the harmonization of farming practices have contributed to increase the correlation between commodity markets. For example, it has been demonstrated that the emergence of bio-fuels has not only increased the integration between energy and agricultural markets but also among crops that are used to produce bio-diesel (soy, oilseeds, etc.) and ethanol (wheat, corn, sugar crops, etc.). This effect may be significant in parts of Europe, Latin and North America, but less in West Africa where the quantities destined to the biofuel market are marginal;
- The second potential effect is an increased specialization in the production of crops with a higher price correlation. In West Africa, the higher share in production of cereals such as rice, maize and wheat and crops such as soybeans has probably contributed to increase the overall exposure to price risks: these commodities are more integrated to international and regional markets than traditional cereals and their prices are known to be highly correlated. For detailed empirical evidence on the co-movements between major agricultural commodities, see for example de Nicola F. et al. (2014).

[13] Crop rotations improve the soil's physical characteristics and structure, reducing or eliminating the necessity to till or plough. The hydrologic supply and the exploration capacity of the plants are therefore improved.

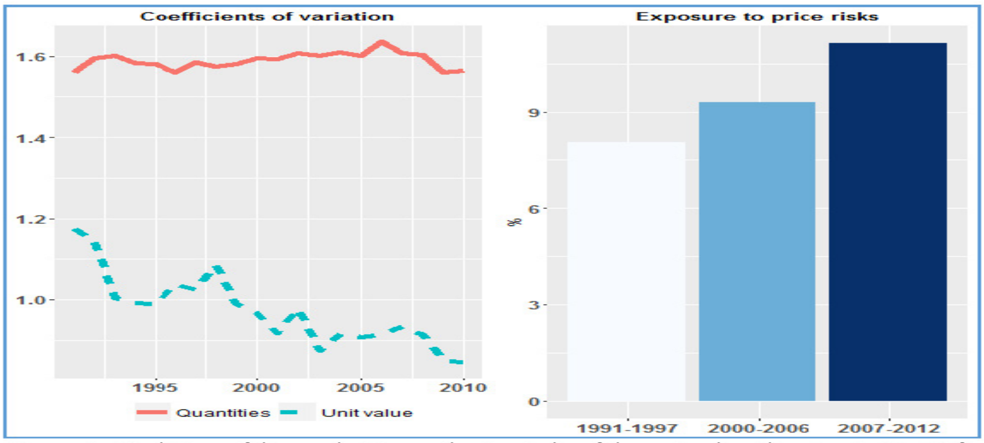

Figure 9: *Evolution of the production and price risks of the agricultural sector in West Africa.*
Source: FAOSTAT 2015, author's calculations.
Note: on the right-hand side figure, data for 1998 and 1999 has been omitted because of the distortion created by the strong devaluation of the Naira, the Nigerian currency, in 1998.

5. Conclusion

This article tried to brush a global picture of the trends in food demand and agricultural production in West Africa. It has first been shown that food diets are getting richer and more diverse, in line with structural socio-economic drivers such as urbanization and increasing income per capita.

At the same time, agricultural production has also evolved: it has responded to changing preferences of West African consumers by scaling-up its output of commodities such as rice, maize and certain animal products such as poultry. This increase in production has failed to match the corresponding rise in demand because yields in West Africa have only started to improve substantially in the past few years. For example, yields for rice (paddy) have been stable around 1.5 tons per hectare during the 1990s and the beginning of the 2000s. They have just recently started to improve to reach levels slightly above of 2.0 tons. In a context of a surging population, a rapid and significant improvement in cereal yields is a pre-requisite to the improvement of food security and a reduction in poverty rates in the region.

Agricultural production has also specialized in commodities that are in greater demand both domestically and abroad, such as cocoa, soybeans or maize. These new specialization patterns have economic repercussions for farmers: they received on average higher prices for their products but prices in the economy rose as well, sometimes faster, such as food prices paid by consumers. This suggests that margins in the agricultural sector have lost ground with respect to other actors of the chain, a structural trend given the higher sophistication and widening of the food chains. New production patterns and higher integration of agricultural commodity markets have also contributed to increase the exposition of West African agriculture to price shocks, a factor that has not yet been a source of concern given the decreasing trend in price variability in West Africa, only mildly affected by events such as the 2007-2008 food crises.

More work and statistics are needed to understand if the specialization of West African farmers has resulted in higher net returns for farmers. High-value or cash crops are also generally grown in input-intensive systems, with high costs. There is a statistical gap that needs to be filled to understand better production costs and returns of agricultural production, especially in West Africa where nation-wide statistically representative data is scarce. Further investigation is also needed to better identify production changes and substitutions within commodity groups, extending the analysis to the agro-food industry in order to see if food production in West Africa is getting higher up in the value chain. Finally, a more formal and comprehensive analysis of the commodity linkages is necessary to better understand the risks to which farmers are exposed, a phenomenon that is often overlooked but which has great implications on the vulnerability of farmers and their households.

ANNEXES

1. Decomposition of the growth rate of agricultural value of production

The change in the aggregate value of production can be decomposed intro three components: a price effect, a quantity effect and a structural (or weighting) effect. The latter measures the extent to which changes in values are the result of a modification in the commodity mix. This annex describes one possible method to perform this decomposition.

The value of production for a given commodity is equal to its farm-gate price times the quantities produced: $v_{i,t} = p_{i,t}q_{i,t}$, where i denotes the commodity and t the time period. The value of production for a bundle of commodities is therefore: $v_t = \sum_{i=1}^{n} p_{i,t}q_{i,t}$, where n is the fixed number of commodities produced[14].

We start by defining two variables:

- The average farm-gate unit value of the basket of commodities produced : $\bar{p}_t = \frac{\sum p_{i,t}q_{i,t}}{\sum q_{i,t}}$; and
- The average quantities produced: $\bar{q}_t = \frac{1}{n}\sum q_{i,t}$

v_t is therefore also equal to: $v_t = \bar{p}_t n \bar{q}_t$

As v_t is a strictly positive variable, we can take its natural logarithm:

$\ln(v_t) = \ln(\bar{p}_t) + \ln(n) + \ln(\bar{q}_t)$

$\Delta\ln(v_t) = \Delta\ln(\bar{p}_t) + \Delta\ln(\bar{q}_t)$, where $\Delta x_t = x_t - x_{t-1}$ is the first-difference operator.

For "small" enough changes in $\bar{p}_t$ and $\bar{q}_t$: $\dot{v}_t \cong \dot{\bar{p}}_t + \dot{\bar{q}}_t$, where the dotted variables indicate simple growth rates. We will now determine $\dot{\bar{p}}_t$ and $\dot{\bar{q}}_t$, starting with the former:

$$\bar{p}_t = \frac{\sum p_{i,t}q_{i,t}}{\sum q_{i,t}} = \sum \frac{q_{i,t}}{\sum q_{i,t}} p_{i,t} = \sum \theta_{i,t}p_{i,t}$$

$$\Delta\bar{p}_t = \sum (\theta_{i,t}p_{i,t} - \theta_{i,t-1}p_{i,t-1})$$

$$\Delta\bar{p}_t = \sum \Delta\theta_{i,t}p_{i,t} + \sum \theta_{i,t-1}p_{i,t} - \sum \theta_{i,t-1}p_{i,t-1}$$

$$\Delta\bar{p}_t = \sum \Delta\theta_{i,t}p_{i,t} + \sum \theta_{i,t-1}(p_{i,t} - p_{i,t-1})$$

$$\dot{\bar{p}}_t = \frac{\Delta\bar{p}_t}{\bar{p}_{t-1}} = \underbrace{\sum \Delta\theta_{i,t}\frac{p_{i,t}}{\bar{p}_{t-1}}}_{ES} + \underbrace{\sum \theta_{i,t-1}\left(\frac{\Delta p_{i,t}}{\bar{p}_{t-1}}\right)}_{EP}$$

$\dot{\bar{p}}_t$ is composed of two effects:

- ES, which measures the effect on the change in average prices of changes in the commodity shares ($\Delta\theta_{i,t}$). For example, a rise in the production share ($\Delta\theta_{i,t} > 0$) of commodities with higher than average prices ($p_{i,t} > \bar{p}_{t-1}$) will contribute to increase the growth rate in average prices beyond the simple share increase ($\Delta\theta_{i,t}\frac{p_{i,t}}{\bar{p}_{t-1}} > 1$). ES is therefore said to measure a structural or weighting effect; and
- EP, which captures the effect on the change in average prices of commodity-specific price variations (price effect).

Turning to $\dot{\bar{q}}_t$:

$$\bar{q}_t = \frac{1}{n}\sum q_{i,t}$$

$$\dot{\bar{q}}_t = \frac{\frac{1}{n}\Sigma(q_{i,t} - q_{i,t-1})}{\frac{1}{n}\Sigma q_{i,t-1}}$$

[14] A fixed n is assumed here for simplicity, but this decomposition method can also be applied to a situation in which the number of commodities $n(t)$ varies in time.

$$\dot{\bar{q}}_t = \frac{\sum \Delta q_{i,t}}{\sum q_{i,t-1}}$$

$$\dot{\bar{q}}_t = \sum \frac{q_{i,t-1}}{\sum q_{i,t-1}} \frac{\Delta q_{i,t}}{q_{i,t-1}}$$

$$\dot{\bar{q}}_t = \sum \theta_{i,t-1} \dot{q}_{i,t}$$

$\dot{\bar{q}}_t$ is equal to the sum of the commodity-specific quantity changes weighted by their respective quantity shares (quantity effect).

It follows from the above that the growth rate in the value of produced for the set of commodity produced is equal to the sum of a price effect (EP), a quantity effect (EQ) and a weighting or structural effect (ES):

$$\dot{v}_t \cong \underbrace{\sum \Delta\theta_{i,t} \frac{p_{i,t}}{\bar{p}_{t-1}}}_{ES} + \underbrace{\sum \theta_{i,t-1} \left(\frac{\Delta p_{i,t}}{\bar{p}_{t-1}}\right)}_{EP} + \underbrace{\sum \theta_{i,t-1} \dot{q}_{i,t}}_{EQ}$$

2. Decomposition of the variance of average agricultural prices

The variance of $(\bar{p}_t)_{t=1,\dots,T}$, $V(\bar{p}_t)$[15], measures the variability in time of average agricultural prices and can be considered as a proxy for the apparent price risk faced by the agricultural sector.

Using the notations of Annex 1, we can write: $V(\bar{p}_t) = V(\sum \theta_{i,t} p_{i,t})$, where $\theta_{i,t}$ is the share of commodity i in the total quantity produced at period t. By decomposition of the variance: $V(\bar{p}_t) = \sum_i V(\theta_{i,t} p_{i,t}) + \sum_{\substack{i,j \\ i \neq j}} COV(\theta_{i,t} p_{i,t}, \theta_{j,t} p_{j,t})$, where COV is the covariance operator[16].

We now decide to compute the variance over several time intervals $T_1, \dots, T_h, \dots T_H$, such that $\bigcup_{h=1}^{H} T_h = [1, \dots, T]$ and, more importantly, $\theta_{i,t} \cong \theta_{i,T_h}$ $\forall h = 1, \dots, H$. This assumption states that quantity shares are stable within the different time intervals T_h (their variance is 0) and that they can therefore be considered as exogenous and not as random variables.

It follows from this assumption and from the linearity of the variance and covariance that:

$$V_{T_h}(\bar{p}_t) = \underbrace{\sum_i \theta_{i,T_h}^2 V_{T_h}(p_{i,t})}_{EP} + \underbrace{\sum_{\substack{i,j \\ i \neq j}} \theta_{i,T_h} \theta_{j,T_h} COV_{T_h}(p_{i,t}, p_{j,t})}_{ES}$$

ES measures the effect of the composition of agricultural production on the apparent average price risk faced by farmers. In other words, it measures the exposure of the agricultural sector to price risks. EP measures the effect of the price variability of individual commodities on the variability in average prices of the bundle of commodities produced by the agricultural sector.

---

[15] The variance of a random variable is a statistical measure of its dispersion from the mean. The unbiased estimator $V(\bar{p}_t)$ is given by $v(\bar{p}_t) = \frac{1}{T-1} \sum_{t=1}^{T} (\bar{p}_t - \bar{\bar{p}})^2$, where $\bar{\bar{p}} = \frac{1}{T} \sum_{t=1}^{T} \bar{p}_t$.

[16] The covariance between two random variables $(X_t)_{t=1,\dots,T}$ and $(Y_t)_{t=1,\dots,T}$ is a statistical measure of the link between these two variables. The unbiased estimator of the covariance is given by: $cov(x_t, y_t) = \frac{1}{T-1} \sum_{t=1}^{T} (x_t - \bar{x}_t)(y_t - \bar{y}_t)$, where $\bar{x}_t$ and $\bar{y}_t$ are the means of the distributions.

3. Correspondence matrices: the example of Cap-Verde

Below is provided an extract of the correspondence matrix of Cap-Verde used to match the products of the producer price classification to the FBS classification and estimate the price of all the items of the latter. It has to be read in the following way:

- Regarding wheat, there is a one-to-one correspondence between the items of the price list ("Wheat") and the item of the FBS list ("Wheat and wheat products"): the price of both items will therefore be equal ;
- Fonio, absent of the FBS list, is added to the item "Cereals, Other": the price of this item will therefore include the price of fonio, as well as other cereals not present in the FBS list;
- Rice is expressed in two different units: in its raw form in the price list ("Rice, paddy") and in milled equivalent in the FBS classification. The coefficient in the corresponding cell is the technical conversion factor: 1.5kg of paddy rice is needed to produce 1Kg of rice in milled equivalent. For a given quantity, the price of the rice in milled equivalent will therefore be equal to the price of the paddy rice times 1.5.
- ... And so on.

As technical conversion factors vary from country to country, the correspondence matrices are country specific.

Table 1 - Correspondence matrix between the Food Balance Sheets classification (FBS) and the producer price classification (PP)

PP \ FBS	Wheat and products	Cereals, Other	Sugar cane	Sugar non-centr.	Sugar (raw)	Groundnuts (shelled)	Butter, ghee	Rice (milled)

Estimating flows of ancillary biomass resources associated to permanent and temporary crops production and their uses

A. Femia | Istat | Rome | Italy
C. Manzi | Istat | Rome | Italy

DOI: 10.1481/icasVII.2016.c19b

ABSTRACT

The growing economic and environmental relevance of biological residues from cultivation (non-edible parts of vegetables, stalks, pruning residues, end-of-life trees…) calls for greater attention to their measurement. Biological residues from cultivation are often gathered and composted, or used as fodder, or for energy production. The remaining quantities are left on the soil or burnt in the open, or landfilled. Different consequences in terms of environmental pressures and economic results arise from different management ways of these residues. It is therefore of great interest for research and policy use, to gain better knowledge on the amounts of biomass involved, as well as of their current distribution between the various possible destinations.
We first introduce the notion of "biological *residues* from cultivation" and clarify its relation to the definitions of "products" and "residuals" in the general SEEA Central Framework physical flow accounts context (SEEA Central Framework 2012, ch. 3), as well as to that of "unused materials" in Economy-wide material flow accounts (Eurostat, 2001; SEEA-CF, 3.6.6). "Residues" covers a broader set of materials than "residuals", which in turn is broader than "unused" (as for biological residues of cultivation).
Not much official statistics is available on biological residues from cultivation. In Italy, estimates were made in the past by using agronomic information. Istat's structural surveys on agricultural holdings, carried out in 2013 (focussing on permanent crops) and 2014, introduced questions for the first time on these flows. In the paper we show the results of these data collection exercises and conclude that, in order to fill this information gap, official statistics needs not embark on regularly surveys but only provide some benchmark as for the supply of residues, while for the management and uses, the phenomenon should be considered in structural surveys and in exploiting administrative sources. SEEA AFF could also play a role in this respect, though maintaining its focus on main crops, by including an account on the connected ancillary biomass flows.

Keywords: SEEA-CF, SEEA AFF, crop residues, biological residuals, unused biomass.

PAPER

1. Introduction

Unused residues stemming from crop, timber, fish and other primary biomass production processes make up for a significant part of the total biomass produced in Agriculture, Forestry and Fisheries activities: 20% of it, i.e. 5.5 billion tons, according to data responding to the Economy-wide material flow accounting (Eurostat 2001) definition of "unused" available on www.materialflows.net. The wise management of these residues, though probably not the key to solving any specific problem, may help reach some sustainable development (SD) goals, many of which rely on an environmentally sound agricultural sector. Indeed, crop residues may be left on the soil; burnt; collected and used - in the same holding or in other establishments – as inputs in the production of other goods (e.g. straw used as fodder; non-edible parts of plants fed into a digester or a composter); collected and put into a landfill. The way they are dealt with has consequences in terms of soils health, greenhouse gas emissions, fertilisers consumption, waste management, energy production, agricultural income. Depending on the way these residues are managed, the nutrients contained in them may be squandered or returned to the soil (directly, or as manure, or after composting). From a policy concepts and programs point of view, this issue is relevant for the *circular economy* (EU, http://ec.europa.eu/environment/circular-economy/index_en.htm), for *sustainable production and consumption* (UNEP - http://www.unep.org/rio20/About/SustainableConsumptionandProduction/tabid/102187/Default.aspx;EU,http://ec.europa.eu/environment/eussd/escp_en.htm) and for the green economy and green growth concepts (OECD, http://www.oecd.org/greengrowth/;ESCAP,http://www.unescap.org/our-work/environment-development/green-growth-green-economy; World Bank, https://issuu.com/world.bank.publications/docs/9780821395516).
In the present paper we first discuss the treatment of residues in SEEA physical flow accounts and then describe calculations and results of two complementary data survey and elaboration exercises carried

out in Italy in the context of a collaborative effort between producers of structural statistics on crops and national accountants in charge of environmental satellite accounts. We conclude by pointing out how, according to our experience, official statistics can deal efficiently with crop residues flows measurement, and highlighting the possible role of the System of Economic and Environmental Accounts for Agriculture, Forestry and Fisheries (SEEA AFF) in promoting knowledge on these important materials.

2. Treatment of crop residues in SEEA-CF physical flow accounts

The SEEA for Agriculture, Forestry and Fisheries (SEEA AFF) is the internationally agreed methodological document in support of the SEEA-Central Framework (SEEA-CF) dealing with the application of the latter in the agricultural field (outcome of the XI meeting of the UN Committee of Experts on Environmental-Economic Accounting – UNCEEA, June 2016). This document focuses on the main products of agricultural activities, and leaves to future developments the "important area of research" of "a more complete and consistent articulation of losses, unused biomass, residues, waste, reuse and recycling in relation to biomass" (§ 2.133, SEEA AFF, draft for consideration by the UNCEEA, June 2016). In trying and contributing to these developments, we therefore will refer directly to the SEEA-CF as for the definitions and treatment of these concepts.
The first and most general concept we use here and in the surveys described in the following chapters, however, is used in SEEA-CF (see in particular §3.99) and AFF (see above), but is not defined in there. It is that of crop residues. The way we use the term here, which we think is consistent with the way it is used in SEEA, it designates all the parts of plants different from their main useful product, such as e.g. non-edible parts of vegetables' plants, stalks or wood resulting from pruning, discarded fruits, crops grown but not harvested for whatever reason. These include not only things that respond to the SEEA definition residuals (§3.73), but also to that of products (§3.64), such as e.g. straw that is gathered and sold (or used on own purpose, which is common for holdings having animals) by the producing units.
In the SEEA-CF, like in the System of National Accounts (SNA), biological resources are distinguished into cultivated and non-cultivated (SEEA-CF §3.54). Non-cultivated biological resources are not covered at all by the present discussion, which only concerns biological residues from cultivation processes, i.e. stemming from cultivated biological resources. In particular, we do not cover here residues from extraction of non-cultivated biological resources (felling residues of natural forests, discarded catch of wild animals) – called natural resource residuals in SEEA-CF (§3.49).

Cultivated biological resources may be considered in two different ways, corresponding to two different system boundaries. Both are described in the SEEA-CF[1]:

▪ In the most general description of physical flows, coherently with the national accounting concept that cultivated plants are assets within the economy, they are considered as "produced within the economy and hence are not flows from the environment" (§3.47). It is important to note however that *natural inputs* comprise the "precursors" (water, inputs from soil, inputs from air) of the *cultivated biological resources*, including of the residues we are interested in (SEEA-CF §3.45, table 3.2). The present discussion is therefore relevant – although only indirectly – for these *natural inputs*. According to this approach, indeed, the physical flow account records, among *natural inputs*, the elements – such as carbon, oxygen, nitrogen, other nutrients and water – entering the cultivated plants, since the nature-economy boundary is set at the trophic level of plants' metabolism (correspondingly, the elements exiting the plant are recorded as residuals flowing to the environment). However, only part of the total plants' biomass, in which the input elements are embodied, constitutes a *product*. The rest is immediately transformed, at the time of harvest or catch, in what the SEEA calls residuals, and precisely into *solid waste*.

▪ In the section dedicated to Economy-wide material flow accounts (Ew-MFA: SEEA-CF, section 3.6.6), instead, the so called "harvest approach" is taken, according to which the treatment is the same as for non-cultivated resources (§3.282). In this approach, the plants and their metabolism are left out of the economic system boundary, so that the flows accounted for as crossing the Ew-MFA environment-economy boundary are directly the quantities of cultivated biomass resulting from the cultivation process. These quantities are then distinguished into *used* and *unused*, according to whether they are subsequently embodied into products or not. Eurostat's 2001 methodological guide (§3.31) gives the following definitions:

o "Used refers to an input for use in any economy, i.e. whether a material acquires the status of a product".

o "Unused flows are materials that are extracted from the environment without the intention of using them, i.e. materials moved at the system boundary of economy-wide MFA on purpose and by means of technology but not for use".

---

[1] The two approaches are reconciled within a common framework in the OECD manual on Material Flows and Resource Productivity (OECD, 2008, vol. 2). Within this framework the two different boundaries define a semi-natural system that extends from the trophic level of cultivated plants nutrition (outer boundary of the economy) to the point of harvest (inner boundary of the economy). An accounting scheme could be defined describing inputs and outputs of this semi-natural system. Its inputs would be exactly the ones defined by the first approach (the trophic level of the SEEA-CF); its outputs would comprise the crop residues we are dealing with here.

Unfortunately, these definitions do not seem to be clear enough as to easily accommodate all crop residues to either category, although the two should be jointly exhaustive with respect to crop residues. In fact, some crop residues are inputs for use in economic production processes (which would qualify them as "used") but do not acquire the status of a product (which would qualify them as not "used"). Think for instance of crop residues that are fed into digestors for biogas production, or into composting facilities for making compost, without their owners (who discard them as waste) receiving any payment or allowance in exchange (as is the general case). It is recognised that these residues are generated "without the intention of using them" (which would qualify them as "unused"), that the guidance for implementation provided by Eurostat (2013) – which provides tools for calculation of used residues – does not foresee these flows, and that the common practice of environmental accountants is to ignore them in their estimation of (used) Domestic extraction. All this notwithstanding, we will consider these flows as of materials that are used, because: a) these destinations are becoming more and more common for crop residues and economically important, at least for their users; b) if these residues are not accounted among the "used" materials, material goods would emerge at some point in the economic process (biogas, compost) and at the output side (air emissions, dissipative use of products) without any corresponding input (used domestic extraction or imports) being recorded, which would contradict the logic of Ew-MFA and the mathematical equilibrium of inputs and outputs in its Direct material flow balance account. As a corollary, only the residuals left on the soil or burnt in the open, or landfilled are unused in Ew-MFA sense.

Summarising, we have *unused crop residues* which are a subset of *residuals from crop residues*; these form the total of *crop residues* together with *products from crop residues* – which are of course made of *used materials* in the sense of Ew-MFA. The following scheme shows this, and in the bottom row the connection to the categories used in the presentation of data in chapter 5 of this paper.

<table>
<tr><td colspan="3">CROP RESIDUES</td></tr>
<tr><td>PRODUCTS FROM CROP RESIDUES</td><td colspan="2">RESIDUALS (SOLID WASTE) FROM CROP RESIDUES</td></tr>
<tr><td colspan="2">USED CROP RESIDUES</td><td>UNUSED CROP RESIDUES</td></tr>
<tr><td colspan="2">E.g. Burning for heat, composting use in husbandry, use for biogas production</td><td>E.g. Leaving on soil possibly after shredding, open-air disposal (including burning), disposal as waste outside the holding</td></tr>
</table>

The peculiar nature of *crop residues* is highlighted by considering that many *crop residues* may a-priori be *products* or *used residuals* or *unused residuals*, and what they actually are only depends on circumstances, i.e. on whether there is a market for them or not. E.g. straw is always a crop *residue*, but it is not always a *residual*, as it is often sold or used in the holding producing it: in this case it is a (by-) *product* with a positive economic value of its own. Use of straw as fodder or for animals' bedding is indeed very common and the value of this straw is accounted for in standard National accounts as included in the agricultural industry's output. But not all straw is gathered and marketed or used: if there are no animals, it is usually left on the soil or burnt, which makes it an *unused residual*. In other words, the concept of *crop residues* is a more "stable" one and this seems a good reason for using this more general concept in combination with the concepts of *residuals* and *unused* instead of either of the two alone, because it provides a more sound reference point for analysis, given that the materials contained in crop residues are always relevant from the environmental and/or economic point of view, whatever their fate.

In the general supply-use scheme of the SEEA-CF, the flows of *products from crop residues* are not distinct from those of all the other products, and only if a detailed waste supply and use account is compiled, the fate (being used or left unused) of the *residuals from crop residues* is visible. The Ew-MFA treatment helps in that it identifies the quantities of residues that are left *unused.* These have potential uses as input materials for other production processes or even as *products* of their own, and as such could provide indirect or direct sources of income for crop producers and of raw materials for the potential users.

The latter potential, which appears to be exploited more and more, is not necessarily a blessing for agricultural holdings, as short-term gains in income may from selling the residues could be offset by longer-run effects of taking the residues away from the soils where they were grown. if the crop residues are taken away, indeed, the nutritive substances embodied in them will not return to the soil where they were taken from. In the long run soil quality and eventually fertility may decline, resulting in lower productivity and/or higher costs for other inputs such as synthetic or organic fertilisers.

3. Data gathered through Istat's structural surveys on agricultural holdings

Information on biological resource residues is not gathered in a systematic way. Whilst it is relatively easy to calculate their quantities supplied by agriculture and forestry, on the basis of agronomic knowledge (much less so for fisheries), on the use side no systematic gathering of basic data is available. Some information is provided by waste statistics. This information, however, is neither complete as for its coverage of the phenomenon – residues not entering a waste collection scheme do not feature in them - nor always clearly referable to harvest or felling residues.

For these reasons, in the framework of a collaborative effort of agricultural statistics and environmental accounts, Istat collected data in two different occasions, by introducing some simple questions in two surveys, namely the Survey on Permanent Crops (Permanent Crops Survey – PCS – 2012) and the Survey on the Structure and Production of Agricultural Holdings (Farm Structure Survey – FSS – 2013). These surveys are limited to crop production systems (permanent and temporary respectively). Both are regulated by binding legal acts of the European Union (regulations 1166/2008 and 1337/2011), but the questions on crop and pruning residues were added as ad hoc information sources for enhancing economic accounts and environmental accounts as well as other possible uses such as greenhouse gas emissions estimation., aimed at knowing more especially about the management of biological resources residues by agricultural holdings. These questions concern residues from permanent crops (PCS) and cultivations on arable land (FSS), i.e. from all cultivated biological resources, excluding only felling of cultivated forests, which are out of scope of the two surveys. The questions were kept as simple as possible, reducing to a minimum the information requested, in order to ensure its reliability and to increase the response rate, in view of the secondary importance of the topic with respect to the general aims of the surveys and of the respondents' ability to provide data on non-core activities.

In particular, for permanent crops, two questions were introduced, one concerning the quantity of pruning residues produced, the other concerning the management of all residues produced, deriving from permanent crops. As for the first question, the quantity was requested by species, for the 12 most important species, but notably excluding wine grapes, nut trees and some other minor species. The second question was referred to all residues including – besides the pruning residues covered by the first question – leaves, removed trees, non-saleable fruits etc. With this question we asked for percentages on total residues' weight, by kind of management. For the major possible uses, the residues dealt with inside the holding were distinguished from those given to others in the first place. The former were detailed into: composted; ground and released on soil; used as fuel for heating purposes; disposed of in the open (including – as specified in the instructions – possibly illegal practices such as on-field burning – which is prohibited in Italy); used in husbandry. For the residues given to others, an attempt was made to ascertain from the producer whether to his knowledge they were destined to be composted, used for energy (heat) or landfilled. Finally "other" was included as a possible answer, for special cases such as e.g. the use of the timber as a raw material for artwork, industrial or construction uses, within or outside the holding.

As for cultivations on arable land, we concentrated on the management and only asked for the percentage distribution of the residues of two broad groups of crops – i.e. cereals and crops on other arable land – among four possible management ways: leaving the residues on the soil (whether burying them or not); reusing them within the holding for forage or bedding for animals or for any other use; selling; managing the residuals as waste (including possibly illegally burning them), whether within the holding or outside it. The first and last management ways correspond to the *unused* case, and the other two to the *used* case, with the "selling" surely points at *products* while "reuse inside the holding" includes the case of residues that are *products* – namely for cereals' production residues, which are given a value in Italian economic accounts for Agriculture – and that of *residuals* that are used but are not *products*, having no market value of their own – the case of residues from crops on other arable land.

In the PCS, 27,234 holdings were sampled. In the FSS, 44,550 of which only 28,141 having arable land (excluding land set aside, or with flowers and ornamental plants). The questions were quite successful, with response rates as high as 87% for the production of pruning residues, 86% for the management of residues from permanent crops, 95% as for residues from cereals, 78% as for residues from other arable land. In the PCS, 98.3% of the holdings who provided data on the production of pruning residues also answered to the question on the management of residues from permanent crops.

It is recognised that the overall accuracy of the permanent crop survey's results is negatively affected by the non-participation in this survey of a whole region (Tuscany). This region however is relevant, among the surveyed species, only for olives, and its contribution to pruning residues production was estimated only for this species, by expanding proportionally the results obtained on the respondents (Italy totals for other species may therefore be slightly underestimated). The same was done in order to estimate non-respondents' contributions also for the other questions. We will not dwell further on the process of going from survey data to final, complete estimates, as we followed standard control and correction procedures. An encouraging circumstance, however, is that corrections turned out to be necessary only in a quite low number of cases, e.g. concerning the order of magnitude of the reported pruning residues where it was evident that the respondents had used tons or kilograms instead of hundred kilograms as requested.

4. Estimates of the supply of agricultural residues in Italy

Estimates of agricultural residues have been made for Italy by Istat (2010 and 2011), Ispra (2010), and Paolantoni (2015).

Table 1 provides a summary of our results, showing the source for each of the figures provided. In order to ensure completeness, for those residues from permanent crops that are not covered by the question on residues generation in the PCS – namely residues from pruning of some tree species, from pruning of vineyards and from removal of whole plants – we complemented the estimates with the quantities calculated by Paolantoni (2015). These are in turn based on updating the information contained in Ispra (2010). Our estimates for temporary crops and main permanent crops are substantially in line with the figures provided by the other sources quoted above.

The residues supplied by the cultivation of temporary crops were calculated by applying agronomic coefficients to the produced quantities. These were in turn estimated in the case of dry pulses and other vegetables by the application of agronomic coefficients to the production data supplied by another Istat survey the "crop estimates survey" (CES). In all other cases, where the FSS survey provides accurate area data we calculated the production of residues by each holding by applying the same coefficients to that holding's production estimate, resulting from multiplying the average yield-per-area-unit provided by the CES with the area declared in the FSS by that holding for that specific crop (area data for pulses in the FSS may be overestimated from wrong allocation to it by respondents of fresh peas, beans etc, with a corresponding under estimation of the area devoted to other vegetables).

It is recognised that these supply estimates do not include residues from cultivation of ornamental plants and flowers, as well as from elements of the rural landscape, such as e.g. hedges, which may also be considered as "cultivated" in SNA's sense but do not yield products and are therefore not considered in agricultural statistics. These have so far not been considered in any material flows accounting exercise, not even for the products' part of them.

Table 1 - Supply of residues from the cultivation of crops and source of information, by crop, Italy 2012 or 2013(000 tons)

	Total Supply	Source of the estimate
TOTAL CROPS	**43,573**	
Temporary crops	**35,611**	
Cereals	*29,040*	*Istat's 2014 survey on the structure and production of agricultural holdings, with yields and some area data from crop estimates survey (2013 data)*
Wheat and barley	11,922	
Rye, corn	13,211	
Other	3,907	
Other temporary crops	*6,571*	
Dry pulses	189	
Tubers	1,211	
Industrial crops	1,829	
Other vegetables	3,342	
Permanent crops	**7,961**	
Pruning of main permanent crop species, excluding vineyards	*3,715*	*Istat's 2013 survey on main permanent crops (2012 data)*
Pruning of vineyards, almond, hazelnuts, plum trees	*2,417*	*Paolantoni (2015) (estimates based on agronomic coefficients)*
Removed plants	*1,829*	
main permanent crop species, excluding vineyards	999	
vineyards, almond, hazelnuts, plum trees	830	

5. The "use" side

Tables 2 provides a summary of results from the two surveys, having the same sources as shown in table 1. As for permanent crops other than pruning residues of main species, again we complemented the survey results by using the estimates made by Paolantoni (2015), who exploited information provided by ISPRA in order to separate the used from the unused part of the residues. As said in section 3, *used* corresponds to either "reused within the holding" or to "sold" (in the latter case we have a product for sure), while *unused* corresponds to "left on soil" or "wasted".

Table 2 - Use of residues from crops production, Italy 2012 or 2013, by crop and kind of use (000 tons and %)

	"USED"		"UNUSED"		TOTAL USE (=TOTAL SUPPLY)
	within the holding	outside the holding	Left on soil	Wasted	
TOTAL CROPS	12,233 (28%)		31,340 (72%)		43,573
Temporary crops	***10,116 (28%)***		***25,496 (72%)***		**35,612**
	4,554 (13%)	**5,562 (16%)**	**24,970 (70%)**	**526 (1%)**	
Cereals	*4,356 (15%)*	*5,195 (18%)*	*19,123 (66%)*	*366 (1%)*	*29,041*
Wheat and barley	1,842	3,101	6,704	275	11,922
Rye, corn	1,994	1,675	9,492	51	13,212
Other	520	419	2,927	40	3,907
Other temporary crops	*198 (3%)*	*366 (6%)*	*5,847 (89%)*	*160 (2%)*	*6,571*
Dry pulses	22	21	145	2	189
Potatoes	55	41	1,093	22	1,211
Industrial crops	47	72	1,699	11	1,829
Other fresh vegetables	75	232	2,910	125	3,342
Permanent crops	**2,117 (27%)**		**5,844 (73%)**		**7,961**
Pruning of main permanent species, excl, vineyards	*905*		*2,810*		*3,715*
Pruning of vineyards, almond, hazelnuts, plum trees	*121*		*2,296*		*2,417*
Removed plants	*1091*		*738*		*1,829*
Main permanent species, excl, vineyards	344		655		*999*
Pruning of vineyards, almond, hazelnuts, plum trees	747		83		*830*

Source: our elaborations on FFS, PCS, CES and Paolantoni (2015)

It can be observed that use is dominant for residues from removal of fruit-bearing trees and significant for straws and similar residues from cereals cultivation and for pruning residues of main permanent species (excluding vineyards), whilst residues from all other cultivations are mostly left on the soil.

Table 3 provides some additional detail from the permanent crop survey, showing how the 4.7 million tons of residues from main permanent species (pruning and removal plants) are distributed among the 9 different possible uses proposed in the question.

Table 3 - Management of residues from cultivation of main permanent crops, Italy 2012 (000 tons and %)

	Within the holding					Outside the holding			None of the others – used within the holding	Total
	Unused, left on soil	Unused, wasted	Used			Used		Unused, wasted		
	Shredding and leaving on soil	Open-air disposal, including burning	Burning for heat	Com-posting	Use in husbandry	For energy use	For composti ng	For disposal as waste		
Quantity in thousand tons	2.832	612,4	948,2	77,5	21,9	151,5	6,4	20,4	44	4.714,2
%	60,1%	13,0%	20,1%	1,6%	0,5%	3,2%	0,1%	0,4%	0,9%	100,0%

The allocation to the categories used in table 2 is quite straightforward. *Burning for heat*, *composting* and *use in husbandry* within the holding correspond to the first column in Table 2, *energy* use and *composting* outside the holding to the second, *left on soil* to the third and *open air disposal* within the holding and *disposal as waste* outside the holding to the fourth. The only uncertain category is *none of the others*, which however only weights 0.9% of the total in this residues category, and has been allocated to "used" in Table 2.

6. Conclusions

Gaining sound and detailed knowledge of the amounts of used and unused biomass residuals from agricultural production is of interest for research and policy use, especially for what concern the current distribution of these precious biomass flows between the various possible destinations. However, very little official statistics is available.

In order to overcome this information gap, as far as the supply side is concerned, official statistics need not embark on regularly surveying the quantities involved, since reliable estimates can be constructed by using agronomic information (ratios of ancillary biomass to crops). However, official statistics should provide some benchmark, allowing to validate existing estimates and add detail (geographical, and by kind of plant) to them.

As for the management side, in any implementation exercise it is necessary to come up with a figure for the share of used quantities (in Ew-MFA terms) over total quantities. This share is also something national accountants dealing with the agricultural sector need, in order to estimate the quantity whose value must be accounted for in agricultural production and value added. Potential users are also researchers in charge of estimation of air emission for official national communications, such as those due under the UNFCCC transparency framework and for CLRTAP. Our experience shows that the investigation of the phenomenon greatly benefits from being considered in structural surveys.

As for the way forward, the data collected could be connected to those on the destination of some agricultural residuals, present in administrative sources, e.g. on compost, biogas and biomass-based electrical energy production plants. The analysis could thus be extended to downstream steps in the use of this biomass, and possibly also transformed in terms of nutrient and pollutant elements cycles.

The System of Economic and Environmental Accounts for Agriculture, Forestry and Fisheries (SEEA AFF), promoted by FAO and UNSD, is a powerful tool for organising information on the environmental dimension of AFF activities, covering among others the data domains of crops, forest products, fisheries, energy, greenhouse gas emissions, fertilisers consumption, water use, soil and agricultural income. The supply and/or the use of biological resource residues are related to all of these aspects of the agri-environmental relation. SEEA AFF, however does not explicitly include crop residues in any of its accounts nor deals with it on the methodological level. Only the part of the residues that is used in the sense of Ew-MFA may in principle feature in the physical account for crops (in principle, because it is quite difficult that crop residues be among the main products – almost by definition). But in the future, it could play a role in promoting knowledge about these important material flows, though maintaining its focus on main crops, e.g. by including in future versions, as a possible application or extension, an account for the supply and use of ancillary biomass flows connected to main agricultural products.

ABSTRACT

This document describes the conceptual basis of two methodological approaches which can be used to fully represent the water use of the fishery sector within the SEEA accounting framework. A broader description of this analysis with reference to several water-related SEEA accounts is available as a FAO Fisheries and Aquaculture Technical Paper (FAO, 2016). The fishery sector uses water resources in two different ways. Fishing, vertical raceways cage and pen aquaculture have an *in-stream* water use as they use water on-site. They do not abstract and do not consume water but they are indissolubly dependent to the availability of surface waters as fish habitats. Pond aquaculture, recirculating aquaculture systems, horizontal raceways have an *off-stream* water use as water is initially abstracted from the natural environment to create a culture environment, which according to the aquaculture method used can require different amounts of water additions during the production cycle. The SEEA accounting framework has been mainly developed for monitoring *off-stream* water uses in terms or water volumes abstracted and consumed. The current limited capacity of the SEEA accounting framework to measure *in-stream* water use raises some concerns in the way to which the water requirements and needs of economic activities that have an in-stream water use can be represented in national water accounting. Several economic activities, including the fishery sector, have an *in-stream* water uses. Due to its nature i*n-stream* water uses tend to overlap to each other as well as to *off-stream* water uses. Therefore, in the SEEA water accounting it is important to further develop methodologies able to better account for *in-stream* water use and to compare *in-stream* and *off-stream* water uses. To advance in this direction two different approaches are suggested below.
A first approach is suggested to measure all kind of *in-stream* water use as water areas. Presently SEEA accounting framework measures in-stream water use as the water area clearly delimited for a specific use such as aquaculture cages and areas for conservation purpose (i.e. single purpose water use) while gathers together all *in-stream* water use that tend to overlap in space and time (i.e. multipurpose water use). A second approach is suggested to measure *in-stream* water use as water volumes. In particular, the amount of water needed by in-stream activities of the fishery sector can be measured as the high (flooding) environmental *water flow* required for the maintenance of aquatic ecosystems and reproduction of resident and migratory fish species. These two approaches are undertaken to be able to subsequently compare *in-stream* and *off-stream* water uses amongst different economic units. The SEEA accounting framework contains a matrix to account for origin and destination of water flows within the economy. The proposal is to expand the scope of this matrix to show interactions amongst *in-stream* and *off-stream* water uses. These interactions are assessed in terms of potential rivalry for water abstractions as well as overlapping use of surface waters in time and space.

Keywords: SEEA, water accounting, water use

PAPER

1. Introduction

Water use is a general, non-specific term that describes any action through which water provides a service (Kohli et al., 2010). Water use can be distinguished into off-stream and in-stream:

. *Off-stream water* use takes the water out of the water source, reducing the amount of available water left on-site;
. *In-stream water use on-site water use* does not remove water from its source or water is immediately returned with little or no alteration.
Some activities such as navigation, hydro-electric power generation[1], recreational activities on water, have an in-stream water use as they occur on-site. Other types of activities such as crop production, municipal water use and sanitation, industrial water use, have an off-site water uses, because they require to abstract water and use it in other locations.

. *Off-stream water use* is usually measured in terms of the water volumes abstracted and consumed and returned to the environment.
. *In stream water use* is usually measured in terms of the water area required for a given purpose. By definition in-stream water use has no water withdrawal, no water consumption and no water return;

The fishery sector is comprised of capture fisheries[2] and aquaculture activities[3] and is characterized by both in-stream and off-stream water use (Table 1)

Table 1 - In-stream and off-stream water use within the fishery sector

Characteristics	Fishery sector		
ACTIVITY	Capture fisheries	Aquaculture	
WATER USE	*in-stream*	*in-stream*	*off-stream*
METHOD	Any types of fishing	Cage (including on-bottom and off-bottom)	Pond
		Pen	Indoor tank
			Recirculating systems
		Vertical raceways	Horizontal raceways

Capture fisheries have an in-stream water use as fishing uses water on-site. Fishing does not abstract and do not consume water but is indissolubly dependent to the availability and access to surface waters as fish habitats. Fishing activities are also highly affected by the seasonal variation of inland waters. The contraction of inland waters is usually detrimental for fishing activities, while their enlargement due to the creation of seasonally flooded areas, caused by overflowing of river and lakes, is highly favorable. Seasonally flooded areas are rich in nutrients and are essential for reproduction of many fish species. For these reasons seasonally flooded areas often are fishing areas characterized by high fish catches. Aquaculture can have both *in-stream* and *off-stream* water use according to the aquaculture methods. Cages, pens are considered to have an *in-stream* water use, while pond and recirculating systems have an *off-stream* water use. For pond culture, water is abstracted to fill the pond, to maintain the water level and compensate evaporation and seepage losses, and to maintain suitable values of temperature and other water parameters. Water is used in the same way for indoor tanks but the amount of water needed to replace evaporation will be lower than for outdoor pond. Recirculating systems use indoor tanks in which water circulates into a closed loop so that water is (partially) reused after undergoing treatment. Thus, an initial water withdrawal is needed as well as limited water addition during the production cycle. In raceways, water is flown through artificial tanks. In horizontal raceways water flows in one end of the device and flow out at the other. In vertical raceways water flows in at the top and out at the bottom. Vertical raceways are usually built as flotation frames and therefore they are considered to have an *in-stream* water use. On the contrary horizontal raceways are considered to have an *off-stream* water use since they are constituted by artificial structures, where water is abstracted and diverted from natural surface waters to create a water flow that artificially mimic the river run-off for aquaculture purposes.

2. SEEA accounting framework and water-related accounts

The SEEA-Central framework (United Nations et al., 2014) has two main categories of water-related accounts related to (i) water areas and (ii) water volumes. The SEEA land cover account describes the landscape composition and specifically measure areas occupied by different water resources. The SEEA land use account describes how the landscape is affected by human intervention and management measuring how water areas are used for different purposes. The SEEA water asset account measures the water volumes of surface water, ground water and soil water yearly available in a country. The SEEA supply and use water account compares the water volume available as yearly national water supply to the water volumes requires to meet water demand by different economic units. The development and degree of implementation of these two categories of water-related accounts vary greatly. SEEA accounting framework has been mainly designed for monitoring water volumes.

This is mainly due to the fact that many policy objectives in water management such as improving water supply and sanitation services, developing a rationale for water allocation permits, managing water supply and demand amongst municipal, irrigation and industrial water users, increasing water treatment and reuse, mitigating the risk of flooding, monitoring climate variability require the accounting of available water volumes rather than water areas.

[1] The hydroelectric plant that uses the river rapids to produce electricity has an in-stream water use. However, if the hydroelectric plant requires a dam for the storage of large quantities of water to create the water drop suitable for power generation, water is retained and consumed through evaporation. In this case the hydroelectric plant has an off-stream water use. In the SEEA framework hydropower generation is generally considered as having an off-stream water uses and therefore quantity of abstracted water is explicitly accounted.

[2] Capture fisheries is defined as the extraction of living aquatic organisms from natural or artificial inland waters, but excluding those from aquaculture facilities (FAO, 2010).

[3] Aquaculture is defined as the farming of aquatic organisms involving intervention in the rearing process to enhance production and the individual or corporate ownership of the stock being cultivated (FAO,2010).

3. SEEA accounting framework and water use

Water accounting is a powerful tool for monitoring and evaluating the use of water resources. It provides a measure of the availability of water resources within a country's territory and also a measure of the pressures on these water resources by different economy activities and overlapping or conflicting uses among different water users. This information can then be used to improve resource management and inform decision making processes by identifying whether a country is using its water resources in an efficient, equitable and sustainable way. Accounting for water use requires to take into consideration both in-stream and off-stream water uses. In the SEEA framework the land use account, which measures water area can be used to describe in-stream water uses, while the supply and use, water which measures water volume can be used to describe off-stream water uses. The current limited capacity of the SEEA accounting framework to measure in-stream water use raises some concerns in the way to which the water requirements and needs of economic activities that have an in-stream water use can be represented in national water accounting. Therefore, there is the necessity to further develop methodologies able to better account for in-stream water use and to compare in-stream and off-stream water uses. To advance in this direction two different approaches are suggested below.

3.1 First approach: measuring in-stream water uses as water areas

A first approach is suggested to measure *in-stream* water uses as water area providing information for both *single-purpose* water use and *multi-purpose* water use. The SEEA classification of water use includes four main water categories: *waters used for aquaculture or holding facilities, waters used for maintenance and restoration of environmental functions, other uses of waters* and *waters not in use*. In principle, these four classes are applicable to inland waters, coastal waters and marine waters. The criterion applied to this classification is that areas of water are be considered 'used' only where they have been clearly zoned or delimited for a specific use. Therefore, the SEEA classification of water use distinguishes specific water use such as aquaculture facilities and areas for conservation purpose (i.e. single water use). In this respect other single water uses could be added as a separated classes such as for example *inland waters exclusively used for irrigation* and *inland waters exclusively used for cooling water to a nearby power plant or industrial facility*.

Despite the addition of other classes the bulk of different *in-stream* water use will remain aggregated into the broad class of other uses of water. All *in-stream* water uses take place in existing surface waters. Since *in-stream* water use do not abstract neither consume water often they often don't occur as single use but tend to overlap in space and time with other water use (i.e. multiple water use).

In order to account for multiple water uses a GIS-based approach is suggested. GIS organizes and analyzes information into overlapping layers and therefore is able to deal with multi-dimensionality of different water uses. In the case of the fishery sector, water areas used as fishing grounds could be represented as well as water areas important as reproductive sites or nursery of important fish target species. In the case of aquaculture water areas could directly identify cage and pen used for aquaculture facilities. In addition, other in-stream water uses such as navigation, tourism and recreation could be made spatially explicit so that an area of use is identified.

Using a GIS-based approach the map of surface water to analyze is divided into a grid. Each water use of a given economic unit constitutes a separate layer of information mapping the grid cells where that use take place.

Each water use records the continuity (e.g. yearly, seasonally, monthly, daily etc.) with which the grid cells are used.

Following such GIS-approach also the spatial and temporal overlap between in-stream and off-stream uses can be captured since water areas used for water withdrawal and water discharge can be also mapped.

Within the same surface water:

. *In stream water* are identified by one continuous area or several disjoint areas

. *Off-stream water use* are identified by points where water is abstracted and (eventually) returned, which often correspond only to one or few grid cells.

On the basis of a criterion of continuous use in time each grid cell can have a primary use of a given economic unit and one or few secondary uses of other economic units.

3.2 Second approach: measuring in-stream as water volumes

A second approach is suggested to measure in-stream water uses as water volumes. This approach is undertaken to be able to directly compare in-stream and off-stream uses.

The fishery sector has an *in-stream* water use, which occur on-site and doesn't consume water, however, this does not mean that the fishery sector don't need water. On the contrary fishing, cage and pen aquaculture are highly dependent on the availability and access to surface waters since they are fish habitats. For this reason the volume of water needed to enable the *in-stream* water uses of the fishery sector is the environmental water flows that support the fish life cycle.

The *environmental water flow* is defined by the quantity, quality and timing of water flows required to sustain freshwater and estuarine ecosystems and the human livelihoods and well-being that depend on them (The Brisbane Declaration, 2007).

There are several methods to estimate the environmental water flow; hydrology-based methods are the most simple to implement as they primarily use time-series of monthly or daily flow records (Thamer, 2003).

Within river hydrology different water flows enable different ecological processes (Postel and Ritcher, 2003).

. *Base environmental water flow* maintains suitable water temperatures, dissolved oxygen and water chemistry and consequently provide adequate habitat for aquatic organisms. A base water regime can enable fish to move to feeding and spawning areas within the surface water. On the contrary when the base flow decreases below the normal level to the drought level this can hamper fish reproduction as well as fish survival;

. *High (flooding) environmental water flow* enables fish not only to reproduce within to surface water but also trigger fish upstream migration of anadromous fish. The increased run-off causes the overflowing of rivers and lakes with consequent creation of seasonally flooded areas. Seasonally flooded areas are rich in nutrient, shallow and often are used by many fish species as spawning areas and nursery areas for fish juveniles.

In order to estimate environmental water flows (base flow and high flow) a GIS-based approach is suggested. The recommended scale of analysis is the watershed defined at an appropriate spatial scale. The 'environmental water flow' or water regime required to support and maintain aquatic ecosystems differs is specific of each watershed. In fact watersheds differ for: climatic condition and seasonality, amount of precipitations, rate of evaporation or evapotranspiration, land cover, land use and management the water inflows received from neighboring countries and consequent water run-offs.

The volume of water needed to enable the *in-stream* water uses of the fishery sector is identified by the high (flooding) environmental water flow. Since the *in-stream* water use by definition has no water consumption, for accounting purposes, a volume of water equal to the high environmental water flow is 'virtually' abstracted by the fishery sector and the same amount is also returned to the environment.

3.3 A matrix of water-based interactions amongst economic units

The two described methodological approaches are undertaken to be able to subsequently compare in-stream and off-stream water uses amongst different economic units.

The SEEA accounting framework contains a matrix to account for origin and destination of water flows within the economy. In this matrix the economic units (industries by ISIC category, household and rest of the world) constitute both rows and columns. The economic units in the rows are considered as '*water suppliers*', those in columns as '*water users*' (United Nations, 2012; para.3.43).

The proposal is to expand the scope of this matrix to show relationships amongst *in-stream* and *off-stream* water uses. The structure of the account is the same of the original matrix in SEEA-Water with the only difference that some economic units can be further disaggregated to be able to account for the different water use of some sub-units. The *environment* is also added as a '*water supplier*' as many activities including pond aquaculture and recirculating aquaculture systems can abstract water directly from the environment without the intermediation of water supplier industry.

The proposal is to compile this matrix of water-based interactions amongst economic units (Table 2) in twin tables with two units of measurement which account respectively for:

2a. Exchange or competition of water flows between units –water volumes

2b. Overlap or competition in space and time between units – water areas

The compilation of the matrix in water volumes gives the possibility to compare *off-stream* uses with those *in-stream* uses which can be expressed in terms of water volumes. Each cell of the matrix records quantity of water originated from the economic unit in the row (origin) and distributed to the one in the column (*destination*). Consequently the matrix highlights the role of each economic unit as water supplier and/or as water user. Aquaculture can be a 'water supplier' since for example as a water supplier as can supply wastewater to sewerage activities but is also a 'water user' often abstracting water directly from the environment. Fishing is a water user of the environmental water flow that support fish life cycle and consequently allow the reproduction of fish stocks.

With the few adjustments made (i) inserting the environment as unit of origin and destination (ii) measuring the in-steam water use of fishing and cage as environmental water flow, this matrix can account both *in-stream* and *off-stream* water use of the fishery sector. It should be noted that the volume of water used by the fishery sector is 'virtual' since it is usually not secured by the fishery sector but in reality remains available for the potential use of all other sectors. Therefore a comparison between the environmental water flow and the major water volumes used by the economic units can reveal a vulnerability of the sector to water conflicts. In particular the matrix can highlight a large share of the existing environmental water flow used for growing non-perennial crops (ISIC 01-1) or the matrix can show a conflicting use in the water volume required for hydroelectric power generation (ISIC 35-1) and the environmental water flow which support upstream fish migration. Less obviously the water volume used by several industrial activity of agriculture (ISIC 01-03), manufacturing (ISIC 10-16) and the volume of water for household consumption can be compared with volumes of water that are collected and treated (ISIC 36 and 39) to gain an indication of the impact of economic activities on water quality.

Table 2 - Matrix of water-based interactions amongst economic units

ISIC description	ISIC category	01	01-111	02	03-1	03-2	10-16	35-1	36	37	39	50-1	50-2	55	56	ENV	HH	WLD
01 Crop and animal production, hunting and related service activities	01																	
01-111 Growing of rice	01-111																	
02 Forestry and logging	02																	
03-1 Fishing	03-1																	
03-2 Aquaculture	03-2																	
10-16 Manufacturing	10-16																	
35-1 Electric power generation, transmission and distributio	35-1																	
36 Water collection, treatment and supply	36																	
37 Sewarage	37																	
39 Remediation activities and other waste management se	39																	
50-1 Sea and coastal water transport	50-1																	
50-2 Inland water transport	50-2																	
55 Accommodation	55																	
56 Food and beverages service activities	56																	
Environment	ENV																	
Households	HH																	
Rest of the world	WLD																	

In few cases the water requirements of water transport (ISIC 50-1 and 50-2) can also be expressed as water volumes required (i) to maintain a depth of surface water suitable for navigation (ii) to operate waterway locks in inland waters for navigation. In these cases the water of volumes used for water transport can be directly compared with those of other economic units. The compilation of the matrix in water areas shows interactions amongst in-stream water uses and qualitatively can pinpoint also situations of overlap between in-stream and off-stream water use.

In the matrix the area of water reserved or delimited for single water uses can be recorded in the diagonal of the matrix, while any each other cell in the matrix records the area of water shared by two economic units. Therefore, the matrix can show the existing balance between the allocation of surface waters allocated to single water use and the area of surface waters freely accessible available for multiple uses. The matrix can be used to report the outcomes of a previous GIS-based analysis aimed at mapping multiple water use and provide a better understanding on the economic units involved their degree of overlap in space and time.

Each cell of the matrix can be used to record the area of surface waters shared by the economic unit in the row (*dominant user*) and another economic unit in the column (*secondary user*) in respect to their different intensity/continuity of their use in time In this way the overlap in space and time amongst different in-stream water users such as for example fishing (ISIC 03-1) and water transport (ISIC (ISIC 50-1 and 50-2), fishing and hydroelectric power generation (ISIC 35-1), fishing and bottom-cage aquaculture can be compared. Although *off-stream* water uses are described by the water abstracted, consumed and returned to the environment, both withdrawal and disposal of used water can occur in surface waters. Therefore a given area can be affected by both off-stream and in-stream water uses. This situation can also be accounted in the GIS analysis and reflected in the suggested matrix.

4. Conclusions

Accounting for interactions amongst *in-stream* and *off-stream* water uses requires water accounting at multiple-scale composed by three main hierarchical levels: the national scale, the watershed and surface waters within the watershed. Correspondingly the *Matrix of water-based interactions amongst economic units* can be compiled at the level of the single surface water, the watershed and the national level. The assessment of *in-stream* water uses is likely to require an analysis at the level of surface waters but an aggregation of the results at the watershed level and at the national level would be equally important. The watershed is a fundamental spatial scale for water accounting. All water resources within a watershed are interlinked in terms of both quantity and quality and the watershed is often the unit where decisions on water management are taken. The national-level is also fundamental since it is the scale targeted by the SEEA accounting framework. Therefore a GIS-based approach becomes a fundamental tool in SEEA for its analytical capacity of integrating information amongst multiple scales, of analyzing interacting biophysical and climatic factors as well as supporting the assessment of different water uses by different economic units.

ABSTRACT

Economic activities depend on the environment and its resources and in turn also have an impact on it. The development of a System of Environmental-Economic Accounting Central Framework (SEEA CF) – a UN statistical standard (adopted in 2012 by the UNSC) – aims at organizing relevant statistical information within an integrated framework, coherent with the System of National Accounts (SNA 2008), to facilitate analysis of key processes and their evaluation. FAO and the UN Statistical Division (UNSD) have further developed a satellite application of the SEEA Central Framework (SEEA CF), the SEEA for Agriculture, Forestry and Fisheries (SEEA AFF). This paper aims to supply overview and updates of SEEA AFF.

Keywords: Environment, economy, accounting, agriculture, forestry, fisheries.

PAPER

1. Introduction

1.1 SEEA Agriculture Forestry and Fisheries (SEEA AFF) is a sub-system of the SEEA Central Framework (SEEA CF), the international statistical standard for environmental economic accounting, and is consistent with this framework. SEEA AFF aims to apply the SEEA CF to Agriculture, Forestry and Fisheries activities, pointing out linkages among and between these sectors, the environment and the economy and also highlighting the connections between underlying physical data in these areas and the conceptual framework of the SEEA.

1.2 The development of a System of Environmental Economic Accounting for Agriculture, Forestry and Fisheries was proposed by the FAO in 2010 and endorsed by the UNCEEA in June 2011. In 2013 FAO, in collaboration with UNSD and other relevant international partners, initiated the drafting of the SEEA AFF, including the description of new accounting tables, as an application of the SEEA-CF needed to cover agriculture, forestry and fisheries activities.

1.3 The feasibility of compiling the accounts and the relevance of the information was tested and further refined in four pilot countries: Australia, Canada, Guatemala and Indonesia. Based on the experiences gathered, a SEEA AFF revised draft was elaborated with contributions from FAO technical divisions, UNSD and relevant international partners.

1.4 The SEEA AFF was presented and discussed at a dedicated Expert Group Meeting at FAO (Rome, Oct 7-8 2014), with representatives from SEEA pilot countries, experts from UNSD, Eurostat, OECD, and FAO. The participants highlighted that initial activities in SEEA AFF pilot countries had generated productive cross-agency engagement towards improved national statistical systems.

1.5 The revised SEEA AFF was further presented to the 9th UNCEEA meeting (June 2014) and at the 20th London Group on Environmental Accounting meeting (October 2014).

1.6 Based on comments and suggestions gathered through the above processes, an updated SEEA AFF draft was submitted for the first Global Consultation in December 2014. Constructive feedback was received from more than 30 experts in National Statistical Offices other government agencies and international agencies on the scope, coverage and content of SEEA AFF.

1.7 A plan for further development of the SEEA AFF, including plans for country implementation, were presented at 10th UNCEEA Meeting (June 2015) and at 21st London Group on Environmental Accounting meeting, receiving broad support (November 2015).

1.8 The second and final Global Consultation process was carried out through December 2015 and January 2016. Constructive feedback was again received from more than 30 experts in National Statistical Offices and international agencies, showing broad endorsement of the content of the submitted SEEA AFF draft.

1.9 A revised SEEA AFF draft was then submitted for adoption to the UN Statistical Commission (UNSC) at its 47th session, in March 2016, under agenda item 3(e) Environmental Economic Accounting, accompanied by a technical document detailing specific changes made in response to the feedback from the second Global Consultation. During the discussions, in line with the tenor of the feedback from the Global Consultation, there was a broad welcoming of the SEEA AFF (EU, Samoa), with one country (Sweden) suggesting more testing in countries.

1.10 Since the UNSC meeting, FAO has continued discussion with experts in countries and in other international organizations in order to effectively incorporate all of the comments received through the consultation process. The additional findings have been incorporated in the SEEA AFF draft submitted to the UNCEEA 11th Meeting (June 2016). The UNCEEA agreed on endorsement of SEEA AFF as an "Internationally Agreed Methodological Document in support of the SEEA CF".

2. OVERVIEW AND UPDATE OF THE SEEA AFF

2.1 The SEEA AFF applies the environmental-economic structures and principles described in the SEEA Central Framework to the activities of agriculture, forestry and fisheries. The SEEA Central Framework was adopted in 2012 as an international statistical standard by the UNSC. It was jointly published in 2014 by the United Nations, the European Commission, FAO, the International Monetary Fund (IMF), the Organisation for Economic Co-operation and Development (OECD) and the World Bank (United Nations et al., 2014a).

2.2 The SEEA AFF also applies the conceptual framework of the System of National Accounts (SNA), the most recent edition being the 2008 SNA (EC, et al., 2009). The value-added of SEEA AFF lies not in terms of conceptual advances in accounting, but rather in the integration of information that is considered standard from either an SNA or SEEA perspective.

2.3 The data coverage of the SEEA AFF is broad including data in both monetary and biophysical terms. More in details SEEA AFF has ten data domains:

i. Agricultural products and related environmental assets

ii. Forestry products and related environmental assets

iii. Fisheries products and related environmental assets

iv. Water resources

v. Energy

vi. Air EmissionsFertilizers, nutrient flows and pesticides

vii. Land

viii. Soil resources

ix. Other economic data

Specific accounting tables are then associated to each domain.

2.4 Asset Accounts and Physical Flow Accounts (or Physical Supply and Use table) are the two main types of SEEA AFF base accounts.

2.5 Physical Flow Accounts are structured to record the total supply of products against their total; the required balance between these, i.e. total supply for each product must always equal total use of each product, is the accounting identity.

2.6 Environmental and Economic Asset Accounts instead record information on stocks of assets at the beginning and end of an accounting period, and changes in them during the accounting period.

2.7 Environmental and economic information are integrated into combined presentations that include monetary and physical information. They are not strictly accounts in that the information they contain does not need to be in the same measurement units, and not all entries in a physical flow or asset account need be translated into a combined presentation. The content of combined presentations may change over time to reflect changing analytical and policy priorities, but the structure of the base accounts will be relatively stable. The SEEA AFF describes five combined presentations

i. Activity-specific and product-specific inputs

ii. Food product consumption, losses and waste

iii. Sustainable use of environmental assets

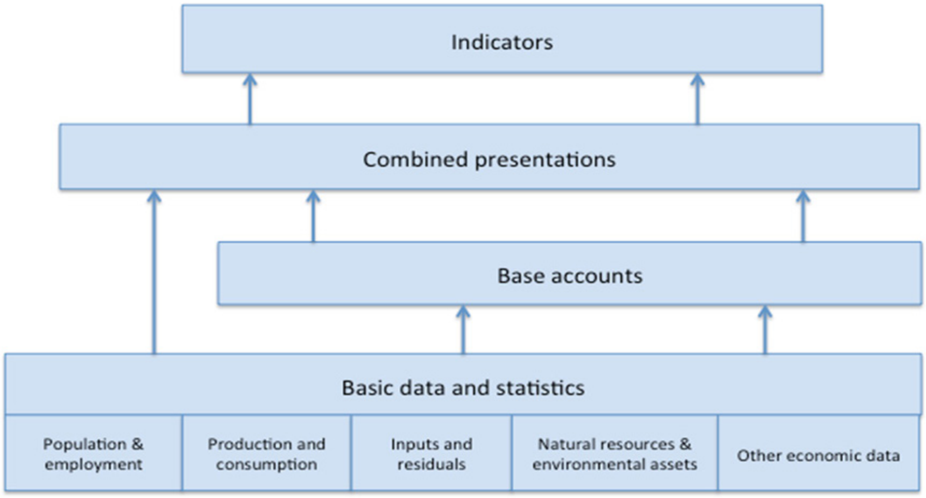
iv. Cross-industry and cross-activity perspectives

v. Reference Combined Presentation

2.8 Combined presentations are valuable mechanisms to focus on a particular theme or to have a synthetic overview of key selected economic and environmental variables (as in the Reference

Combined Presentation). Moreover combined presentations enable the extraction of variables relevant to the derivation of indicators.

Figure 1 - SEEA AFF information pyramid (Source: System of Environmental-Economic Accounting for Agriculture Forestry and Fisheries, White Cover version)



2.9 A critical concept of the SEEA AFF is the phased, tiered approach to implementation. It is recommended that users proceed in three successive phases, starting with the use of national-level default data, including from international organizations (tier 1); it is then foreseen a wider engagement of the country and data gaps estimation (tier 2); and a very complete and full implementation of the SEEA AFF accounts through the use of modelling and GIS information is expected at tier 3.

2.10 SEEA AFF has been already tested in Australia, Canada, Guatemala and Indonesia and additional countries volunteered after the June 2016 UNCEEA meeting (Australia, Canada, and The Netherland). Interaction with the country through a tiered approach is a key element of SEEA AFF methodology and capacity development activities. The capacity development module has been successfully applied during the Uganda Training on Environmental Economic Accounting and Greenhouse Gas Emissions (15 - 17 April 2016, Kampala, Uganda) and further capacity development activities are foreseen on December in Morocco.

2.11 As next step, Technical Notes will supply additional details on SEEA AFF accounting tables' compilation to facilitate SEEA AFF country implementation.

COMPETITIVENESS INDICATORS OF AGRICULTURE AND OF THE AGRIBUSINESS SECTOR

Session Organizer
C. Russo | University of Cassino and Southern Lazio | Cassino | Italy
F. G. Wijnands | Wageningen University Research | Wageningen | The Netherlands

ABSTRACT

This track focuses on competitiveness indicators and measurement at all levels of the agricultural value chain. The session aims at provoking scholarly debate about the basic mechanisms determining the recent trends in the competitiveness of the world agribusiness. A special focus on measurement issue characterizes the scope of the session.

Background

Competitiveness is an elusive concept that has been represented by abstract theoretical definitionsand by a number of diverse and partially inconsistent 'working', applied definitions. Thus, real world measuring of competitiveness in the agribusiness section remains a controversial issue and full consensus has not been achieved yet among scholars, managers and policy makers.

Applied studies in this topic face several challenges as the inherent complexity of the task leads researchers to difficult choices. A field of studies compromised on theoretical foundations in order to develop easy-to-implement indicators. Other approaches grounded on theory at the expenses of more complex methodologies and extensive data requirements. In both cases, there is a substantial demand for new research aiming at improving measurement quality and fostering the use of the indicators in policy and business decisions.

Such state of the art calls for new research in three main areas: i) definitions of competitiveness for the agribusiness sector, ii) innovative and feasible measures and indicators and iii) use of competitiveness measures for policy and business.

Track topic

The track has specific interests in the following themes:

1. Approaches to competitiveness measure of agriculture or agribusiness sectors, incorporating internal and external developments. Contributions in this track may cover topics related to the statistical definition of competitiveness, measuring competitiveness in a multifunctional framework, survey design for competitiveness studies, issues in the organization of competitiveness surveys in the agribusiness sector.

2. Indicators for measuring competitiveness. Examples of topics in this track may include: innovative measures of competitiveness, applications of existing methods to the agricultural and agribusiness sector, analytical framework,

3. Organization of data collection and statistical analysis. Papers in this track may consider: survey design methodologies, data issues, feasibility of statistical systems and other issues related to the organization of statistical systems.

4. The impact of the measured competitiveness. This track covers topics related to the use of competiveness measure for policy and business, dissemination of survey results, data-driven policies for competitiveness.

5. Cross space/time/industry empirical studies on competitiveness, comparing particular products, actors, chains, and/or countries. The contributed papers can address either conceptual or empirical work. Case studies and comparative analyses of best practices from less developed and developed countries are welcome.

Effect of quality assurance deficit on market competitiveness for export commodities and household income in Nigeria

K. Akanni | Department of Agricultural Economics College of Agricultural Sciences Olabisi Onabanjo University,Ago-Iwoye | Ogun State | Nigeria

DOI: 10.1481/icasVII.2016.c20

ABSTRACT

The Nigerian's agricultural sub-sector contributes about 37 percent of her Gross Domestic Product (GDP) and employs about 65 per cent of the adult labour force. It is thus the major source of food and fibre for the nation. It also provides basic raw materials for the agro-industrial sector and contributes about 88 percent of the nation's foreign exchange. Some of the major agricultural export commodities are cotton, maize, groundnut, hides and skin, beniseed (sesame),cocoa, palm produce, rubber and timber, among others. Nigeria's major trading partners include the United States of America, United Kingdom, India, South Africa, Germany and Spain. However, there are increasing concerns about the quality and level of safety of many of these export commodities. Many of them were recently considered as sub-standard and unsafe for both human and animal consumption, particularly in the European markets due to the level of unauthorized pesticides and were therefore rejected. This is a major challenge to the level of market competitiveness for these commodities in the international markets. It also has an over-bearing effect on household income of the farming households and many Nigerians. This study therefore examined the effect of quality assurance deficit on market competitiveness and household income levels. Trends in Nigeria's agricultural export trade between 1980 and 2014 were examined and emphasis was placed on cowpea,dried maize, melon seeds and palm oil. Both primary and secondary sources of data were used. Primary data were obtained with the aid of structured questionnaire and personal interviews with some randomly selected private exporters of agricultural commodities and officials of relevant government agencies in agricultural sub-sector. Secondary data were again obtained from the records/ publications of the Ministry of Agriculture, Nigeria Export Promotion Council (NEPC), National Bureau of Statistics (NBS),Central Bank of Nigeria (CBN) and others.

Descriptive and qualitative statistical methods were used to analyze the data. Descriptive statistics included the use of mean, median, mode, graphical illustrations and other measures of central tendencies. Quantitative statistics included the use of econometric models such as demand and supply elasticity measures. Results indicated that there was an increase in the general price level of the commodities at the international market over time. The aggregate market demand for each of them dropped sharply in the last one decade even when the market price per unit increased steadily (Price inelastic).This negatively affected the households' average income level as returns on sales of export commodities declined. Huge quantities of the commodities were then forced to be sold at the local markets at cheaper prices. This development negatively affects the consumptions patterns of the exporters as they now have reduced disposable income. Appropriate agencies of government need to be awake to their responsibilities of assessing and certifying the quality of the Nigerian agricultural commodities before exporting them abroad. This will help to further boost the level of consumer confidence in these export commodities especially at the international markets.

Ultimately, the level of aggregate demand for the export products and the household income levels of many Nigerians will increase.

Keywords: Agricultural Export Commodities, Market Competitiveness, Quality Assurance

PAPER

1. Introduction

Nigeria's agricultural sub-sector is the largest contributor (88%) to the non-oil foreign exchange earnings. Development in the sub-sector is therefore capable of bringing about a broad-based economic growth that is characterized by increased per capita income, reduction in poverty and expansion of employment opportunities. Some of the major agricultural export commodities are cotton,maize, groundnut, hides and skin, beniseed,cocoa,palm produce,rubber and timber, among others(Olukosi and Isitor,1990;NBS,2002;NBS,2009). To compliment local supply, Nigeria imports poultry products (such as chicken and turkey) and processed foods mostly from European countries.

Other food imports include canned beef and frozen fish (such as tilapia, mackerel, bonga and stock fish), wheat and fruits and canned juice among others. Huge quantities of these commodities however find their ways into the Nigerian markets through illegal (unofficial) channels. Hence they are often regarded as part of Nigeria's unorthodox trading activities since they do not enter the official transactions of the government. International trading is necessary in order to balance the trade position with Nigeria's trading partners. However, there are increasing concerns on the level of safety of these export and import commodities. For example, just recently, the Nigerian government started enforcing the ban on imported poultry products and frozen fish before they find their ways into the domestic market. This decision was premised on the claims by the Nigeria's Ministry of Agriculture that a large proportion of these imported commodities harbor harmful parasites,bacteria,viruses,chemicals or radioactive substances. In a similar vein, the European Union recently suspended some agricultural food exports from Nigeria. These food items include beans (cowpeas), sesame seeds, melon seeds, dried fish and meat, peanut chips and palm oil. Reasons for the suspension are hinged on the allegations that the items constitute danger to human health because they contain a high level of unauthorized pesticide. For instance, the European Food Safety Authority observed that the beans from Nigeria contain between 0.03mg per kilogramme to 4.6 mg per kilogramme of *dichlorovos* pesticides when the acceptable maximum residue limit is 0.01mg/kg.

Again, in 2013, about 24 of the Nigerian agricultural export commodities were rejected from the United Kingdom and the number increased to 42 food products in 2014.Some of these items were said to have been contaminated by aflatoxins. This makes them unfit for human and animal consumption. The health risk that is associated with the consumption of the imported commodities is further heightened due to the relative market competitiveness and preference they enjoy among Nigerian consumers most of whom care less about the chemical composition and possible health implications (such as cancer, skin irritations, internal organs defect and migraine headaches).These imported food products are ironically cheaper than the locally produced food items; thus putting the latter into some market demand risks and uncertainties. This development has remained a source of worry and concern to the local producers of these food products hence they have often called on the Nigerian government to properly address the situation by reversing the ugly trends.

1.1:Objectives of the study

The broad objective of this study is to examine the level of market competitiveness for selected agricultural commodities and farmers' household income. Specifically, the study;

a) Investigated the level of market competitiveness and consumer preference for selected internationally traded food products in Nigeria.

b) Established the existing relationship between the level of quality assurance deficit of export commodities, market competitiveness and farmers' income.

2.0: Literature Review and Theoretical Framework

Before the discovery of crude oil in commercial quantities in Nigeria, the agricultural subsector was the chief foreign exchange earner constituting between 65 -70 per cent of the Gross Domestic Product (GDP) (Olayemi,1980 and Adeyokunnu,1980;CBN,2006).Some of the major agricultural export commodities include cowpeas, sesame seeds, melon seeds, dried meat and fish, peanut chips,palm produce (kernel and oil),kolanut,cashew nuts and foodgrains (such as millet, maize and sorghum),among others (Olukosi and Isitor,1990;Adekanye,1988;Helleiner,1988;CBN,2006 and NBS,2009).According to Adeyokunnu (1980) and Olatunbosun and Olayide (1980), the marketing of agricultural export crops and the marketing board system dominated the business space in the early period of the nation's post- independence in 1960. The basic intention of the government then was to stabilize producer prices, conduct market research and development and to accumulate the trading surpluses. Between 1955 and 1951,the marketing boards accumulated reserves totalling N43.6 million (Helleiner,1988) and they operated successfully in the Nigeria's agricultural crop marketing space until 1986 when they were proscribed by the Federal government for alleged professional inefficiency and mistrust.

Today, the marketing and distribution of the bulk of agricultural products are in the hands of private individuals and co-operative societies (Adekanye,1988).Again, some acts of corruption bordering on adulteration, distortion of measuring apparatus and poor product qualities now characterize the marketing of agricultural export commodities.Perhaps,the most disturbing implication of this scenario is the recent ban of 42 Nigeria's agricultural food products from the European Union (EU) markets for alleged non-compliance with the minimum quality standards. Some of the affected food products were said to have been contaminated by *aflatoxins*, making them unfit for human and livestock consumption. This development has grossly affected the level of competitiveness of the Nigeria's agricultural export products, particularly at the international markets (NEPC,2015). It has again negatively affected the household income levels of the farming households in the past months (CBN,2015). It therefore becomes imperative for all exporters of agricultural products in Nigeria to adhere to the global standards (international best practices) in food product exports, especially on quality assurance.

3.0: Research Methodology

3.1: Method of Data Collection

Both primary and secondary data were used for this study. Primary data were obtained on the income levels of the exporters of four (4) purposively selected Nigeria's agricultural food exports (cowpeas, dried maize, palm oil and melon seeds).These commodities were sampled for the study because of their strategic importance in the list of Nigeria's agricultural export food items. Samples of export food items were taken with the support and guidance of Nigeria Export Promotion Council (NEPC) and National Agency for Food, Drug Administration and Control (NAFDAC).Secondary data were also used to source data and information from the various publications of the Central Bank of Nigeria, National Bureau of Statistics, Federal Ministry of Agriculture, Nigeria Customs and Excise Department, Federal Ministry of Health, and other relevant bodies. These data consisted of information on the Nigeria's major agricultural export commodities since 1980 to 2014.Emphasis was placed on the export quantities, domestic price of the export commodities and the equivalent foreign price, the destination countries of export and challenges of international trading among other issues. Information was also sought on the types of preservations, preservative chemicals being used for the export agricultural commodities and dosage levels.

3.2: Method of Data Analysis

For objective 1, data were collected on the price regime of four (4) of the Nigeria's major agricultural export products (cowpea, melon seed, dried maize, and palm oil) at the international markets. Then, average market prices were obtained for these food products (in the UK markets) and the equivalent amounts of similar commodities at the local markets in Nigeria and these prices are compared to appreciate the level of parity (or otherwise).The closer these prices, when compared, the more competitive they are. Own-price elasticity was also computed to again observe the degree of responsiveness of the export quantities to declining market prices at the international market in the UK. Thus, according to Frank and Bernanke (2004), own-price elasticity,

$$\mathcal{E}_{op} = \frac{\delta Q/Q}{\delta P/P} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$= P/Q * 1/Slope \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Where,

$\mathcal{E}_{op}$ = Own-price elasticity of the export commodities.

Q=Quantity of Nigeria's export at a given time ('000 tonne)

δQ=Change in quantity of Nigeria's export at a given time ('000 tonne)

P=International Market Price (own) of Nigeria's export commodity at a given time (£)

δP=Change in International Market Price (own) of Nigeria's export commodity at a given time (£)

Thus,own-price elasticity was computed for all the four (4) selected agricultural commodities to ascertain the level of reaction of the international market to changing price situations.

For objective 2, a multiple regression model was used to establish the relationship that existed among the level of quality assurance deficit of the export commodities, market competitiveness and farmers' income,among others.

Thus, $Y_N = \alpha_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_4 + \beta_5 X_5 + e_i$ ……………… (3)

Where, Y_N is the annual farm income of the exporter,

X_1 =Level of quality assurance deficit (mg/kg).Quality assurance deficit was captured by the difference between the estimated quantities of pesticide residues found in samples of selected food items which were prepared for export to international market (in UK) and the acceptable maximum residue limit of 0.01 mg/kg.These samples were collected with the assistance of Nigeria Export Promotion Council (NEPC), Lagos, Nigeria.

X_2 = Level of market competitiveness for selected Nigeria's internationally- traded agricultural export commodities (i.e. cowpea, melon seed, dried maize and palm oil) (in £). Basically, market price competitiveness measures the level of equality/ parity (or otherwise) between international (UK) market prices of the Nigeria's agricultural export food items and the prices of similar items in the Nigerian market.

X_3 = Tax paid on Export commodity (Naira)

X_4 = Annual Output of Export Commodity (tonnes)

X_5 =Government Policy on Export Commodity (Dummy: If favourable to export=1,if otherwise=0)

e_i=Stochastic error term, which is random in behaviour.

N=Number of agricultural commodity exporters which is equal to 200

This model was used to run the analysis separately for each of the four (4) selected agricultural export commodities listed above.

4.0: Results and Discussion

4.1:Market Behaviour and Volatile Prices of Nigeria's Internationally -traded commodities

International market for Nigeria's export commodities continue to vary in reaction to changing market prices and consumer preferences which is often reflected by the direction of consumer demand for the commodities. From Table 1 below, it is indicated that own –price elasticity values drastically declined for all the export commodities between 2004-2014 (compared with the previous years) because the demand for the selected Nigerian agricultural exports dropped at the international (UK) market. This development was largely due to the rejection of many of the nation's agricultural export commodities by the UK market as a result of allegation of noncompliance with the regulations on standards and international best practices on food storage/preservation techniques, especially in the past one decade.

Table 1 - Determination of Own-Price Elasticity for Nigeria's Export Commodities

Export Commodity	Year/Own-Price Elasticity (%)		
	1980-1992	1993-2003	2004-2014
Cowpea	124.6	66.4	34.6
Dried Maize	118.3	58.3	43.1
Melon Seed	106.4	67.6	22.4
Palm Oil	122.6	45.7	18.3

Source:Nigeria Export Promotion Council,(NEPC),Lagos, Nigeria.

4.2: Nigeria's Agricultural Export Trade

Between 1980 and 2014, there was a mere marginal increase in the quantities of agricultural export commodities that were produced domestically in Nigeria (Table 2).The least yearly increase was observed in the case of palm oil while maize recorded the highest. The use of traditional farming technologies, poor storage/preservation techniques, low-yielding production technology and largely aged farming population were responsible for the generally low output levels of the major export commodities in Nigeria. On the whole, only about 35 per cent of the official production output was exported abroad (Table 2).These development had negative implications on the general income level of the farming households.

Table 2 - Profile of selected Nigeria's agricultural export commodities (1980-2014)

Export Commodity	Year /Average Yearly Production level in metric tonne			Year/Average Annual Export Quantity[1] (metric tonne)		
	1980-1992	1993-2003	2004-2014	1980-1992	1993-2003	2004-2014
Cowpea	3669.6	4210.7	4328.3	1284.36	1473.75	1514.91
Dried Maize	8527.9	8685.1	9503.4	2984.77	3039.79	3326.19
Melon Seed	421.1	450.1	479.4	147.39	157.54	167.79
Palm Oil	161.5	172.7	187.0	56.53	60.45	65.45

Source:National Bureau of Statistics,NBS,Lagos,Nigeria,2015.

[1]Only about 35 per cent of the official yearly output was exported.

The level of market acceptability and consumer preference for good is often measured by the price consumers are willing to pay for such commodities, particularly at the international market level here the Nigerian export commodities are in strong market competition with other commodities from other sources. Thus, the average domestic market price (per tonne) was estimated and then compared with the international (UK) prices of the selected export commodities, using the average foreign exchange rate of the Nigerian local currency,(Naira) to the US Dollar (Table 3). Between year 2000 and 2008,it was shown that the domestic prices of the export commodities were highly competitive as their local prices were very close and sometimes higher than international prices.However,the reverse was the case between year 2009 and 2014,as the domestic prices of the Nigerian export commodities declined and the demand for them dropped hence they could not favourably compete with their international market prices (Table 3).A huge quantities of the export commodities were again rejected at the international market largely due to alleged compromised qualities. The US Dollars equivalent values of these commodities were higher than the international prices. This again indicated that there was no parity price2 especially for cowpea, dried maize,and palm oil in the last one decade.Thus,many exporter farmers were discouraged from exporting their commodities and were therefore left with option of patronizing the Nigerian local markets. This led to a decline in the sale of farm produce and a reduction in the general household level of many Nigerian farmers.

Table 3 - Market Price Competitiveness of selected Nigeria's agricultural export commodities

Export Commodity	Year /Average Domestic Market Price per metric tonne (Naira)			Year /Average International Price per metric tonne (Dollars)		
	2000-2003	2004-2008	2009-2014	2000-2003	2004-2008	2009-2014
Cowpea	49,370.0 ($509.81)	56,045.0 ($449.62)	62,717.2 ($403.53)	97.6	101.3	615.85
Dried Maize	28,054.2 ($289.69)	36,782.3 ($295.08)	47,921.0 ($308.33)	42.8	65.9	342.37
Melon Seed	22,134.0 ($228.56)	29,006.0 ($252.69)	34,974.7 ($225.03)	22.3	34.9	118.7
Palm Oil	88,300 ($911.81)	110,151.1 ($883.68)	133,003.6 ($855.77)	121.4	147.5	920.89
Mean Exch.rate of Naira/US$	96.84	124.65	155.42			

Source:National Bureau of Statistics,NBS,Lagos,Nigeria,2015

Note: All values in parentheses were the domestic market prices of the selected Nigeria's agricultural commodities in US Dollars.

[2]Parity price provides the farm products the same purchasing power per unit for goods and services used in both production and family consumption relative to prices that prevailed in the base year. It often reflects the concern of government about the purchasing power of the farmers. It a popular parameter by which many developed economies show concern about the purchasing power of their farmers.

4.3: Farmer's income, market competitiveness and level of quality assurance deficit of Nigeria's export commodities

The level of market competitiveness and quality assurance of the farm output often determine the amount of income farmers realise at the end of the farming season. This is so because the farmers have to present their farm products at the international market where these products compete with other commodities from various sources. Hence, the need to observe and comply with the international best practices on standards and grading of these agricultural commodities, especially with respect to the use of chemical as preservatives. These farmers therefore need to mind the types, quantities and methods of preservatives being used for their farm products so that the quality of these products is assured in the market; since this has a serious implication on market prices. The most common types of chemicals being used for the preservation of farm products include Gamma BHC/lindane,Malathion,Iodafenphos (such as Nuvanol and Elocril),Dichlorvos and synthetic pyrethroid (e.g. permethrin),among others.

For all the four (4) agricultural export commodities, the estimated values of parameter co-efficient estimates (Table 4) indicated that the level of market competitiveness and quality assurance deficit were significant determinants of the annual farm income of the exporters of the agricultural commodities. Specifically,for cowpea, melon seed and palm oil the two parameters were significant at 1 per cent level .In the case of dried maize, quality assurance deficit was found to be a significant parameter at 1 per cent while market competitiveness was significant at 5 per cent level.In addition,tax paid on export commodity, annual output level and government policy on exports were also found to be significant at various levels.However,tax payment and government policy were not significant in the case of dried maize and cowpea respectively. High values of adjusted R2 ,which varied between 0.67 (for melon seed) and 0.92 (for palm oil) indicated the correctness and exactness of the specification of the regression model as stated in equation (3). High values for Log likelihood function, which ranged between 233.04 (for cowpea) and 771.53 (for melon seed) again corroborated the feeling that the regression model had a reasonably acceptable level of reliability.

***=Significant at 1 % level **=Significant at 5 % level

5.0 Conclusion

This study has investigated the effect of quality assurance deficit and market competitiveness on the household income of the Nigerian agricultural commodity exporters. Many of the export commodities now fail the quality assurance test hence they cannot sustain their competition in the international markets which also display many quality products. The immediate implication of this development is that many of the Nigeria's export commodities were restricted from the UK markets. This has caused a huge decline to the annual income level of the Nigerian farm producers who often export their products. But all hopes are not lost, especially if these farmers are able to observe and comply with the global best practices on the use of chemical preservatives for their exported farm products. This will reduce the level of chemical residues which are considered injurious to the health of the consumers of these food items. The local (traditional) methods of product storage and preservation which do not involve the use of chemical substances could be adopted by the farmers as alternative ways of protecting the qualities of farm produce. With this, the Nigerian agricultural export commodities will again be accepted and remain competitive at the international markets. This will bring a higher income to the Nigerian agricultural commodity exporters and ultimately improve the general income levels of the farming households in Nigeria.

The "sophistication indices" for the international agri-food trade analysis: the view point of imports

A. Carbone | University of Tuscia | Viterbo | Italy
R. Henke | CREA | Rome | Italy

DOI: 10.1481/icasVII.2016.c20b

ABSTRACT

In this paper we look at a family of indicators originated around the concept of "sophistication" of traded goods. Usually the sophistication indices focus on export flows and are based on the relationship between the level of per capita GDP and the complexity of exports in terms of technological content, branding and packaging, quality features and so on. We use the same concept to explore import flows of agri-food products, assuming there is a relationship among the level of per-capita GDP of an importing country and the level of sophistication of its agri-food imports. We build and analyse two indices, one looking at the level of sophistication of imported goods (Consy) and one looking at the aggregated level of sophistication of an importing Country (Impy). The indices give a synthetic measure of the sophistication of the final market or, in other words, the kind of demand and competition that the product is going to face in the destination markets. With regards to this, the ranking produced by the two indices are relevant and consistent with the main world trade specialisation and the correlations with GDP confirm the assumption on which the indices are built.

Keywords: trade sophistication, agri-food export specialisation, agri-food import demand

PAPER

1. Introduction

The family of indices that move around the concept of "sophistication" is generally used in the trade literature to analysis the complexity of export flows and is based on the assumption that the higher the GDP of a country the more "complex" is its set of exports. The concept of sophistication includes the technological content, the branding and the packaging of the goods, the quality, and other features that add value to the products. These characteristics of the traded goods have increasingly importance in the international arena, becoming the ground for non-price competition, even in the food sector where, in order to meet a clear trend in the demand, producers and exporters have increasingly focused on product differentiation and quality attributes (Krugman, 1980; Helpmann, 1981; Schott, 2004; Fabrizio et al., 2007).

The sophistication of export flows is measured in the literature by two indices, respectively referred to the set of products exported and the countries exporting them (Lall et al., 2006; Hausmann et al. 2007).

The Prody index refers to a specific good and is given by the per-capita GDP (GDPpc) of all the countries exporting that good weighted by the specialisation of that country in the export of that product.

Similarly, the Expy index is referred to a single country and it is given by the sum of all the Prody indices of the goods exported by the country weighted by the share of the exports of any single good on the total exports of the country. This family of indices has been used for comprehensive studies analysing the entire set of exported items and a wide range of competing countries as well as for trade analysis of specific Countries and/or sectors (Rodrick, 2006: Minondo 2008; Di Maio and Tamagni, 2008). A stream of more recent literature has explored how the measure of export sophistication works when applied to the agri-food sector (Carbone and Henke, 2012; Carbone et al., 2015). In this case, especially for the primary basic goods, factors like climate, resources, conjunct productions, as well as policies, might influence significantly localisation and, hence, the export specialisation patterns. Nonetheless, different papers have shown that quality is a major export driver also in the agri-food sector, especially for processed food (Gehlhar and Pick, 2002; Fischer, 2010). In this paper we move from exports to imports, assuming there is a relationship among the level of per-capita income of an importing country and the level of sophistication of its agri-food imports. This approach is not entirely new, since other works have dealt with the shift from exports to imports[1].

1 See, for example, Marvasi (2013). In his paper, Marvasi builds an Impy index for China which is given by the Sum of the Prody indices of China exports weighted by the share of imports of China for each of the same products.

However, both the construction of specific indices and the analysis have been focused on the comparison of the level of sophistications of the export and import flows of a single country. In our work, we turn the attention to the construction of a new set of indices, defined as Consy and Impy, which are symmetrical to the Prody and the Expy. These indices look at the sophistication of the set of imports of a country, independently from its set of exports.

The Consy is defined as the sophistication index for imported goods: the higher is the role of high income countries in the imports of a good the more sophisticated will be the product. The income level of the destination markets for a product can be considered an indicator of the kind of competition that the product would likely meet.

In the same line of the measure of the export sophistication, the most interesting result is the ranking generated by the index and its time variation. In the same streamline of the Expy index, it is possible to build an Impy index, starting from Consy, that is given by the weighted values of the Consy vector of the whole set of imports of a country, where the weights are the shares of imports performed by the country per each product. We will discuss the following uses of the indices: 1) rank the sophistication of products as measured by the income level of importing Countries; 2) Compare the sophistication measures resulting from the Consy and that one measured by the Prody indices for agri-food items; 3) Show the overall sophistication of trading Countries considered as destination markets for agri-food products 5) compare between them the rankings of Countries obtained with Expy and Impy and among them and to the GDPpc.

The paper is organized as follows. Section 2 first presents and discusses the Consy and Prody indices and, second, shows the Expy and Impy indices. Results are presented in Section 3 while Section 4 concludes.

2. New indices of sophistication

In recent literature the use of the sophistication indices have been focusing especially on the export side, and in particular on the Prody index. More specifically, recent studies have associated this concept of sophistication to the level of prosperity of the exporting Countries, alias their level of GDPpc (Lall et al., 2006; Hausmann et al., 2007). The underlying idea is that, other things being equal, the more a country is specialised in producing and exporting high value products, the higher is the remuneration of inputs and, consequently, the higher the level of its GDP. The Prody index associated to each exported good is a synthetic indication of its level of sophistication and, at the same time, gives an idea of the type of countries exporting that good, so that it gives indirect information about the type of competition that the good in question has to deal with on the international markets (Lall et al., 2006). The core idea is that product sophistication is linked to the country productivity level and that it is important as an export driver. This is in line with Porter's view of the competitive advantages of locations and the strand of empirical literature that stemmed out from his seminal work (Porter, 1985; Ketels, 2006; Sterns and Spreen, 2010).

The sophistication of a given exported item is the result of the sum of the GDPpc of the countries exporting that item, each of them weighted with the trade specialisation of each country in that item. This measure is called Prody and, according to the version proposed by Lall et al. (2006) can be calculated as follows:

$$Prody = \Sigma_j s_{i,j} GDPpc_j$$

where $s_{i,j}$ is the weighting factor of the GDPpc of each country j exporting the i product and it is given by the share of product i on total exports:

$$X_{i,j}/X_i$$

where $X_{i,j}$ is the amount of the agri-food product i exported by the country j and X_i is the world agri-food export of product i.

it is worth noting that this index does not catch all the possible factors influencing the exporting performance of a good. Different localisation factors are at work, especially in the agri-food sector, where natural resources, transport costs and policy interventions, just to mentions some among the most relevant ones, are crucial in explaining the dynamics of export goods (Di Maio and Tamagni, 2008; Carbone et al., 2012). However, previous results showed that, especially for processed food exports, the relationship still stands and works quite well (Carbone and Henke, 2012; Carbone et al., 2015).

The main outcome of the application of the Prody index is a ranking of the products analysed according to their level of sophistication. Moreover, an interesting use of the Prody index and of the family of indices is their variation in time[2]. In this paper we look at the sophistication in a different perspective associating it also to imports rather than only exports.

This is based on the following considerations: i) looking at the destination markets, rather than the markets of origin, reduces significantly the influence of localization factors other than GDPpc; ii) destination markets are the actual competitive arena that products are going to meet, focusing on these seems valuable when the interest of the analysis is more on the competitive conditions relevant to the products rather than the growth effects of exports; iii) focusing on imports allows for narrowing the definition of the relevant markets and thus allows a more accurate analysis.

[2] Its variation in time, in fact, can be due to a change in the GDPpc of the countries exporting the good or as a consequence in the change of the export share, or, also for the change of the set of countries exporting it (new exporters entering in the competition game, or countries phasing out).

This approach can provide a complementary viewpoint to the one based on export analysis, thus bringing new insights and developments to the agri-food trade analysis. Economic literature provides wide theoretical rationale for a positive relationship between GDPpc and demand for diversification and quality (Gabszewicz, and Thisse, 1979; Kearney, 2010). Thus, the assumption the new sophistication indices would rely on (i.e. the sophistication level of demand/imports increase with the average GDPpc of the importing countries) seems based on solid grounds. The first index we consider here is the Consy. This is the sophistication index for imported good i, and it is defined as:

$$Consy_i = \Sigma_j GDPpc_j * c_{ij}$$

where GDPpc $_j$ is the per capita income of importing country j and c_{ij} is the share of total world imports of item i imported by country j:

$$M_{i,j}/M_i$$

where $M_{i,j}$ is the amount of the agri-food product i imported by the country j and M_i is the world agri-food import of product i.

The higher is the role of high income countries in the imports of a good the more sophisticated is the product. In other words, we posit that the income level of the destination markets for a product indicates the kind of competition that the product would likely meet. In the same line of the measure of the export sophistication, also in this case, the most interesting result is the ranking generated by the indices and their time trends.

This index works very well also in order to measure the sophistication level of a subgroup of importing countries. One could, in fact, compute a ConsyiA related to a group (A) of importing countries (lets' say the clients of an exporter under study). By confronting Consyi with ConsyiA it is possible to assess whether Country A (or Countries in group A) forms a more or less sophisticated market for product i with respect to the world markets. It is obviously also possible to do bilateral confrontations between the sophistication levels of destination markets of competing Countries.

In the same streamline of literature, the Prody index is often associated to the Expy index, which is referred to a single country. The Expy index for a country j is given by the sun of the Prody indices associated to the products exported by that country:

$$Expy_j = \Sigma x_i/X_j * Prody_i$$

This index provides a ranking of the countries analysed according to their ability to export "sophisticated" products. As in the case of the Prody index, also for the Expy it is interesting to see the variations in time of the country ranking, which can be due to the different components of the Expy.

As in the case of the Prody and Expy, starting from Consy it is possible to build a symmetric index (Impy) that is given by the weighted values of the Consy vector of the whole set of imports of a Country, where the weights are the shares of imports performed by the country per each product.

$$Impy_j = \Sigma M_{ij}/Mt_j * Consy_i$$

Where M_{ij}/M_{tj}, is the share of the import of the country j of the good i and M is the total import of the country j.

The Impy indices measure the overall level of sophistication of the imports of a given country, thus giving an idea of the kind of market an exporter may find in that country. Obviously, here also it is possible to build sectoral versions of the index that enable to make comparisons.

First empirical results on the rankings associated with indices as well as on the comparison with the results obtained with the export sophistication indices provide scope for discussion on their advantages and further understandings that may stem from the use of such a methodology.

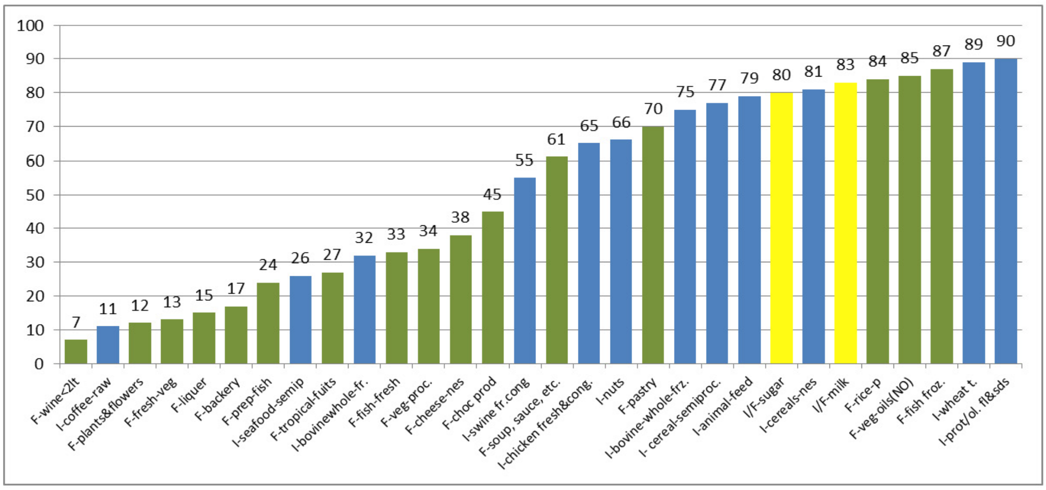
3. Preliminary results of the import sophistication indices

This Section presents and discusses some preliminary results obtained by the application of the indices of import sophistication to agri-food trade data[3]. Throughout the section, for clarity purposes, the comments are restricted to the thirty major items in terms of their shares in world trade, these are labelled in all figures; however, the analysis includes 92 items that represent the whole range of agri-food items. Figure 1 shows the import sophistication ranking of the selected items as measured by the Consy index. The prefix *F* denotes goods that are mainly for final consumption in the destination Country while prefix I stands for goods that are mainly used as inputs; a few items are labelled as *F*-I due to their double nature of intermediate and final goods. This specification is quite useful when comparing the values of the Consy and in particular its ranking. The top positions in the ranking include mainly goods for final consumption. These are complex processed goods, highly differentiated and with a high value added such as prepared fishes, wines (in bottles smaller than 2 litres), spirits and liqueurs, bakery products, processed veggies, cheeses, chocolate products, soups/condiments/sauces/etc. and so forth.

[3] The dataset includes 92 agri-food items aggregated starting from 700 Comtrade HS 1996 at 6-digit level and exchanged among 130 Countries that represent around 90% of all world trade exchanges.

Besides, also some fresh produces are ranked high according to the Consy values; again, these are differentiated and high value perishable products that require complex logistics functions and high transport costs like fresh veggies, tropical fruits, fresh fishes and plant and flowers. At the opposite end, the bottom of the ranking features mainly semi-processed goods, raw materials or commodities for final consumption. These are far more simple goods, non-significantly differentiated and for which competition is mainly performed at the price level. Among these there are wheat and other cereals, flours of cereals, flours/seeds of industrial plants, frozen swine, frozen bovines and frozen poultry, processed rice and vegetable oils (excl. olive oil).

Figure 1 - The sophistication level (ranking) of selected agri-food import items

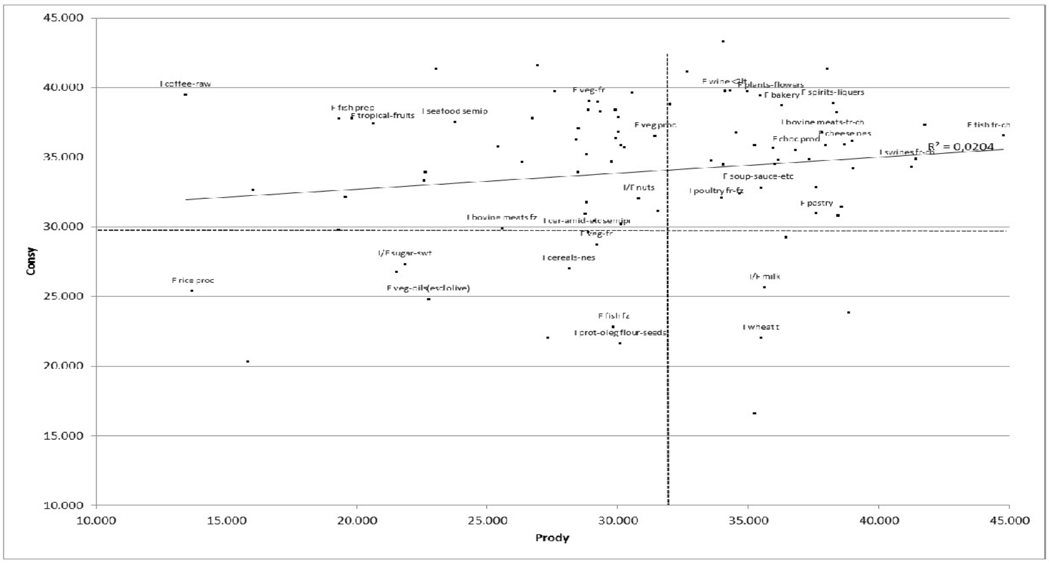


Note: (green bars: products for final consumption; blue bars: intermediate goods; yellow bars: double destination)

The values of the sophistication indices measured on the export and on the import side are compared in figure 2. As expected these two sets of values are not significantly correlated as factors influencing the localization of exports of a good and those affecting the geographical pattern of imports of the same good are different and widely unrelated(R2=0.025).

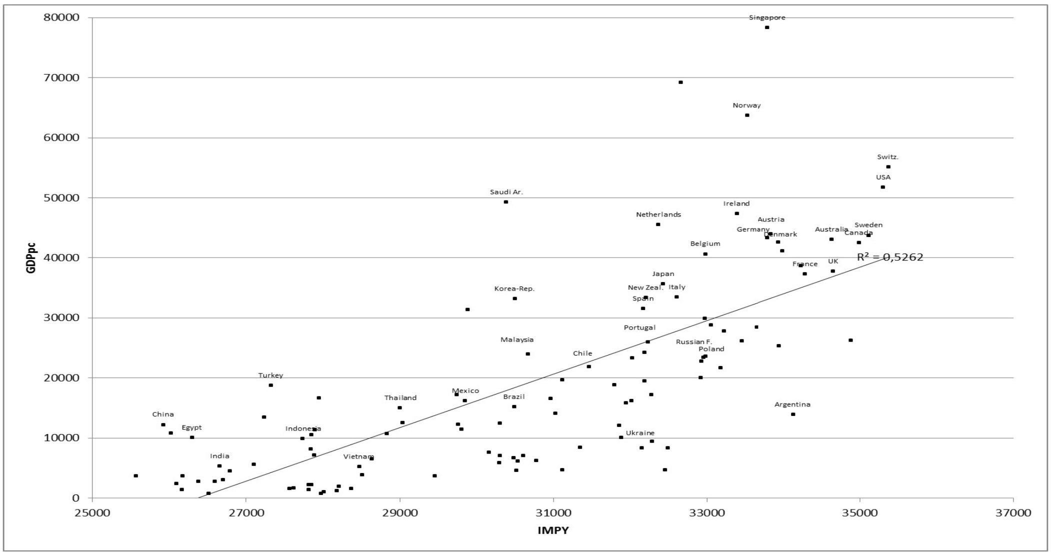
One additional evidence shown in figure 2 is the concentration of products in the up-right end of the graph; this is not surprising as it is the consequence of the major role played by richer Countries in international trade also in the agri-food sector.

Figure 2 - The sophistication of selected agri-food traded items: a comparison between Prody and Consy.



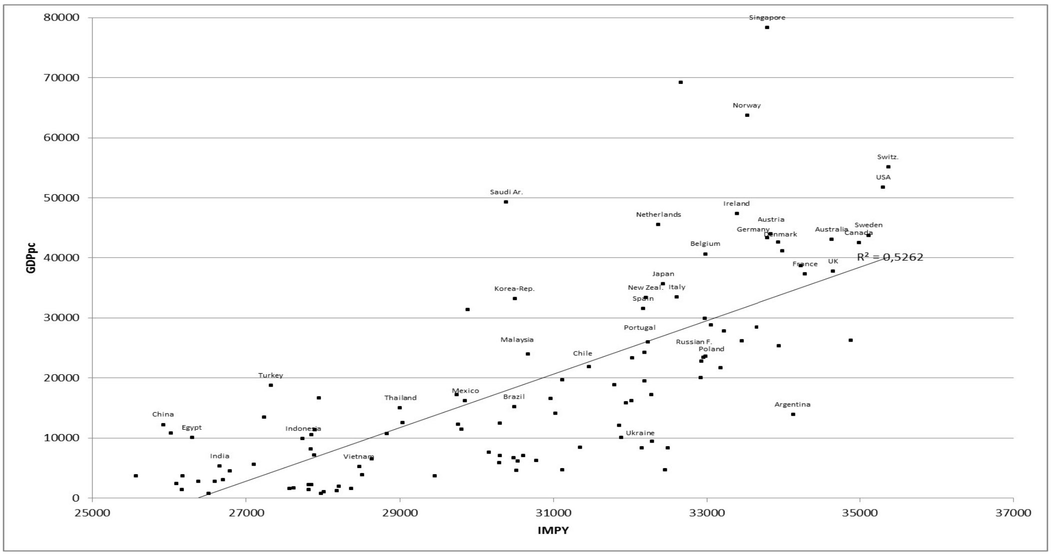
The subdivision of the quadrant of the graph into 4 sub-regions helps to interpret the meaning of the position of the different products in this graph. In the top-right area we find products with a value of both the indices above the average of the group. This is the case for products whose production and consumption is mainly located in rich developed countries and are highly processed and incorporate a higher value added. In the top-left region of the graph we find coffee (raw), tropical fruit, and other products whose main characteristics is to be produced in specific parts of the world, generally, low to mid level of GDP, but heavily exported into developed countries. This justifies the fact that their Consy is significantly higher than their Prody. In the bottom-right sub-quadrant we find fewer products that are also raw materials for the processing industry; however these are mainly exported by rich-developed countries that enjoys comparative advantages due to natural resources endowment (wheat, milk, and so on). In this case, the exporting countries are quite wealthy, while the buying markets are much more heterogeneous. Finally, the bottom-left area of the graph displays commodities or products that could be defined as "quasi-commodities" being semi-processed or semi-prepared which often are inputs for further stages of transformation. They features both Consy and Prody below the average values, but, with the only exception of the processed rice, are basically in the low-mid region of the ranking for both the indicators.

Figure 3 - The correlation between Impy and GDPpc



The Impy index shown in figure 3 is built on agri-food imports data. The graph opposes the import sophistication measure to the GDPpc. The figure displays data for 130 Countries while only the first 37 more important ones in terms of trade shares (either imports or exports of the Country shall be at least 1% of world total trade) are labelled. The first evidence shown by the graph is that there is a significant correlation between the Impy index and GDPpc (R^2=0.526), thus confirming the hypothesis on which the Impy is built and interpreted. At least for the limited case of the agri-food sector, we can affirm that, other things being equal, the more one country is well-off the more its imports basket include goods imported also by other rich countries, or, in other words, its imports are sophisticated. The distribution of the dots in figure 3 also shows, on one hand, that the relationship between GDPpc and Impy is tighter for higher income Countries and in particular for the European ones. On the other hand, relatively poorer Countries are more loosely located around the regression line. Ukraine and Argentine do not seem to follow the general rule as they are both Countries with a medium-low income level but their agri-food imports are relatively more sophisticated.

Figure 4 - A comparison between Impy and Expy for the agri-food trade



Finally, figure 4 explores whether Impy and Expy are associated to some extent. As always in this paper we limit to build Expy and Impy referred to agri-food trade. These are quite clearly correlated (R2=0.499), thus indicating that both indices catch elements that are relevant in influencing the composition and quality of traded products.

Moreover, the degree of association of the two indices leaves room for other relevant issues to play a role in the localisation of production and consumption and, consequently, as determinants of trade directions. The dotted line in figure 4 helps visualising the countries that do not reflect the average correlation. As expected, Countries rich in natural resources enjoy a comparative advantage in producing agricultural raw materials and commodities and, thus, their Expy is higher compared to their Impy. This is the case, for example, of rich Countries such as USA, Canada, Australia, but also of middle-to-low income Countries such as Argentina, Malaysia, Vietnam and others. Differently, the figure shows also the case of countries whose imports are much less sophisticated than their exports. This is the case of Egypt, China, Tukey, among others. These seems to be Countries where both income distribution and economic policies play a role in fostering economic growth via pushing exports while taking under control consumption levels.

4. Concluding remarks

The paper discusses new indices for describing and understanding international trade. These belong to the family of the so-called sophistication indices introduced about ten years ago with respect to exports. The indices here proposed consider imports instead of exports, following the standard hypothesis on consumption that the basket of demanded product is highly driven by income level. Within the limits of our field of observation, we think that the outcomes of the exercise are interesting and encourage further exploration of the theme. The basic results we obtained can be summarized as follows:

i) Goods for final consumption for which quality is much relevant and whose markets tend to be highly segmented are high in the Consy ranking;

ii) together with the previous goods, the higher positions in the ranking are also occupied by goods whose production/transport/conservation/marketing are costly and/or require complex technologies;

iii) on the contrary, at the bottom of the ranking there are basically simpler unprocessed (less processed) products, commodities, agricultural raw materials;

iv) better-off Countries tend to import sophisticated goods, i.e. goods that are also imported by other richer Countries;

v) the hypothesis at the basis of the concept and measure of import sophistication seem compatible and complementary to that one underlying the concept and measure of export sophistication. Both rely on visions of trade determinants that seem to be able to explain at list part of the observed flows.

More insights will come from deepening the analysis, including focusing on specific agri-food products and filieres, observing the time dynamics of the indices, but also analysing more in depth the sophistication level of imports of different sets of Countries that are differently related to competing supplying Countries and so on. The floor is open to further research and to a more articulated and integrated use of this "new family" of rather promising indicators.

DOI: 10.1481/icasVII.2016.c20c

ABSTRACT

The European Union is the world leading producer of wine. Since the introduction of the common market organization (CMO), the wine market has developed considerably. One of the main goal of the last wine reform was of making EU wine producers even more competitive preserving the best traditions of European wine growing and boosting its social and environmental role in rural areas.

The aim of this paper is to measure a multidimensional phenomenon, the "Competitiveness of EU wine business sector" in the nuts2 regions, through the use of a composite index. The results highlight both areas of the territory for which it is known the strong vocation and less known areas where you need to do further investigation.

Keywords: agribusiness, wine, enological vocation, composite index

PAPER

1. Introduction

The European Union is the world leading producer of wine. Between 2009 and 2014, the average annual production was 167 million hectolitres. It accounts for 45% of world wine-growing areas, 65% of production, 57% of global consumption and 70% of exports in global terms. Inside the European Union the picture is quite different among the Member States and the NUTS2 areas. Beside France, Italy, and Spain that are traditionally the largest EU wine producing countries, representing 81 per cent of total output, other Countries are significant in the sector as Germany, Portugal, Romania, Greece, Hungary, and Austria. And new Countries are emerging as Bulgaria, Croatia, and Slovenia. The aim of the paper is to try to measure the competitiveness of this sector in the EU nuts2 regions and its evolution in the period 2010-2013, through the use of a composite index. The source of data are the EU Farm Structure Surveys.

The competitiveness of EU wine business sector is clearly a multidimensional phenomenon since it is not possible to represent it only with a descriptive indicator; in fact, the phenomenon is composed of different dimensions that need to be considered contextually. In this regard, we have represented the phenomenon by three pillars: Structural, Entrepreneurial, and Qualitative. And each of the three pillars is composed of some individual indicators. In order to obtain a measure of each pillars and a "unique number" that represents the phenomena it is necessary to apply a composite index, combining the individual indicators. In fact, it is common awareness that multidimensional phenomena cannot be measured by a single descriptive indicator and that, instead, they should be represented with multiple dimensions applying methodologies known as composite indices. The paradigm of work for the measurement of these phenomena is developed as: 1) identification of a theoretical framework; 2) selection of the representative dimensions; 3) selection of individual indicators; 4) definition of the synthesis methodology (standardization and aggregation function).

2. The competitiveness of EU wine business sector

In the general context described in the previous section, the study and measurement of the competitiveness of EU wine business sector in the Nuts2 areas seems a necessary step in order to understand such an important sector for the economy and the social development of the rural areas. Among many factors, the structural characteristics of the viticulture, of the vineyard holding' management and of the quality production vocation are relevant and crucial in defining the capability of producing and marketing wine in a certain area. Therefore, three pillars have been chosen in this study, to represent the phenomenon:

Structural, Entrepreneurial, and Qualitative. Variables used are reported in Table 1.

Their relevance in regard to the pillar and the availability in official statistics of the parameters used have been the main criteria for choosing the elementary indicators. In fact, in order to select the individual indicators a formative approach is chosen: the selected individual indicators are causes of an underlying latent variable, rather than its effects. Therefore, causality is from the indicators to the concept and a change in the phenomenon does not necessarily imply variations in all its measures. In this model, the concept is defined by, or is a function of, the observed variables. In this case, indicators are not interchangeable (omitting an indicator is omitting a part of the underlying concept), the correlations between indicators are not explained by the measurement model (Diamantopoulos et al., 2008) and then their level is substantially negligible.

Table 1 - List of indicators of competitiveness of EU Wine business sector

Indicator	Pillar
Area under vines/utilised agricultural area	Structural
Vineyard holdings/agricultural holdings	Structural
Production value at basic price of the wine sector on agricultural output	Structural
Production value at basic price of the wine sector/resident population	Structural
Area of the specialised vineyard holdings/utilised agricultural area	Entrepreneurial
Specialised vineyard holdings/vineyard holdings	Entrepreneurial
Standard Output of the specialised vineyard holdings/Number of Specialised vineyard holdings (euro)	Entrepreneurial
specialist vineyard holdings marketing more than 50%	Entrepreneurial
Vineyard holdings with Standard Output >50.000 euro/vineyards holdings (%)	Entrepreneurial
Vineyard holdings with area under vines > 150 ha/Vineyard holdings	Entrepreneurial
DOC/DOCG area under vines/utilised agricultural area	Qualitative
Organic area under vines/utilised agricultural area	Qualitative
Organic vineyard holdings/agricultural holdings	Qualitative

3. Mazziotta-Pareto Index

The composite indices of competitiveness were constructed by the MPI (Mazziotta-Pareto Index). The MPI is a non-compensatory composite index that can be used to measure multidimensional phenomena, such as development and poverty (De Muro et al. 2011).

The index is designed in order to satisfy the following properties: (i) normalization of the indicators by a specific criterion that deletes both the unit of measurement and the variability effect; (ii) synthesis independent from an „ideal unit (i.e., a hypothetical geographical unit represented by the best values of the individual indicators), since a set of „optimal values is arbitrary, non-univocal and can vary with time; (iii) simplicity of computation; (iv) ease of interpretation.

The steps for computing the MPI are given below.

Let us consider a set of individual indicators positively related with the phenomenon to be measured. Given the matrix $\mathbf{X}=\{x_{ij}\}$ with n rows (geographical areas) and m columns (indicators), we calculate a standardized matrix $\mathbf{Z}=\{z_{ij}\}$ as follows:

$$z_{ij} = 100 + \frac{(x_{ij} - M_{x_j})}{S_{x_j}} 10 \qquad (1)$$

where M_{x_j} and S_{x_j} are the mean and standard deviation of the indicator j respectively.

Denoting with M_{z_i} and S_{z_i} ,respectively, the mean and the standard deviation of the standardized values of the area i, the composite index is given by:

$$MPI_i^- = M_{z_i} - S_{z_i} cv_i \qquad (2)$$

where $cv_i = S_{z_i} / M_{z_i}$ is the coefficient of variation for the area i.

This approach is characterized by the use of the product $S_{z_i} cv_i$ to penalize the areas with unbalanced values of the indicators. The 'penalty' is based on the coefficient of variation and it is zero if all the values are equal. The aim is to reward the units that, with equal mean, have a greater balance among the indicators values. Therefore, the MPI decomposes the score of each unit in two parts: mean level (M_{z_i}) and penalty ($S_{z_i} cv_i$) (Mazziotta and Pareto 2015).

The method provides a 'robust' measure and less 'sensitive' to inclusion or exclusion of individual indicators. In fact, over the past few years, the method has been subjected on several occasions both to influence analysis that to robustness analysis (through the introduction of a stochastic disturbance in the matrix) in order to verify the 'goodness of fit' compared to many other composite indices (Mazziotta C. et al. 2010). The results have always been the 'strength' of the method thanks to its statistical and mathematical properties. Three composite indices of Structural, Entrepreneurial and Qualitative enological vocation were computed by (1) and (2). Then, a global composite index was obtained by applying (2) to the three previous indices.

4. The results

The results of the global composite index, at NUTS2 level in European Union, are showed in Figure 1 and 2. The areas with highest values of the composite index (green in the map) are located in France (Figure 1). Languedoc-Roussillon has reached the highest score followed by Provence-Alpes-Cote d'Azur and Aquitaine.

Medium values of the composite index are recorded in some areas of Spain (La Rioja, Castilla-la Mancha, Region de Murcia), of Italy (Toscana, Abruzzo, Trento, Veneto e Friuli-Venezia Giulia), Austria (Burgenland), Germany (Rheinland-Pfalz) and France again (Alsace, Champagne-Ardenne, Corse and Bourgogne).

These results confirm the importance of some traditional areas under vines and are generally expected. Languedoc-Roussillon, for instance, is the single biggest wine-producing region in the world, being responsible for more than a third of France's total wine production

Figure 1 - Global index of the competitiveness of EU wine business sector. Year 2013

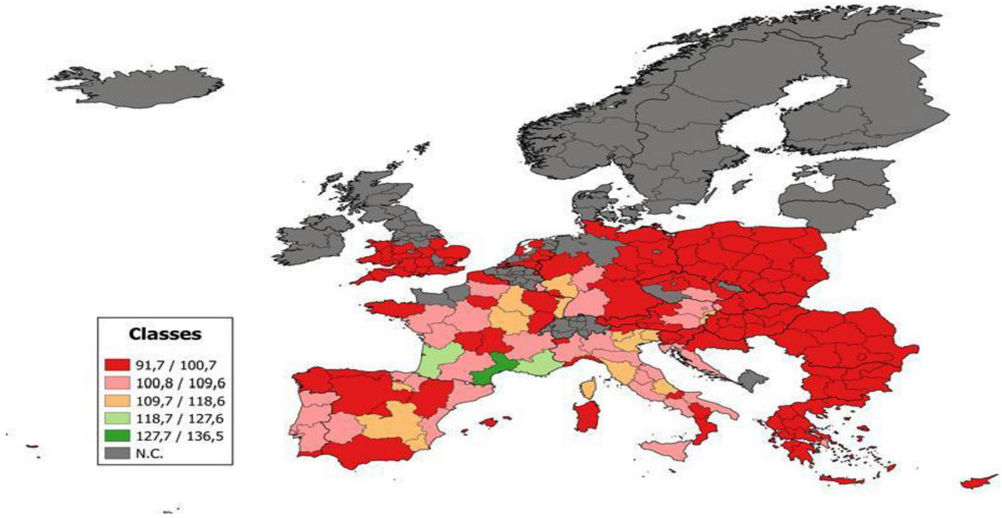

Figure 2 shows the results of the trend of the composite index in the period 2010 -2013.

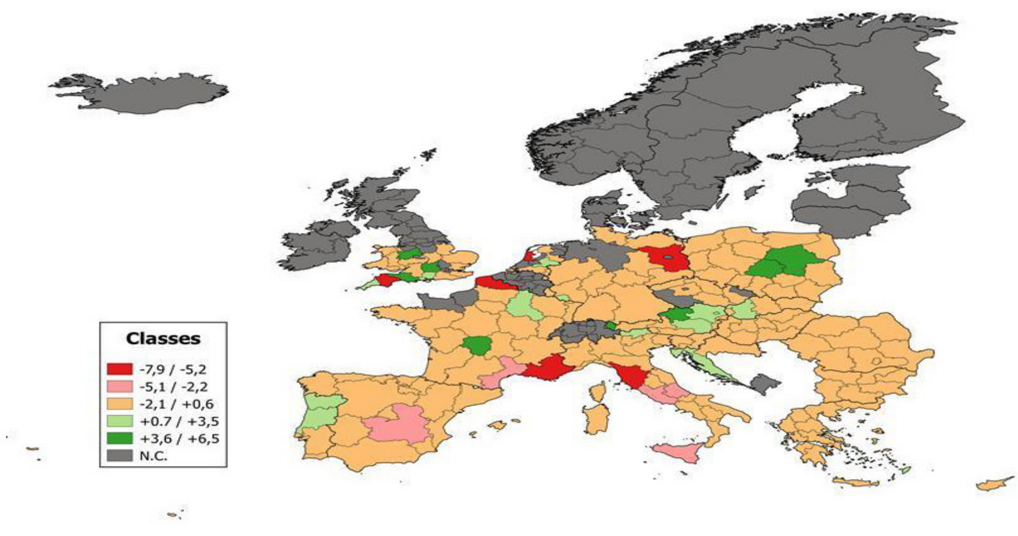
As can clearly be seen, the score of the areas in this figure is completely different from the first one. The most suitable areas reached generally less points than the emergent but still marginal areas in the business wine sector. This can be explained with the fact that the new areas have more rooms for improvement than the traditional ones. At the opposite, the leader areas have more difficulties to improve or to keep their front-runner position. The areas with the highest values of this composite index are located in some regions of United Kingdom, Austria, Poland and in France. While, among the areas with the lowest scores (red in the map) there are two very important for the sector: Toscana and Provence-Alpes_Cote d'Azur, immediately after Languedoc-Roussillon that was the leader region in the first map.

Figure 2 - Global index of the competitiveness of EU wine business sector. Trend 2010-2013



Let us have a look to the results of the simple indicators associated to the three dimensions. In the following maps the colours are in function with the score (more dark is the colour and more high is the value of the index).

Figure 3 - Simple index of the structural dimension. Year 2013 and trend 2010- 2013

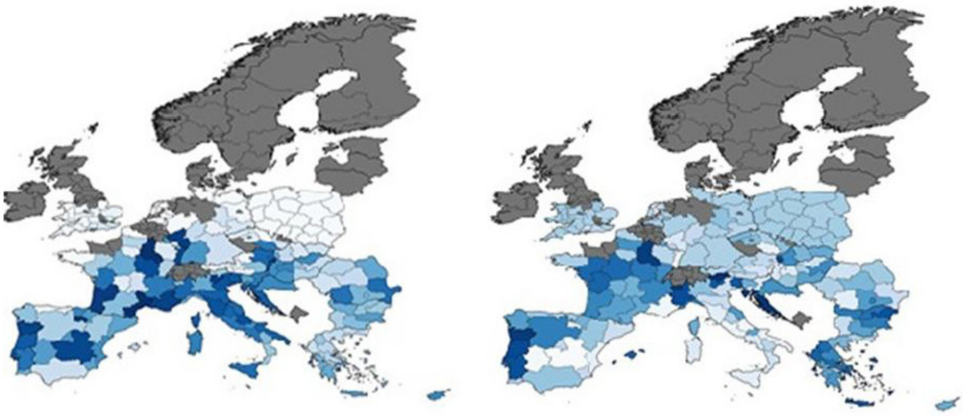


Figure 4 - Simple index of the entrepreneurial dimension. Year 2013 and trend 2010- 2013

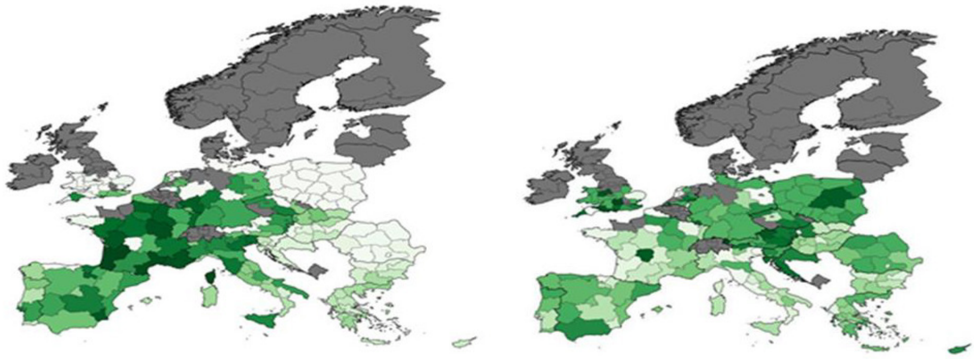

Figure 5 - Simple index of the qualitative dimension. Year 2013 and trend 2010- 2013

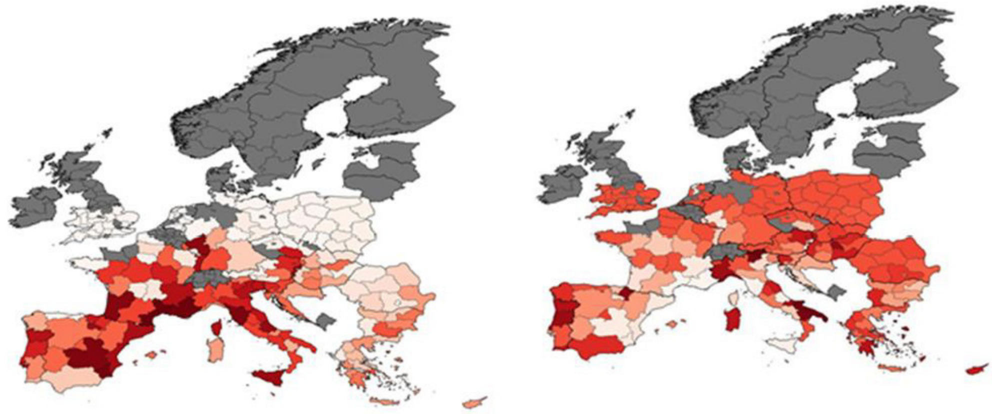

For the structural pillar (figure 3) areas with the best performances in 2013 are Languedoc-Roussillon, Champagne-Ardenne and La Rioja while in Bolzano/Bozen, Jadranska Hrvatska and Valle d'Aosta/ Vallee d'Aoste there have been the best trend.

France is the leader Country also in the entrepreneurial pillar (figure 4) placing 7 regions (Aquitaine, Corse, Languedoc-Roussillon, Bourgogne, Provence-Alpes-Cote d'Azur, Poitou-Charentes Champagne-Ardenne) in the first eight positions of the rank. The supremacy of the France in this pillar is broken only by the Region of Murcia (in seventh position). Considering the trend, United Kingdom has placed 3 areas in the first four positions of the rank (Berkshire Buckinghamshire and Oxfordshire, Dorset and Somerset, Shropshire and Staffordshire). Austria fit in the second position with Vorarlberg.

For the qualitative pillar (figure 5), France confirm its leadership placing Languedoc-Roussillon and Provence-Alpes-Cote d'Azur at the first two positions in the rank. They are followed by Region de Murcia, Toscana and Castilla-la Mancha. The trend shows as Italy is investing much in the quality wine. In fact, the first 5 regions in the ranking (Bolzano/Bozen, Puglia, Basilicata, Trento, Liguria come from this Country.

5. Final remarks

The study proposes a composite index to measure the competitiveness of wine business sector inside the European Union combining individual indicators distributed in three pillars: Structural, Entrepreneurial and Qualitative. We start from the assumption that the phenomenon considered is multidimensional and then it is necessary to reduce the dimensions.

The index, derived from the MPI method, classify the nuts2 areas in five classes, from the most devoted to the less devoted in the wine sector. The temporal reference of the analysis is 2013 and 2010-2013 trend.

The results confirm the leadership of the traditional Countries (France over all, followed by Spain and Italy) and rank the European regions according to the three pillars. Less expected are the results of the indexes on the trends that show, even in a very short time of the three years, the improvements of an emerging Country as United Kingdom (in the entrepreneurial dimension) and of a traditional one as Italy (in the structural and qualitative dimension). The UK is become a premium wine-producing region, with around 500 vineyards in England and Wales covering some 4,500 acres and producing sparkling and still wines. English and Welsh wines have also been winning many prestigious awards.

Further developments of the work could be to improve the number of the simple indicators in each pillar and to weight the simple indicators.

FAO's new macro-economic statistics: Agricultural Capital Stock and Agro-Industry Measurement

M. Vander Donckt | FAO, ESS Division | Rome | Italy
S. Dubey | FAO, ESS Division | Rome | Italy

DOI: 10.1481/icasVII.2016.c20d

ABSTRACT

This paper reports on recent work in FAO's Statistics Division (ESS) in developing two new global agricultural statistics databases: an analytical database that estimates agricultural capital stock, and a database on agro-industry measurement (AIM). It describes the data sources, methodology and content of these databases, which provide key national accounts type indicators.The overall approach relies on the use of internationally accepted methodologies and the harvesting of data compiled by multilateral agencies, to minimize burden, duplication of efforts and inconsistencies. Priority is placed, where possible, on the use of official country data reported to these agencies. The paper also presents some key results from our cross-country analysis performed based on the databases. It is set to illustrate how the new databases can help improving our understanding of how countries can benefit from the links between agriculture and agro-industrial development and how agriculture and agro-industry can contribute to economic development. The objective of this paper is to solicit feedbackon the data sources, methodologies, indicators, and overall approach in order to enable improvements and establish key next steps.

Keywords: Agro-Industry Measurement, Capital Stock, Gross Fixed Capital Formation.

PAPER

1. Introduction

As economies grow and develop, the productive landscape undergoes structural transformations, sectors become more interrelated, and determining the importance of any specific sector becomes difficult. This is certainly the case for agriculturewhere agricultural production understates the sector's overall contribution tothe economy through its links to numerous industries such as fertilizer production, food processing and manufacturing, transportation, wholesale, and retail distribution.This raises the questions about the relative roles of these sectors as an economy develops, the impact of agriculture on the entire value-chainand the drivers behind time trends and country-level differences.

To answer these questions and to meet the growing need for consistent statistics to measure the agriculture value-chain, FAO s Statistics Division (ESS) began construction of a new FAO "Macro-Statistics domain" that covers two main areas: the "Agro-Industry Measurement" (AIM) and the "Agriculture Capital Stock" (CS) database. The AIM helps determine agriculture and food-processing industry contributions acrosscountries and time. The CS database aims at providing analytical statistics on capital stock and its components in order to inform questions about investment and productivity.

These databases use the System National Accounts (SNA) framework to ensure data comparability over time and across countries. To reduce burden and duplication, they integrate information from existing international databases from the UN Statistics Division (UNSD), the OECD, the World Input Output Database (WIOD) consortium, and UNIDO. These databases have the advantage of covering a large set of countries, and their use minimizes burden, duplication and effort, while maximizing efficiency and coherence.

The AIM and CS are analytical databases providing provisional indicators. While official country data is the backbone of these indicators, the databases require a significant number of imputations, estimations and assumptions. Data sources and assumptions are well documented, in the hopes that official country statisticians and other experts will help validate or improve the databases and the underlying assumptions, and where possible, provide official country data to replace missing data.

To provide some additional insight to the importance of such data, the rest of this section describes some key trends in the GDP contribution of the agricultural sector and the food processing industry. This rest of this paper presents a technical roadmap to the development of the AIM and CS databases. Section 2 proposes an in-depth description of the database content and the overall approach to database construction. Section 3 discusses the main data and methodological challenges and how they are addressed. Section 4 presents analysis and key findings in order to illustrate some of the potentialities of the database. Section 5 concludes.

2.Database Content and Overall Approach

2.1.Data Coverage

The basic set of variables covered in the AIM and CS databases includeValue-added, Gross Output, Gross Fixed Capital Formation (GFCF), and Net and Gross Capital Stock. These variables are provided in both local currency units (LCUs) and US dollars; current and constant prices for capital stock variables. The built-in indicators include productivity-related indicators, such as the AIR (agriculture GFCF to agriculture value-added); value added shares, such as the Food, beverage and tobacco (FBT) value-added share of manufacturing and of GDP; and the Agriculture Orientation Index (AOI) for capital formation, which normalizes agriculture's physical investmentratio by that of the total economy. Capital related variable are currently limited to the agriculture sector in the current version of the database.

The sector's and industries cover the following:

- Agriculture, forestry and fishing (ISIC Rev. 3 divisions 01 to 05);
- Food-processing activities covered by ISIC Rev. 3 divisions 15 and 16, which includes the FBT industry sector.

The current geographical coverage includes over 200 countries and territories, though for the food-processing variables, indicators have been constructed for a reduced sample of 46 countries captured in the OECD and WIOD databases. Subject to resources, the intention is to expand geographic coverage of the food processing sector, subject to data availability, and to expand variable coverage to include among others trade variables. At update, the targeted time span for data coverage is 1970 to year-2.

2.2. Overall Approach to Database Construction

The methodology in compiling both databases followed similar steps. A first step was to identify and bridge data across sources. The second was to estimate missing values for countries that had reported at least some official data, using established statistical estimation and imputation methods. A third step was to calculate final indicators, which included current price versions in both local currency units (LCUs) and US dollars; constant 2005 price indicators in LCUs and USD for capital stock variables; and the above-mentioned set of built-in indicators.

The original data sources used in compiling AIM and CS were as follows:

- United Nations Statistics Division, National Accounts Estimates of main aggregates
- (NAE), and official country tables;
- OECD, STAN and National Accounts databases;
- WIOD, Socioeconomic accounts;
- World KLEMS; and
- UNIDO, INDSTAT database.

Section 3. Data and methodological challenges

3.1. The Agriculture Value Chain and the Input-Output Model

The original motivation for the AIM project was to develop a database tomeasure the farm-to-fork contribution of the agricultural sector. In its widest concept, the agriculture value chain would coverall economic operations involved in the production and distribution of products that originate from or are used in the production of agriculture output. The first challenge was to define a framework for measuring the agriculture value chain. TheInput-Output (IO) model,developed by W. Leontief in the 1930s, was acknowledged as one of the most powerful tools to measure a value-chain as well as a sector's full contribution to an economy through its inter-sectoral linkages. In particular, the IO model shows how output of one sector is used as an input into another sector, showing sectoral interdependenceby identifying buyer of outputs and supplier of inputs. Due to the resource and time intensity of this approach, limited IO data available for developing countries, and lack of timeliness in the IO data that is available, this approach was discarded in favour of the approach used: to integrate and bridge existing national accounts data/indicators across multiple data sources. However, the absence of an IO framework is also creating challenges in measuring the agriculture value-chain, and determining where to start.

3.2. Agro-Industry, Definition Issue

Because the agriculture value chain includes all the suppliers of inputs to agriculture, and all the users of its outputs, direct and indirect, the project needed to first measure a narrow portion of this value-chain. FAO value chain experts recommended the project begin by focusing on the Agro-industry, starting with the food-processing industry. This was recommended both due to constraints on data availability, and due to the absence of international statistical definitions that covered the breadth of the "agro-industry."

An important future step for FAO will be to help define "agro-industry," a request frequently received by both FAO and theUN Statistics Division (UNSD).

3.3. Bridging of Series for AIM and CS Databases

In the actual compilation of data, an important first important database construction stepis to identify and bridge data acrosssources and across varying methodological and classification versions in order toensure time-series continuity and comparability. For both databases, series are rescaled whenever necessary to match the ISIC Rev. 3.1 classification of economic activities and the 1993 version of the System of National Accounts (SNA).Continuity of long time trends is particularly important in constructing indicators such as GFCF, the basis to our capital stock estimations. In bridging data, the first step is to bridge within an input data source, such as between the SNA and ISIC revisionswithin the UNSD National Accounts Official Country Data.The second step is to bridge across data sources.

3.4. Agricultural CS: New Methodology based on the Perpetual Inventory Method

In developing a new agricultural CS database, two approaches were considered. The first is to estimate capital stock using the physical inventory approach, which adds up the sector s components of produced assets. Physical investments in capital, or capital formation, can then be calculated as changes in capital stock between two time periods. In the case of agricultural capital stock, produced assets include land development, machinery and equipment, farm structures, livestock, and orchards. This approach, which had been previously used in a FAOSTAT agriculture capital stock series, was evaluated and abandoned due to several factors:

- Data quality issues in the underlying datasets: This arose in part from low and declining response rates to the FAO questionnaire sent to countries, and low rates of questionnaire completeness. This problems also resulted in limited country coverage.

- Methodological issues in component calculations: A large number of assumptions were required to calculate capital stock components, such as estimating land improvements from land value.

- Exclusive focus on the narrow agriculture sector: the approach excluded forestry and fisheries, making it more difficult to benchmark the capital stock estimates even against those published by some countries in their national accounts, covering the broader "agriculture" sector.

The second approach, adopted by FAO, is to use the internationally accepted perpetual inventory method (PIMs). In this approach, capitalstock in one period is the sum of capital stock in the previous period, plus the current periodflow of capital investments (GFCF) minus the consumption of fixed capital. The central equation to compile net capital stock (K) is

$$K_t = K_{t-1} + GFCF_t - \delta * \left(\frac{GFCF_t}{2}\right) - \delta * K_{t-1} + X_t, \quad (1)$$

where $K_t$is the net capital stock at the end of year t;$GFCF_t$ is gross fixed capital formation in year t; the term $\delta*(GFCF_t/2+K_{t-1})$ measures the consumption of fixed capital in year t, or total depreciation;and X_t is the "other changes in volumes" of the group of assets and it is set equal to zero[1].If series on GFCF are available, this method requires assumptions about the initial stock of capital in $t_0$as well as the depreciation rate.

Depreciation rates, δ.

The first step towards computing the net stock above is to select a rate of consumption of fixed capital, δ, also known as the depreciation rate. In the absence of good information about rates of depreciation, δ can be set in reference to other countries' depreciation rates of similar types of assets or other countries' service lives of similar types of assets.

Following Hulten and Wykoff (1996), we apply the declining balance model that converts an average service life of a group of assets, TA, into a depreciation rate, δ. They propose a two-step procedure based on the 'declining balance' formula:

$$\delta = r/T^A, \quad (2)$$

where parameter$r$ is an estimated declining-balance rate.

In order to fix the depreciation rate and assuming the declining balance model of depreciation in the FAO capital stock database, we need thus to make assumptions on the value of the declining balance parameter, r, and on the average service life of agriculture, T^A.

[1] Other flows are changes in the value of assets and liabilities that do not result from transactions. Examples are losses due to natural disasters and the effect of price changes on the value of assets and liabilities. For more, see SNA2008, paragraph 3.99.

Our review of practices by national statistical offices that apply the declining balance model tend to support a value of r greater than one. In the FAO capital stock database, we assume a unique declining balance parameter common to all countries for which agriculture capital stock has to be estimated that we arbitrarily fix to 1.5.

As for the average service life of assets used in agriculture, it is clear that service lives differ depending on the type of assets considered with structures having the longest average service lives. The average service lives varies also considerably among countries.

We arbitrarily fix T^A to be equal to 25 years. Combined with a declining balance parameter value of 1.5, the derived depreciation rate used in the FAO capital stock database is δ = 1.5/25 = 0.06.

This depreciation rate is consistent with implicit average depreciation rates retrieved using country series on NCS and GFCF for select countries.

<u>Initial capital Stock.</u>

Once a depreciation rate is selected, the next step is to estimate a starting stock of capital. According to Kholi (1982), a simple approximation can be used when geometric age-price profiles apply for thenetstock at the beginning of the benchmark year *t0*:

$$K_{t0} \approx [GFCF_{t0-1} + (1-\delta)\, GFCF_{t0-2} + (1-\delta)^2 GFCF_{t0-3} + \ \dots] \qquad (3)$$

Assuming that the long-run growth in the volume investment is equal to the long-run growth rate of volume agriculture value-added, θ: $GFCF_t = GFCF_{t-1} * (1+\theta)$; and inserting this relation into the equation above, the initial capital stock at the beginning of period *t0* is approximated by :

$$K_{t0}(geometric) \approx \frac{GFCF_{t0}}{(\delta+\theta)} \qquad (4)$$

3.5. Estimating the GFCF Series

Calculating capital stock in periods after t0requiresa relatively long and bridged time series of national accounts variables, particularly on GFCF for agriculture ($GFCF_{AFF}$), but also on auxiliary variables used to estimate missing GFCF variables. Imputation and estimation of missing valuesused a combination of hot deckimputation methods (carrying forward data from previous years for a country within a data series), cold deckimputation(using data from a “nearest neighbour”, in terms of structure and level of economicdevelopment, measured by GDP/capital), and linear interpolation.

The Agriculture Investment Ratio (AIR) was used to construct the $GFCF_{AFF}$ series in the FAO Capital Stock database, where $AIR=GFCF_{AFF}/VA_{AFF}$. The following two-steps procedure was used:

- Estimate the AIR in time *t* for country*i*, through regression analysis;
- Compile the level of investment in agriculture by applying the AIR to value-added:

$$GFCF_{AFFi,t} = AIR^{estimated}_{i,t} * VA_{AFFi,t}. \qquad (5)$$

Two approaches were used to compile AIR series: the first for countries with fully missing AIR data; the second for countries with some but incomplete AIR series.

3.5.1. Estimation of AIR for countries with fully missing series.

The estimation of the AIR for countries with fully missing series is based on panel data analysis, derived from an input datasetcovering 86 countries thathave AIR observations. Data in the input dataset model and estimate the AIR, our dependent variable, based on one or more independent variables. The fitted model infers an AIR series for those countries with missing agriculture investment data.

The approach follows the followingsteps.

1) **Model pre- selection**: Potential predictors considered for inclusion in the model were: log of GDP per capita; log of real GDP (measured in 2005 USD); the trade openness index in agriculture; the total economy investment ratio; the annual GDP growth rate; total population; and VA in agriculture as a

share of GDP. The list of explanatory variables was determined, in part, by data availability. For instance, employment in agriculture and VAAFF over employment in agriculture would have been interesting variables to include and to test for in the regression analysis, however due to lack of consistent data, these variables haven't been included in the analysis so far.

Countries were divided into two sets: low income countries and middle- and high-income countries (separation criterion set at 10,000 USD of GDP per capita, 2011 value).The best models for each set wereselected based on stepwiseregression and on the leaps-and-bounds algorithm (Furnival and Wilson, 1974).

2) **Regression method**: Once the benchmark model was chosen, different regression methods were assessed: pooled OLS, panel fixed-effects (FE); and panel random-effects (RE). The FE method was selected based on the following results:

a. OLS vs. RE: Breush-Pagan Lagrange multiplier. The null hypothesis of no panel effect (no significant difference across units) was rejected, and the RE model selected.

b. FE vs. RE (and OLS): Hausman test. Reject the null hypothesis of a RE. By transitivity, the OLS specification is also rejected (it can be shown that the RE is equivalent to an OLS generalized for panel effects).

3) **Sensitivity analysis and MSE based evaluation**: We next perform an in-sample Mean Square Error (MSE) analysis of the AIR estimated under our alternative model specifications and we select the final benchmark model that will be used for the underlying estimation of GFCFAFF for countries with fully missing series based on MSE and the by-country Symmetric Relative Efficiency measure, following Tratar and Toamn (2014), which is defined as:

$$SREM_{model\,1/model\,2} = \begin{cases} 1 - \frac{MSE_{model\ 1}}{MSE_{model\ 2}} & for\ MSE_{model\,1} < MSE_{model\,2} \\ \frac{MSE_{model\ 2}}{MSE_{model\ 1}} - 1 & for\ MSE_{model\,1} \geq MSE_{model\,2} \end{cases} \quad (6)$$

3.5.2. Imputation of AIR for countries with incomplete series

In this sub-section we discuss alternative techniques to fill incomplete time series on AIR. While, the targeted time coverage for publication in the capital stock database is 1970-2014, most countries present incomplete time series with missing data for the most recent years that have be imputed. The length of "missingness" varies across countries from just a couple of years to over two decades.

Approach 1: Constant ratio

The first approach imputes a missing AIR as an average of the last three to five years of available AIRs. This technique is naïve in the sense that it does not identify and, therefore, fails to project, any trend or cyclical component embedded in the time series.

Approach 2: Exponential Smoothing

Forecasts produced by exponential smoothing models are exponentially weighted moving average of past observations. As such, these models extract information endogenous to the historical time series regarding its four components – level, trend, seasonality, and noise – and use it to produce forecasts.

In the second approach, the ETS package in R (Hyndman et al., 2008) was used to forecast missing values. The ETS statistical framework allows selection of the best exponential smoothing model based on the AIC information criteria. In total, 30 model combinations are possible in the ETS framework depending on the type of trend and seasonal components considered (e.g. additive/multiplicative/damped additive/damped multiplicative trend, etc.) as well as on the underlying statistical model (additive vs. multiplicative errors).

This approach is better able to capture trend and/or cyclical components contained in the historical profile of the series. However, the information in the series is insufficient to address the structural break in countries' agricultural investment profiles that originated from the financial crisis.

In the next two sections we present the results obtained from applying time series regression techniques that allow for the inclusion of exogenous variables: the ARIMAX and, its generalization, the autoregressive distributed lag model (ARDL). These methods are preferred as they make use of both the information embedded in the historical series of the indicator under consideration and the knowledge of relationships between the indicator and external factors so that special events as the crisis can be account for.

Approach 3: ARIMAX

In the third approach, we fit ARIMA class models with exogenous variables before using the best model for forecasting purposes. The autoregressive integrated moving average model including exogenous covariates, ARIMAX(p,d,q), extends the

ARIMA(p,d,q) model by including the linear effect that exogenous series have on the stationary response series y_t. The general form of the ARIMAX(p,d,q) model is

$$\phi(L)y_t = c^* + x_t'\beta + \theta^*(L)\varepsilon_t \qquad (7)$$

where $c^* = c/(1-L)^d$ and $\theta(L)^* = \theta(L)/(1-L)^d$. Vector x_t'holds the values of the r exogenous, time-varying predictors at time t, with coefficients denoted β. We use this model to check if a selection of exogenous variables has an effect on a linear time series.

It should be noted that ARIMAX models have the same stationarity requirements as ARIMA models. If the response series y_t is not stable, we need to difference it to form a stationary ARIMA model with d degrees of integration. In addition, it is also required to assess in the pre-estimation phase whether the predictor series x_t are stationary and to difference them if necessary. If $x_t$is nonstationary, then a test for the significance of β can produce a false negative. As usual, the practical interpretation of β changes if you take a transformation (difference) the predictor series.

For each country, we perform a best model fitting exercise looping through a maximum of 144 models (8 combinations of explanatory variables times 18 possible combinations of ARIMA(p,d,q) specifications). The preferred model is selected based on the BIC minimization criterion, we then backcast/forecast the country series using preferred model.

Approach 4: Auto-regressive distributed lag model (ARDL)

The fourth approach tested relies on the autoregressive-distributed lag (ARDL) model, which takes the following general form:

$$y_t = \alpha + x_{i.t-q}^{'}\beta_i + y_{t-p}^{'}\gamma + \varepsilon_t, \qquad (8)$$

whereE_t is a random disturbance term that is assumed to be serially independent. The model is autoregressive in the sense that it contains one or more lagged values of the dependent variable, yt..The model also has a distributed lag component, in the form of successive lags of the explanatory variables, xt. A model containing p lags of y and q lags of x is denoted ARDL(p,q).

Due to too short a time series and because of multicollinearity in the data, the ARDL approach fails in most cases. We therefore prefer the ARIMAX based approach.

3.5. Food-processing industry.

The AIM database uses national accounts (NA) variables for the FBT when available, as for many OECD countries, and the INDSTAT2 database from UNIDO, otherwise. Since INDSTAT2 data are based on national industry surveys, which do not correspond to NA data for coverage and conceptual reasons, the INDSTAT2 series is re-scaled and estimated to national accounts levels. Re-scaling is performed using composition ratios, such and manufacturing to total economy value-added.

Since indicators relating to the food-processing industry are jointly compiled with UNIDO, and UNIDO provides a complete series, see Boudt et. al. for the methods used to impute missing data.

4. Analysis and findings

In this section, we present and comment a few results extracted from the new FAO macro-statistics database. We first look at the relative contribution of agriculture and food processing.Looking at select countries, Figure 5 shows that agriculture as a share of GDP tended to decline between 1970 and 2013, while food processing remained relatively stable.

Figure 6 presents the value-added share of food and beverages processing in total manufacturing against the contribution of manufacturing to total GDP, and shows the resilience of the FBT sector even during crises such as the 2009 Financial Crisis. This can be interpreted simply by the fact that the population still needs to eat, that is there is a low income elasticity of demand for food and beverage products.

Figure 1 - Contribution of Agriculture and Food-processing to GDP.

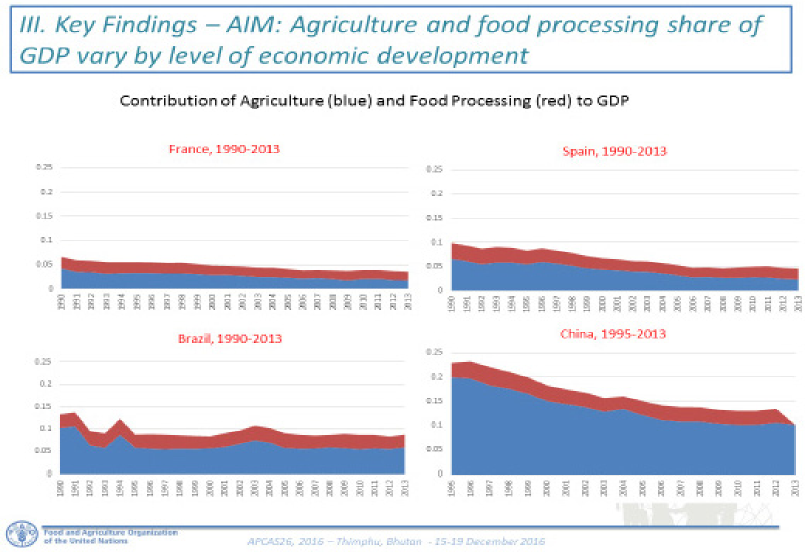

Figure 2 - Resilience of the Food-Processing sector

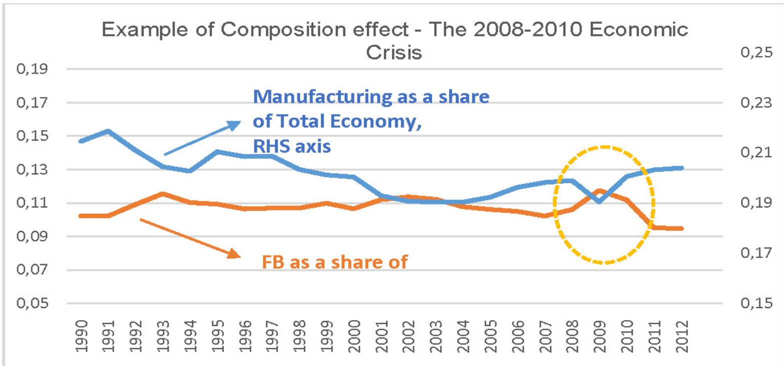
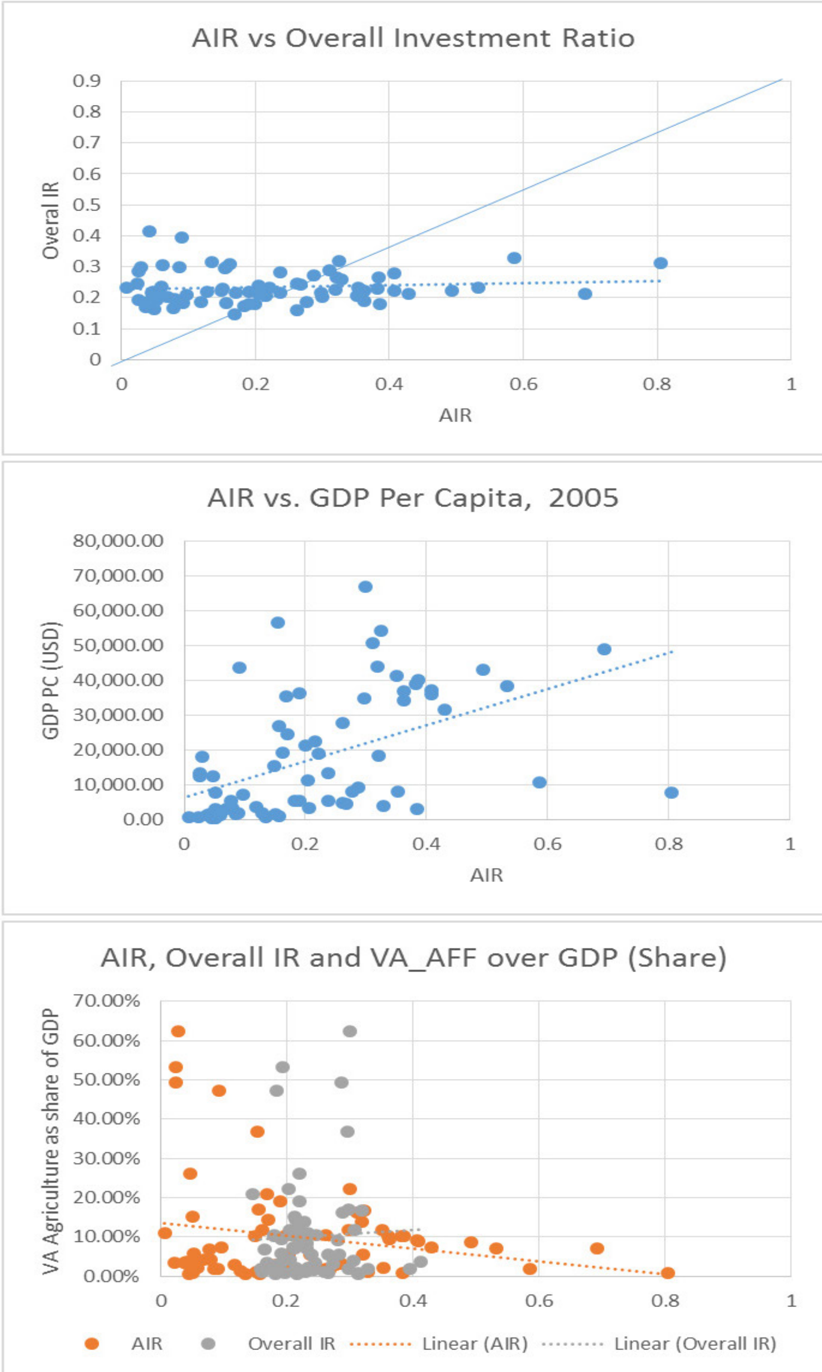


Another possible line of analysis bears on capital stock related variables in the agriculture sector.[2] The following set of graphs present the AIR as defined in Section 3 against a set of economic variables.

The upper part of Figure 8 indicates that there is no clear positive relationship between the overall investment ratio (calculated for the total economy) and the AIR. It also shows a larger variability of the AIR relative to the overall economy investment ratio. When presenting the AIR against GDP per capita, we instead find a clear positive relationship; and when presenting against the agriculture share of GDP, we find a negative relationship (i.e. countries with a high agriculture share of GDP tend to have a low AIR).

[2] The insertion of capital stock variable for the food processing sector will constitute an extension of the current AIM database.

Figure 3 - AIR against overall investment ratio, agriculture VA and GDP (2005 data)



An interesting pattern (Table 1) emerges between the AIR and the overall investment ratio when we divide the countries into two groups, low-income countries versus middle- and high-income countries. While countries in both groups present a similar average overall investment ratio, the average AIR is much lower in low-income countries, indicating that in those countries – where agriculture often remains an important contributor to GDP – the primary sector is behind in terms of investment in physical capital with respect to the other sectors of the economy. On the other hand, industrialized countries tend to have much more mechanized agriculture sector.

Table 1 - Average AIR: Total economy vs. Agriculture

(all years)	All countries	Low income countries	Middle- and high-income countries
Avg. AIR	0.214	0.109	0.255
Avg. Overall IR	0.231	0.222	0.235

5. Conclusion

The aim of this paper is to present a new macro-statistics database developed by the statistics division FAO, in order to meet the growing need for consistent statistics measuring agricultural capital stock and the agriculture value-chain.

While largely based on secondary data, the database construction implies a large number of data challenges to be overcome, from integrating series based on different SNA versions and classification systems, to imputing missing values, to making assumptions about depreciation rates. This leaves wide scope for further improvements, as country experts provide better information and replace FAO estimates with their own, as well as extensions of the database in terms of geographical, variable and subsector coverage.

It is hoped that presenting the work and making available the databases in 2016 will facilitate the type of feedback that will lead to an even more useful evidence-base for agriculture and food policies.

ABSTRACT

In the era of climate change uncertainty, water scarcity, soil fertility degradation and disease-pest dynamics, it is hard for the farmers to obtain the optimized yield and sustain their agri-business. This has led to increased incidents of farmer suicides and has a direct impact on the India's food security. To make agriculture sustainable, an integrated analytically enabled Digital Farming Platform - ***InteGra*** (derived from **Inte**lligent **Gra**m (Village)) – has been proposed. InteGraprovides holistic services, including efficient crop planning, operations scheduling and management by minimizing climate and market risks.The resulting "climate smart" and "market smart" entities called ***SmartPRIDEs*** (Smart Progressive Rural Integrated Digital Enterprises) can transform the lives of millions of farmers across the globe and lead to self-sustaining and economically viable farming. The business model around ***InteGra*** is inclusively designed to bring together agricultural input and output companies, financial and insurance institutions, and policy makers with the appropriate clusters of farmers on the same platform enabling the formation of a mutuallybeneficial and self-sustaining, vibrant ecosystem.

PAPER

1. Introduction

Agriculture plays a vital role in India's economy. The GDP of Indian agriculture reached US $259.23 billion in FY15 while providing livelihood to nearly 58% of the population and is one of the largest contributor to the Indian GDP [1]. However, all is not well in this sector. India is home to 25 percent of the world's hungry population [2]. India ranks 55 among 63 countries on the Global Hunger Index (2015) and 135 among 187 countries on the UNDP Human Development Index (2014), [3]. Food production has seen only a marginal increase over the past 20 years while there has been an exponential jump in the population. Productivity is extremely low due to unscientific farming practices, fragmented land holdings, lack of agro-climatic focus for crops selection and access to the right farming advice at the right time. Thus food security is a rising question to feed the growing population.

Food security is a situation that exists when all people, at all times, have physical, social and economic access to sufficient, safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life [4]. Climate change is a fundamental threat to global food security, sustainable development and poverty eradication [5]. Anticipating appropriately the impact of climate change on agriculture requires data, tools and models at the spatial scale of actual production areas [6]. There is an urgent need to organize farming groups which will enable affordability to use modern technologies for sustainable agricultural development.

In order to make Agri business sustainable within the farmers groups, the PRIDE™ (**P**rogressive **R**ural **I**ntegrated **D**igital **E**nterprise) model has been proposed for farmer cooperatives and similar setups [7]. PRIDE™s leverage the power of farmer social networks and ensure that the farmers are able to reassert their place in the agriculture value-chain. To empower PRIDE™s and all associated stakeholders with precision agriculture capabilities obtained from various sensors and other data sources, we propose an integrated digital farming platform –***InteGra***empowered by advanced analytics systems.

PRIDE is digitally enabled a collective group like a cooperative or a farmer producer company is the central channel through which various business and agricultural activities are carried out. This collective group is generally an entity that operates in the field to connect various organizations like agri-input industries, food-processing industries, government organizations, financial institutions, agricultural machinery industries and the stakeholders, i.e. the farmers. In addition, they also trade in large quantities collectively associating with all the farmers.

Through a process of cyclic data optimization involving continuous data collection from the field, data analytics on the backend and directing on-field operations on the basis of intelligence derived from the data, the PRIDE™s are converted into ***SmartPRIDEs. InteGra*** augments the PRIDE™ with precision farming capabilities facilitated through intelligent decision support. **InteGra** is supported by a proprietary, patented scouting application, Intelligent Rural Integrated Sensing (IRIS)which facilitates data collection from the PRIDE™ group of farmers. The regional level agricultural knowledge and data is being stored in an Agriculture Knowledge Base, (AgriKnoBTM), which enables experts to provide recommendations.

As a first step towards transition to ***SmartPRIDEs, InteGra*** offers a variety of services such as crop and variety selection, disease and insect pests' incidence forecasting for selected crops, weather, fertilizer recommendation, irrigation scheduling, market price predictions, and valuation of crops based on consumer pay-off. It is believed that the advanced services for the famer groups in **SmartPRIDE**s will not only lead to a self-sustainable livelihood but also ensure the food security in a collective manner through the formation of an increasing number of intelligent farmer groups.

2. The Analytical Framework of InteGra

The key capabilities of **InteGra** can be captured by the 4As: Acquire, Analyse, Advise, and Actuate. **InteGra**has various components such as *KwikSense, aNutva, ChurnBot, DataPlus, mPush* and CROPS that play a key role in enabling these capabilities.KwikSense can acquire data from personalized sensors installed in farms and can also actuate farm-equipment. aNutva (analytical tool) and *ChurnBot* provide a mechanism to plug in rule-based and statistical algorithms that give useful results from a variety of data sources. Integrated data management is carried out with *DataPlus*. Data is the key driver for the **InteGra** analytical engine to provide intelligence for the farming business. Farming activities depend on multiple phases with inputs from a variety of sources. Hence, data from the corresponding sources is required for better decision making. The cultivation of a crop can be divided into the following four phases.

Table 1 - Cropping phases and Activities

Phases	Present or Upcoming Activities
Phase 1 – Crop Planning	Crop Selection based on Resource estimates, Farmer Constraints, Historical Climatic Conditions and Localized Weather Forecasts, Market demand
Phase 2 – Aggregation and Ordering	Aggregating the Input Requirements across the PRIDE™ and ordering for timely delivery
Phase 3 – Crop Cycle Management	Crop Advisory, Farm Management, Plant Protection, Fertilizer recommendation,Certification, Yield Monitoring & Irrigation scheduling
Phase 4 – Harvest Planning	Crop Valuation and Market Linkages

The core component of InteGra, Crop Rotation, Optimization and Planning System (CROPS™), provides recommendations on the appropriate crops taking into account macro parameters like the historical climatic conditions, market dynamics and micro parameters like the farmer constraints, localized weather conditions, soil fertility and projected market demand. For the selected crops, the revolutionary **InteCrol** (Integrated Crop Protocol) is created by the system. **InteCrol** is the DNA of the platform and has embedded within it a wealth of information which is used by all the downstream phases as well as by various stakeholders in the agricultural value-chain. We discuss in the following sections a variety of analytical techniques that help in critical decisions for the different crop phases:

Crop and Variety Selection: The crop selection is the first and vital step of the entire cropping cycle, which falls under Phase 1- Crop Planning. The selection process is based on two criteria.

Crop Selection: The crops are selected based on the maximum return on investment, considering the resource availability (can be based on quantity orcosts), Agro climate, Soil conditions and market price availability. The Linear – Programming model is used to select the best possible crop and area of cultivation. Following is the Linear Programming model in Matrix form.

$$\text{Maximize } [S_1 \quad S_2 \quad \dots \quad S_n] \begin{bmatrix} x_1 \\ x_2 \\ \dots \\ x_n \end{bmatrix} \qquad (1)$$

$$\text{Subject to } \begin{bmatrix} 1 & 1 & \dots & 1 \\ I_{11} & I_{12} & \dots & I_{1n} \\ I_{21} & I_{22} & \dots & I_{2n} \\ \dots & \dots & \dots & \dots \\ I_{m1} & I_{m2} & \dots & I_{mn} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \dots \\ x_n \end{bmatrix} \leq \begin{bmatrix} L \\ I_1 \\ I_2 \\ \dots \\ I_m \end{bmatrix}, \begin{bmatrix} x_1 \\ x_2 \\ \dots \\ x_n \end{bmatrix} > 0 \qquad (2)$$

where,

$S_i = Selling\ price;\ I_{ji} =$
$Inputs\ allocation$ (Fertilizer, Pesticides, Labour etc.) $with\ respect\ to\ crops;\ I_j =$

$Maximum\ Inputs\ available$, (Fertilizer, Pesticides, Labour etc.), $j = 1,2, \dots, m$; $x_i = Crops, i = 1,2, \dots, n$; $L = Land\ Availability$

Crop-Variety Selection: The crop variety is selected based on the productivity in the available conditions. The crop variety responses are recorded based on prior yield estimates and historical weather information and inputs assisted in yields. The variety selection has been done in following two steps –

1. Stepwise Regression determining the relation between yield and other independent variables – Stepwise regression equations have been fitted with yield response of the respective crop varieties with respect to weather and input variables (depending upon the available data):

$$Y_{cv} = W_{tf} + I_{uf} \tag{3}$$

where, $Y_{cv} = Yield\ of\ respective\ crop - variety$; $W_{tf} = Weather\ effect$; $t = Weather\ type\ (Temperature, Relative\ Humidity\ etc.)$; $I_{uf} = Inputs\ for\ yield$; $u = Input\ types\ (Fertilizer, Pesticide, etc.)$; $f = Frequency\ (cumulative\ seasonal\ weather, average\ monthly\ weather, etc.)$

2. Forecasting for the upcoming season

The estimated yield responses for the crop-varieties are obtained based on the fitted regression equation (3) with the forecasted weather variables and available input resources for the upcoming season(s). The forecast for the Weather variables are obtained based on time series forecasting, Auto Regressive Integrated Moving Average (ARIMA) model.

A case study has been conducted to select the best Soybean variety with farm level data of Michigan area of United States. The selection is based on the number of trials, average yield and yield differences and their relational responses with respect to weather, irrigation and soil characteristics for 182 Soybean varieties. Five varieties have been selected, which are suitable for recommendation to provide a better yield for the coming season, based on the above mentioned technique.

Plant Protection: Plant Protection is one of the major aspects to increase crop productivity by saving the crop harvests. It is part of Phase 3- Crop Cycle Management. Presently, it has been envisioned for two aspects – a) plant disease-pest forecasting framework and b) plant insect-pest forecasting framework.

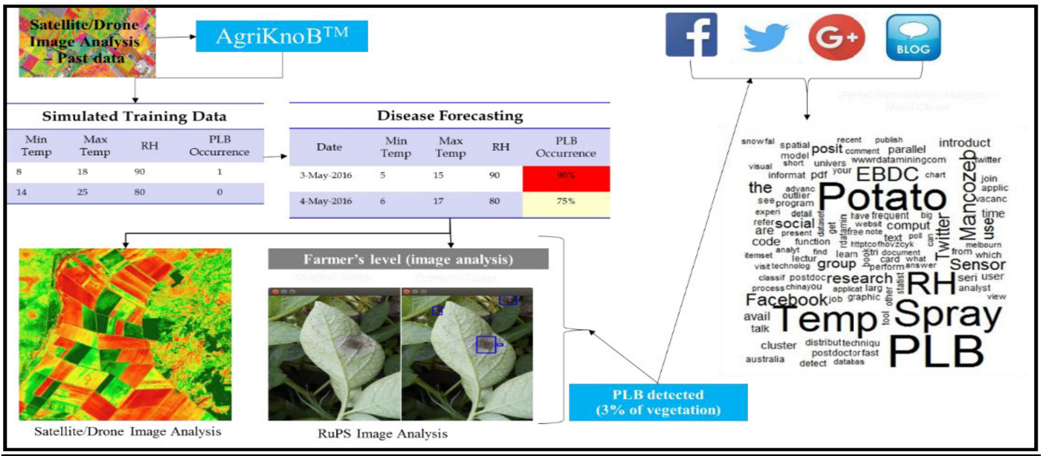
a) *Plant Disease-pest Forecasting Framework*- The framework is designed to accommodate various crops and their diseases. The approach can be initiated having prior knowledge of the disease incidences with the vital causal variables, mostly weather. Having the data of disease occurrences helps to build specific crop-disease models for forecasting and broadcast the alerts. But in the situation where we lack data, disease occurrences data has been simulated based on the weather variability and distributions. The literature thresholds of disease occurrences are mapped with the simulated weather data of the crop growing season with respect to the crop varieties. The historical remote-sensing data (satellite images) can also help in enriching the simulation data. Thus the training data can be used for disease forecasting through Machine Learning algorithms (Logistic Regression, Artificial Neural Network, etc.).

The disease occurrences are broadcast to the farmers at least 7-15 days prior to manage their logistics to protect the crops. The data acquired through the various data sources below the soil, on the soil and above the soil is augmented with geo-tagged, localized field level data obtained from a proprietaryIntelligent Rural Integrated Sensing (IRIS) application. The geo-tagged data is further processed through Image Analysis (Image Enhancement, Region of Interest Segmentation, Feature Extraction and Machine Learning algorithms). Thus we can get the scale of disease severity of different geo-spatial regions, which is posted to the farmers for their region of interests.

The above validation process can also be facilitated through high resolution images either captured by drones or satellites. Thus,remote sensing data analysis for various crop reflectance with respect to the disease helps to generate the disease severity map of the region of interests.

The disease severities evaluated in the validation phase is prompted to the users to post in Social Networking groups. The power of social networking helps to evaluate various factors related to the crop diseases and associated diseases. Additional knowledge is gathered through Social Networking Analysis. This knowledge in turn enhances the knowledge base (AgriKnoBTM) and thus the training data, which is advantageous for disease forecasting during the next season.

Figure 1 - Disease forecasting framework demonstrated for Potato Late Blight (PLB) disease, Hapur region, Uttar Pradesh, India



Besides the simulated data approach for forecasting disease incidences, proven statistical models have been explored for Rice Blast disease, with some modifications. The EPIBLA model was developed to forecast disease incidences for South India region based on the spore counts of *Pyricularia oryzae*,using Burkard volumetric spore trap [10]. The spores per cubic meter have been estimated with respect to daily temperature and relative humidity, through multiple linear regression. The proportion of disease incidence is modelled through step-wise regression model with respect to minimum, maximum and dew point temperatures and relative humidity.

In our context we have modified the EPIBLA model based on observation of disease occurrences.We took samples from five zones of a rice field (average 1 acre) with an average of 40 tillers inspected under a ring. The count of affected tillers is recorded among the inspected tillers in Chennai Horticulture Produce Producer Company Limited (CHPCL) PRIDETM, Villupuram district of Tamil Nadu. The observations are recorded for every week of rice growing season for twelve farmers with average rice growing area of 1 acre. The disease incidence is calculated with the ratio of infected and observed tillers for each of the observation. The calculated disease incidences are fitted with weather variables following step-wise regression model, as followed in EPIBLA model.

The management practice to control EPIBLA was followed by four farmers during the season.

Following is the developed model –

$$DI = 0.150 - 0.005 \times W_1 + 0.003 \times W_2 + 0.005 \times W_3 + 0.002 \times W_4 \qquad (4)$$

where, DI = Disease Incidence (%); W_1 = Dew Point temperature;

$W_2 = Minimum\ Temperature; W_3 = Maximum\ Temperature; W_4 = Relative\ Humidity$

b) Plant Insect-pest Forecasting Framework- The insect-pest framework is another sub-module of ***InteGra*** under Plant protection. The framework is supported by mathematical models, derived from Lotka Volterra, Predator-prey model, with statistical estimates supporting the initial values for the model.

$$\frac{dx}{dt} = ax - \alpha xy + (w_{1x} + w_{2x} - w_{3x})x \qquad (5)$$

$$\frac{dy}{dt} = -cy + \alpha\gamma xy + (w_{1y} + w_{2y} - w_{3y})y \qquad (6)$$

where, $x(t) = pest\ population$; $y(t) = predator\ population$;
$a = natural\ growth\ rate\ of\ pest$; $\alpha = predation\ rate$;
$w_{ix} = growth\ of\ pest\ due\ to\ weather\ variables, i = (1 - Max\ Temp; 2 - Min\ Temp, 3 - Rainfall)$; $c = reduction\ rate\ of\ predator\ due\ to\ natural\ death$; $w_{iy} = growth\ of\ predator\ due\ to\ weather\ variables$; $\gamma = increase\ of\ predator\ population\ due\ to\ predation$

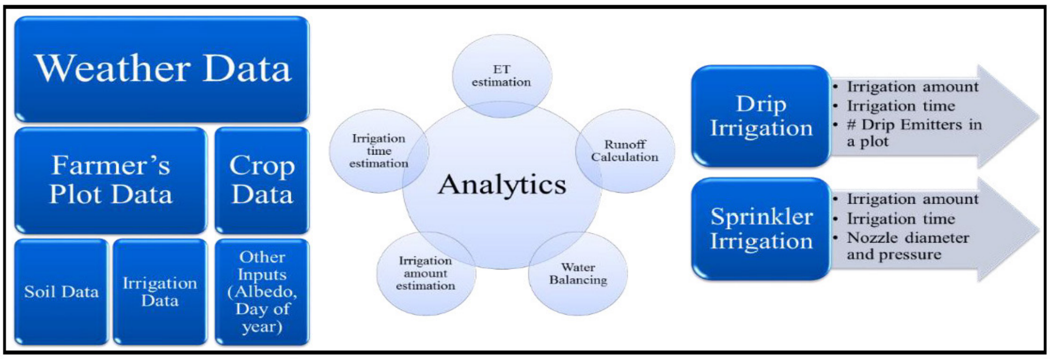
The cultural and biological control measures and its effects on prey and predator are adjusted in the above equations, based on the statistical estimates of population and growth rate. The numerical simultaneous solution of the differential equations 5 and 6 suggest the effective control measures of the pest. The growth rates are estimated based on variety of interactions, preypredator (compound annual growth rate), prey-weather-predator (regression), prey-chemicalpredator (regression) and prey-cultural/biological-predator (regression). The yield component being added in the model will complete the production system, considering growth components of yield.

The insect-pest model is being tested and explored for controlling the devastating Tea looper (*Hyposidra talaca*) of north-east region of India.

Fertilizer recommendation: The fertilizer recommendation module for other crops has been explored through Monte Carlo Markov Chain (MCMC) model. The MCMC process considers a set of states. After initiation from one state it flows to the successive states following the transition probabilities. The probability does not depend upon which states the chain was in before the current state. The depletion rate of fertilizers due to natural erosions and plant uptakes have been considered to determine the available nutrients in soil on periodic basis. Initial soil sample tests have been done to determine the nutrient status. The fertilizers are recommended when the nutrient status get depleted as per plant requirements. The fertilizer recommendation has also been explored through a software (named as Nutrient Expert) developed by International Plant Nutrition Institute (IPNI) for rice.The Nutrient Expert is presently available for Rice, Wheat and Maize. The fertilizer recommendation and irrigation scheduling are important modules under Crop Cycle Management of Phase 3.

Irrigation scheduling: The water requirement is one of the major inputs for the plants to grow. In the era of climate change, precision in irrigation is needed to have "per drop more crop". A novel framework has been designed comprising the modern methods of estimations for irrigation scheduling (Figure 2). The irrigation scheduling is believed to be more efficient having sensors installed in the field, through which precise information on temperature and moisture levels is obtained.

Figure 2 - Irrigation framework



The Evapotranspiration (ET) has been estimated through Penman Monteith Model.

Crop Valuation: The market price forecasting for the crop and variety is one of the most advantageous attributes of the **InteGra**, under Phase 4 – Harvest Planning. It has been noted that the seasonal variation of the crop prices is pretty much predictable, except for some unpredictable occurrences caused by Nature and/or policy makers (which are reported more often). In this scenario, the price prediction models (through ARIMA) fail. There is a need to develop a methodology to evaluate value of crops based on the amount paidby end consumers. The crop valuation has been mathematically structured by solving three partial differential equations considering demand of crop products due to population growth, urban growth and cost of production and products and productivity, respectively.Let c(t), p(t) and u(t) be three dependent variables representing crop valuation, population and urbanization, all depending on time t. The crop valuation includes the crop productivity, costs related to crop production and processing and valuation of crop products in market.

Thus, $\frac{dc}{dt} = \frac{\gamma}{n}c + \delta c - \rho c + \frac{\varphi}{q_1}cu + \frac{\theta}{q_2}cp$ (7)

where, γ = % of growth of c per unit of μ per unit time; n = crop units processed to produce a product; δ = % of growth of c per unit of μ per unit time; ρ = % of loss of c per unit of μ per unit time; φ = % of growth of c per unit of u per unit time; q_1 = unit of products of crop available in urban space; θ = % of growth of c per unit of p per unit time; q_2 = unit of products of crop available; μ =the units of products processedin unit time

$$\frac{dc}{dt} = \{(\frac{\gamma}{n} + \delta - \rho) + \eta p\}c \quad (8)$$

where, $\eta = (\frac{\varphi}{q_1}\lambda + \frac{\theta}{q_2})$, $u = \lambda p, \lambda = growth\ of\ Population$ (9)

$$\frac{c}{c_0} = e^{F(t)},\ F(t) = \left(\frac{\gamma}{n} + \delta - \rho\right)t + \frac{K\eta}{\alpha} ln\left\{\frac{1+\beta e^{\alpha t}}{1+\beta}\right\} + b.\eta(1 - e^{-mt}) \quad (10)$$

The numerical analysis of the model through statistical estimates for various crops, crop-products for different geographies need to be evaluated.

Population theory

Verhulst [8] suggested the famous logistic growth model for population,

$$\frac{dp}{dt} = \propto p\left(1 - \frac{p}{K}\right) where, K = \frac{\propto}{a}, \text{ at } t = 0,\ p = p_0 \quad (11)$$

Solving equation (11) we get

$$p(t) = \frac{Me^{\propto t}}{1+\frac{M}{K}e^{\propto t}} \quad \text{where, } M = \frac{p_0}{1-\frac{p_0}{K}},\ \lim_{t\to\infty} p(t) = K \quad (12)$$

The law of entropy in Informatics suggests that as the population grows a census of a nation will miss some number of people which is likely to be caused mostly by the dynamics of the very system of recording the census. So let us assume,

$$p(t) = P(t) + \varepsilon(t) \quad (13)$$

where, $P(t)$ is recorded by the census and $\varepsilon(t)$ is the error in the record.

Thus, $\frac{dp}{dt} = \frac{dP}{dt} + \frac{d\varepsilon}{dt} = \frac{K\beta e^{\alpha t}}{1+\beta e^{\alpha t}} + \varepsilon_0 e^{-mt}$, where,if $\beta = \frac{M}{K}$, then $\beta = \frac{\frac{p_0}{K}}{1-\frac{p_0}{K}}$ (14)

This gives,

$$\frac{P_0}{K} = \frac{\beta}{1+\beta} \; and \; \frac{d\varepsilon}{dt} = \varepsilon_0 e^{-mt} \; , m > 0 \tag{15}$$

$$\text{Urbanization, } \frac{du}{dt} = \lambda \frac{dp}{dt}, \text{ att} = 0, u = u_0 = \lambda p_0 \tag{16}$$

The developed mathematical model is developed considering the cost involved in producing the crop based products, productivity of the crop and the demand of the crop products due to urban tastes and population growth. The model framework is expected to provide the farmers the valuation of the crops before cultivation, which will enable the farmer to choose themost profitable crop. It also provides the farmers betterbargaining power and encourages building food processing enterprises to reach the consumers through the least possible channels. This helps famers to createsuccessful business groups and organize profitable farming business units.

3. Conclusion

The Digital Farming Initiatives of Tata Consultancy Services [7] is empowering the farmers, especially the small and marginal agrarians to combat against all the uncertainties such as weather risk, water and soil degradation, pest and disease attacks and market price fluctuations. The farmers are facilitated through a collaborative network called **SmartPRIDEs** supported with an advanced analytical platform **InteGra**. A Smart Ecosystem is enabled for farmers to collaborate and produce optimized yield with appropriate inputs overcoming major risks associated with climate & pest/disease and to market their produce to obtain maximum profit. In addition, the real time data driven framework ensures operational efficiency and resource optimization at every stage of crop cycle, thus making Agribusiness systems more productive, profitable and competitive to ensure food security across the globe.

ABSTRACT

Computer and Internet access have become essential tools in modern society. The use of computers and the Internet on Finnish farms has been surveyedseveral times since the year 2000.

90% of farms used computer in 2013 whereas in 2000 only 50 % of the farms did so. By 2013 the use of the Internet had increased to the same level as the use of computer.

The use of mobile broadband connection has increased rapidly and by 2013 it was at the same level as the use of fixed broadband. The proportion of the farms using mobile broadband is higher and that of farms using fixed broadband is lower in sparsely populated areas, probably due to lower availability and speed of fixed broadband in those areas.

Almost half of the Internet-using farms access the Net with mobile phone and about 20% of the farms use tablet. Access to the Internet also in sparsely populated areas will be crucial for farms in the future, as an increasing proportion of farm management activities are carried out overthe Net.

Keywords: computer, Internet, broadband, mobile, farm

PAPER

1. Introduction

In Finland the development of the access to the Internet in the rural areas has been monitored in the national rural policy. As the development of the digitalisation of both public and private services has accelerated in the last decade, it has become an issue of general and governmental interest to support the development of Internet networks across the country. Equal access to the Internet has become an issue related to an open and democratic development of the Finnish society. In relation to its population Finland is scarcely populated country. In addition to the concentration of population to urban areas, the rural areas are both very scarcely populated and remote. This reflects also to the technical functionality of Internet services. In remote areas, costs of fixed broadband networks per customer may be very high which favours mobile connections. However, if the number of customers is low, operators are not motivated to develop the coverage and speed of the mobile networks.

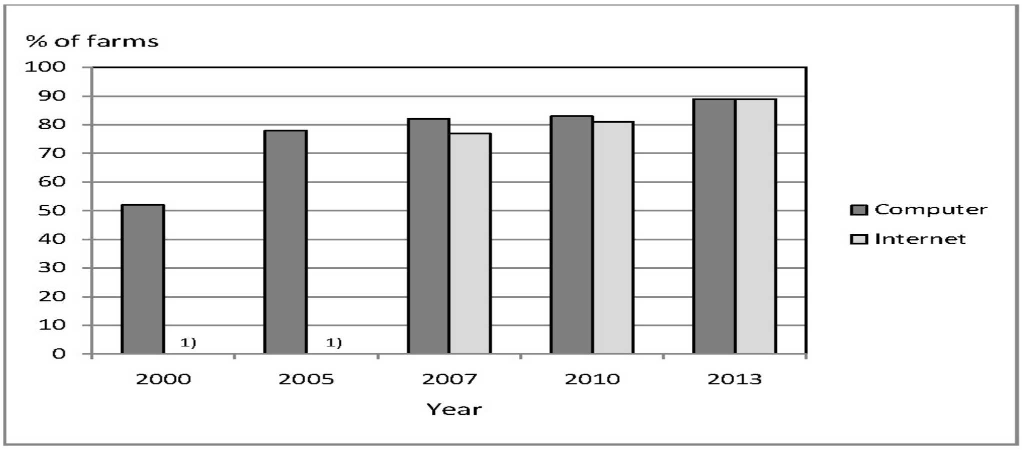
The Finnish agricultural Farm Structure Survey (FSS) has collected information on the use of computers and of theInterneton farms since the year 2000. The FSS covers 30 % of the farms; and in 2010 the survey was conducted as a full census. The composition of the questions will be revised for the forthcoming FSS 2016.

2. Use of computers and the Internet on farms

The use of computers has increased rapidly since 2000, and now almost all farms use computer and the Internet in the running of the farm (Figure 1).

Fixed broadband is still the most common type of Internet connection but the use of mobile broadband has increased to an equal level (Figure 2). Some of the farms use both of the two techniqes. The use of mobile broadband on the farms was lessthan in Finnish enterprises in general. In comparison 68% (2010) and 92% (2013) of all enterprises had a mobile broadband connection to theInternet(Statistics Finland 2010 and 2013).

Figure 1 - Share of Finnish farms that use computer and theInternet.



1) The use of the Internet was not surveyed in 2000andin 2005.

Source: Farm Structure Survey

3. Differences between regions

There are no large differences between regions in the share of the farms that use computer and the Internet.However, the frequency of the use of fixed broadband is lower and that of mobile broadband higher in north and east than in other regions (Figure 3). This may be a reflection of a lower availability of fixed broadband in the more sparsely populated north and east. For some farms mobile broadband is the only alternative, even though in many cases it has been slower and less reliable than fixed broadband.

In the FSS of 2013, the farms that did not use fixed broadband were asked, whether they could subscribe to fixed broadband if they wanted to. In north and east, fixed broadband was unavailable for 57% of these farms, where as in other regions about 40% of the farms not using fixed broadband could not get it. The region north and east differs also for the availability of high-speed fixed broadband for households in 2014: in north and east fast fixed broadband was available for 60 % of households, whereas in south and west these percentages were 72% and 62%.(Finnish Communications Regulatory Authority 2015).

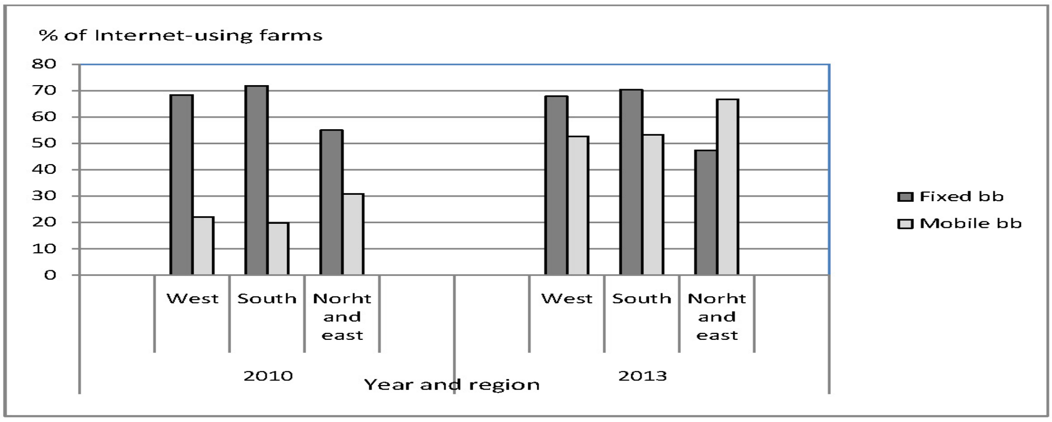
The use of mobile broadband has increased clearly from 2010 to 2013 in all regions (Figure 3). This reflects the increased use of mobile Internet applications as a supplement to fixed broadband.

In north and east, the use of fixed broadband has reduced slightly from 2010 to 2013 (Figure 3). This may relate to the dismantling of fixed telephone network in some areas due to a rapid reduction in the number of fixed telephone connections.

4. Differences between production sectors

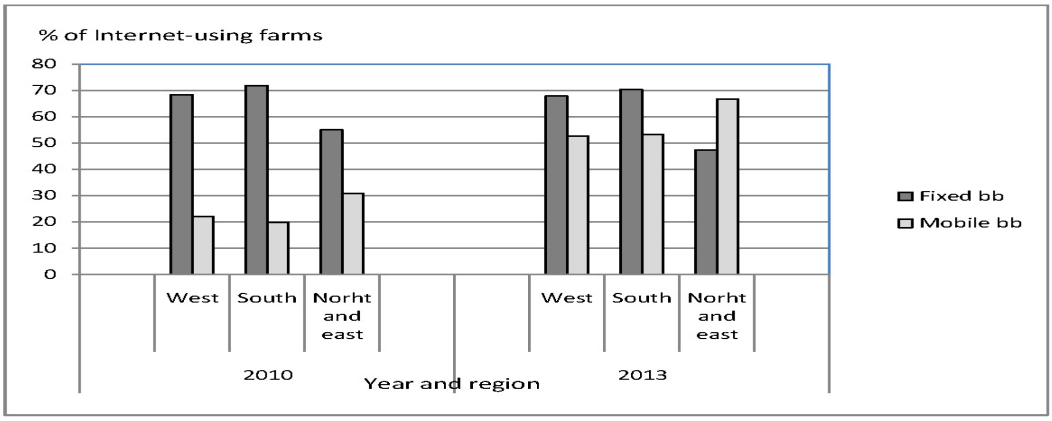
In the comparison of the production sectors, pig and poultry farms seem somewhat more advanced in the use of new technology. In 2010, they had a slightly higher rate in using fixed broadband and, respectively, a lower rate in using mobile broadband. By 2013 the rate of fixed broadband use was still higher on pig and poultry farms and the use of mobile broadband had increased on these farms relatively more than on other farms. Pig and poultry farms may have been somewhat more active in adopting new mobile Internet applications, which is also indicated by a higher rate in the use of mobile phones and tablets (Table 5).

Figure 4 - Use offixed and mobile broadband on Finnish Internet-using farms in the years 2010 and 2013 by selected production sectors.



Souce: Farm Structure Survey

Figure 5 - Devices used to access Internet on Finnish Internet-using farms in 2013 by selected production sectors.



Souce: Farm Structure Survey

Horticultural sector has a little higher rate in the use of mobile phones and tablets compared with cereal and dairy farms (Figure 5). Especially greenhouse enterprises use the newer devices more than average.When looking at all production sectors, it seems that farmers who are younger than the average and more business oriented are more active in using new technology.

5. Use of the Internet in farm surveys and in the application of subsidies

According to the Agricultural Census of 2010, about 80% of the Finnish farms used computer and the Internet in farm management. However, only 57% of the farms that responded to the survey used the web service of the Census while 43% used telephone interview. In the FSS of 2013, less than half of the respondents used web survey.

A study was carried out to investigate the factors affecting the use of theInternet service of the 2010 Agricultural Census in Finland (Unkari 2011). The web service was more likely used by younger and more educated farmers. 31% of the responses were from farms that used computer but did, however, not use the web service of the Census. Reasons for not using the web survey included slow and unreliable Internet connection, insufficient instructions, difficulties in the use of the web survey and a negative general attitude towards surveys.

In the Agricultural Census of 2010, 4% of the respondents declared in the survey that they did not use computer but, nevertheless, submitted their answers in the web service. In these cases, the web service may have been used by a person other than the farmer, such as an advisor, an accountant or a relative. Some farmers may have used a public Internet access, for example in a library.

In the application of farm subsidies, the use of web service has increased rapidly in Finland (Mavi 2016). In 2010, 21% of the applications were made in theInternet, while the percentage was 66% in 2013 and 90% in 2016.

6. Conclusions

The Internet has become an essential tool in farm management as in any other activity where ITC is used. Therefore, the availability, speed and quality of Internet connections will be of the utmost importance. Farms in sparsely populated areas may face a problem here, because supplying the best available connections is not always profitable for the operators in these areas. This is a concern for all activities and has already caught public attention and measures to ensure sufficient Internet connections in all regions.

How to analyse the farm structure, how to support innovation by data

E. Laczka | Deputy President Central Statistical Office | Budapest | Hungary

DOI: 10.1481/icasVII.2016.c21c

ABSTRACT

Thanks to the natural characteristics of the country, Hungarian agriculture has played an important role in our country's economy over the past centuries and this is still the case nowadays. In 2015 the share of Agriculture in GDP was 3.7 percent. The total gross output of agriculture was more than 2 000 billion HUF, out of which crop production represented 58 percent, animals and animal production 35 percent, agricultural services and secondary activities 7 percent. From the 9.3 million hectares surface area of Hungary 5.3 million hectares are agricultural land area (in the European Union it is only in Denmark that this proportion is higher).

According to the Agricultural Census 2010, in the period of the census 8.6 thousand enterprises (legal units engaged in agricultural activities) and 567 thousand private holdings performed agricultural activity. 54 percent of the enterprises were exclusively engaged in crop production, 6 percent in animal husbandry only, while the proportion of enterprises with mixed activity amounted to 40 percent. The proportion of the different types of activities performed by private holdings differed to some extent. Nearly half (49 percent) of private holdings dealt with crop production, 22 percent with animal husbandry, and 29 percent with both activities. In Hungary the census has been observing for more than 10 years the purpose of the production of private holdings as well. According to the 2010 census data 60 percent of private holdings produced exclusively for own consumption. There has been a change in the proportion of private holdings producing specifically for the market (it increased from 8 percent to 20 percent over the past decade). The rest of the private holdings sold the surplus remaining after own consumption.

The distribution according to the legal forms of farming of agricultural product output provides also important information on the structure and efficiency of Hungarian agriculture. This is especially the case when the proportion of the output is presented for different legal forms of farming, size categories or in the case of private holdings according to the purpose of the farming as well. There are significant differences in farming methods, the use of internet, adopting precision agriculture or incorporating new or improved machinery, etc. by legal forms of farming and size categories.

If a country intends to have a competitive, modern agriculture and make a better use of its natural resources, it is indispensable to form well-trained qualified experts and - as the age of Hungarian farmers is quite high – to promote a change of generation as well. With a view to implementing this change, the Hungarian Association of Young Farmers (AGRYA) in cooperation with Hungarian agricultural statisticians launched 5 years ago a special research. Using the statistical data available (supplemented by special surveys) statisticians analysed the situation, characteristics, innovation of farms managed by farmers under the age of 40. We used for this purpose the databases of agricultural and population censuses, regular statistical surveys (including surveys on social issues too). Two separate publications have been published up to now, the purpose of the presentation is to present the results of the research as well. The collaboration between statisticians and the AGRYA can be an example of how to support decision makers with statistical data, information.

Keywords: structure of agriculture, efficiency, education, collaboration with users

PAPER

1. Introduction

Thanks to the natural characteristics of the country, Hungarian agriculture has played an important role in our country's economy over the past centuries and that is still the case nowadays. In 2015 the share of Agriculture in GDP was 3.7 percent. The total gross output of agriculture was more then 2 000 billion HUF, out of which crop production represented 58 percent, animals and animal production 35 percent, agricultural services and secondary activities 7 percent. From the 9.3 million hectares surface area of Hungary 5.3 million hectares are agricultural land area (in the European Union it is only in Denmark that this proportion is higher).

The distribution according to the legal forms of farming of agricultural product output provides important information on the structure and efficiency of Hungarian agriculture. This is especially the case when the proportion of the output is presented for different legal forms of farming, size categories or in the case of private holdings according to the purpose of the farming. There are also significant differences in farming methods, the use of internet, adopting precision agriculture or incorporating new or improved machinery, etc. by legal forms of farming and size categories.

2. Structure of Hungarian Agriculture

When we analyse the current farm structure in Hungary – for the sake of a better understanding – we have to go back to the period of the change of the political and economic system of 1990. The structural transformation of Hungarian agriculture at the end of the 19th century took place gradually and in various stages. The restitution of the land to the original owners and new applicants was not a smooth process, the transformation of the cooperatives of production and state farms caused considerable loss of assets.

In the 1990-ies different forms of holdings were created, a great number of small private farms with a less viable size emerged. Great part of the state farms and cooperatives were liquidated and replaced by different forms of farming. The change of property did not always entail the change of the type of farming, in many cases the property and use of the land diverged. Different forms of renting or use changed the situation prevailing during previous years, which would not have been a problem if it had contributed to a more rational and rentable form of farming.

The change of ownership of the means of production was in the centre of the changes in agriculture, but it occurred extremely slowly and not always in the most suitable way. The establishment of productive types of farming, the optimal distribution of subsidies were not coupled with sufficient foresight and firmness. The means of production of the previous great farms and the lands were not distributed according to local needs. Many of the newly created holdings – lacking of the necessary means of production – had only a low-level production and quite a great number of farms did not even cultivate the land recovered.

While before 1990 agricultural enterprises for large-scale production were producing on nearly 90 percent of the land, at the turn of the millennium this proportion decreased by half. From 2005 land use of enterprises and companies has been increasing at the expense of private holdings, and other legal forms began to use land. Another characteristic of the processes was that land use of cooperatives (despite the creation of new forms of cooperatives) became negligible.

Land-use according to the legal forms 1990–2015

Year	Enterprises and Companies	Cooperatives	Private holdings	Other	Enterprises and companies	Cooperatives	Private holdings	Other
	hectare				proportion of land area, percent			
1990	2 867	5 147	1 289	..	31	55	14	..
1995	2 593	2 208	4 035	467	28	24	43	5
2000	2 711	1 160	3 902	1 529	29	13	42	17
2005	3 384	462	2 984	1 317	36	5	32	14
2010	3 488	290	3 016	1 144	38	3	32	12
2015	3 404	150	3 263	1 032	36	2	35	11

It was only in 1988 that land use of **private holdings** exceeded that of agricultural enterprises, it was the only year when it reached 50 percent of the territory of Hungary. After the turn of the millennium this proportion began to decline and ten years later the proportion has stabilised at the same level (enterprises and companies 36 percent – private holdings 35 percent). In 2013 – year of the last Farm Structure Survey – the average size of agricultural enterprises was 310 hectares, the land used by private holdings was 5.5 hectares.

3. Structure of Agriculture by type of activity

Although the Statistical System of the European Union classifies holdings according to a defined Typology, in Hungary we use to analyse agricultural holdings three types of farming – more suitable for our domestic conditions – livestock farming, crop farming and mixed production.

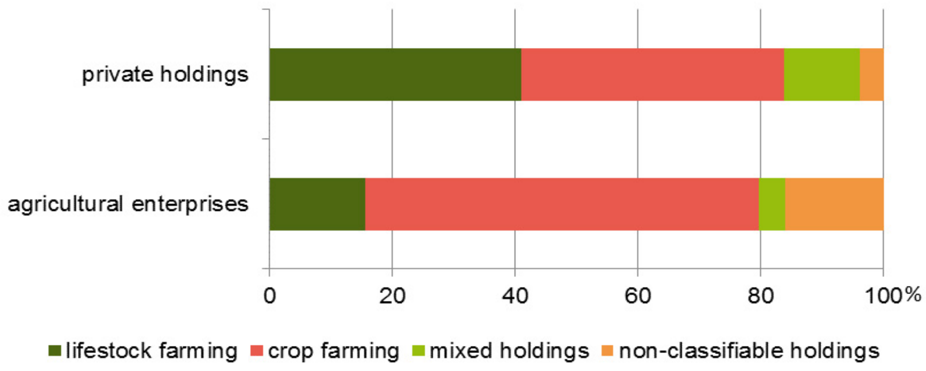
– **Livestock farming** are holdings where only the livestock has reached or exceeded the threshold applied for the census in 2000.

– **Crop farming holdings** are holdings where only land use has reached or exceeded the threshold applied for the census in 2000.

– **Holdings with mixed production** are holdings where both land use and livestock have reached or exceeded the threshold applied for the 2000 census.

In the year 2000, from the existing 5007 **enterprises** performing agricultural activity more than half (52 percent) were engaged in crop production, more than a quarter (28 percent) in mixed production and 20 percent dealt only with livestock production. The distribution of **private holdings** by type of production shows a different structure; while the share of livestock farming is higher, that of crop farming is lower.

Distribution of the holdings by type of production, 2013 (%)



4. Structure of Agriculture by purpose of production

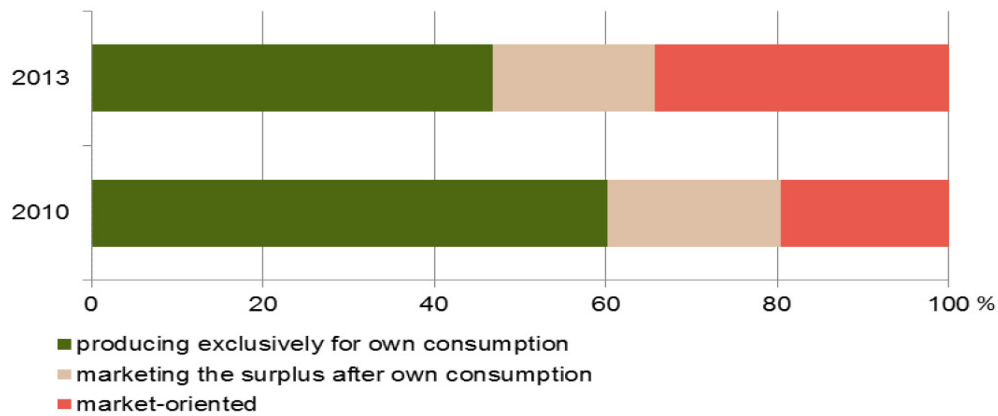
Great number of statistical tools are at our disposal to analyse holdings. **The size of the holdings can also be measured in innumerable ways.** The size of agricultural holdings can be characterized by the size of the area used, the size of livestock, the combination of different indices, labour input, the size of the output, the value of the products or services marketed or the gross value added produced. The – specific – Hungarian agricultural structure requires nevertheless the examination of other aspects as well.

Goods production is tangible, traceable and measurable. But what do we mean in Hungary by goods production? Can we call for example goods production if somebody sells regularly some eggs or some kilos of fruit (which still happens frequently in Hungary)? The answer is probably "yes" from the point of view of the producer/seller for whom it counts, it is a source of revenue, but from an economic point of view such a unit of production cannot be considered as a market oriented holding. It was the reason why we have defined a category such as producers **producing exclusively for own consumption** (these agricultural units are not holdings in the economic sense). In addition to the previous one we have established two additional categories; **holdings selling the surplus remaining after own consumption and the market oriented holdings.**

In the case of **agricultural enterprises** (legal units of production) the purpose of the production is undoubtedly market production, income, even if in certain cases they perform agricultural activity only as a complementary, ancillary activity, but the situation is different for **private holdings**.

For the above mentioned reasons, Hungarian censuses, surveys have been observing for more than ten years the purpose of production of private holdings as well. According to census and survey data, in 2010, 60 percent of private holdings produced exclusively for own consumption (despite the considerable decline of the number of private holdings, this proportion is the same than the one measured during the census of 2000). There has been a change in the number of private holdings producing specifically for the market, in 2010 they represented 20 percent of private holdings, the rest of the private holdings sold the surplus remaining after own consumption.

Distribution of private holdings by purpose of production, 2010-2013 (%)

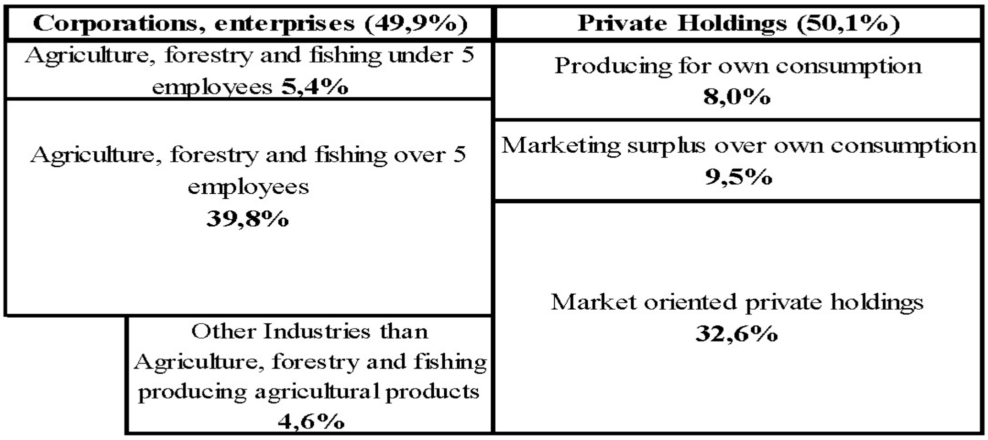


5. Output of Agriculture, efficiency

From the point of view of the analysis of efficiency and productivity the distribution of agricultural gross output by legal forms and use provides valuable information. This is especially the case if we take into consideration the size categories of agricultural enterprises, the output of agricultural activity performed as main or ancillary activity, and in the case of private holdings the output of the holdings producing for own consumption, for the market and selling the surplus.

Since the turn of the millennium the gross output of the two main types of agricultural enterprises (agricultural enterprises, private holdings) has been more or less on the same level. It is not surprising, that in the case of **agricultural enterprises** two third of the output is produced by medium-sized and big enterprises performing agricultural activity as main activity. The picture is more varied if we examine the output of **private holdings** according to the purpose of production. It is not surprising that major part of the output is produced by the market-oriented private holdings.

Share of Agricultural Gross Output by type of organisations, 2013

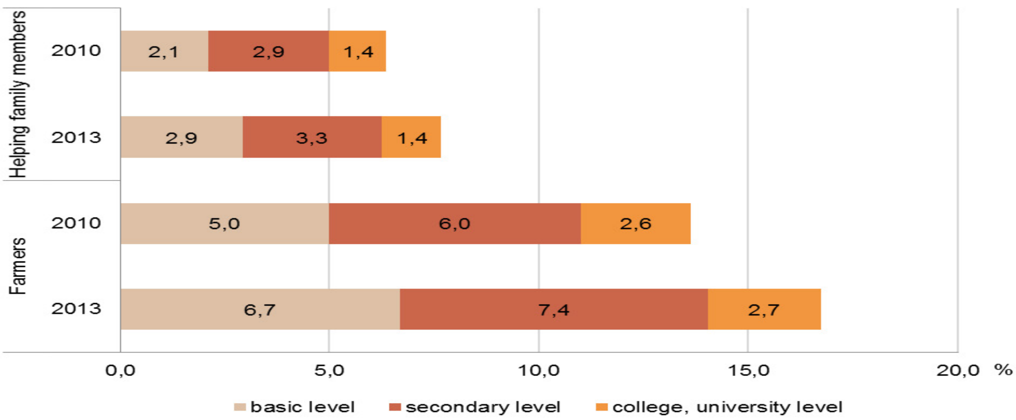


On the basis of the data it is legitimate to ask in the case of which agricultural enterprises efficiency and productivity could be analysed? In my opinion **the analysis of efficiency, productivity makes sense mainly in the case of agricultural enterprises and market-oriented private holdings**. This does not mean of course that we don't have to analyse the output of private holdings producing for own consumption, or selling the surplus, but in their case the focus should be more on the place and role they have in society with special emphasis on social questions.

6. Ageing, education

In Hungary the **age structure and qualifications** of Hungarian farmers reach the critical level. Despite all the efforts, the age composition of persons engaged in agricultural activity has not improved in the past years. In 2013, 31 percent of the farmers performing agricultural activity were above the age of 65, the proportion of farmers under the age of 35 was hardly superior to 6 percent. Similar efforts are needed to improve **the qualifications of farmers** as well. In 2013 only 3 percent of the farmers had college or university degree, the proportion of farmers with secondary school degree was also low (7 percent), the majority of the farmers performed agricultural activity relying on their practical experiences. The specialized (agricultural) qualifications of the persons employed in agriculture is also below the expectations and it has not been changing significantly.

Proportion of persons with agricultural qualification in private holdings



7. Technology of agricultural production

In the case of EU member countries Farm Structure Surveys (FSS) constitute the backbone of statistical data related to agriculture. The FSS system is composed of full-scope censuses carried out every ten years and sample surveys conducted every three years. Among the data surveyed, there are data which are surveyed in each case, but there are also data that are surveyed less frequently, there are additional modules in some cases. The latest case refers for example to the observation of technology of production. Due to our natural conditions I would highlight one important issue which is the irrigation.

In the case of irrigation only enterprises belonging to the bigger size categories possess irrigable areas. Irrigation equipment of higher capacity is mainly available in agricultural enterprises. Orchards have the highest proportion of irrigable area, but even this remains still below the ideal level.

8. How to support innovation by statistical data

Data on the Hungarian agriculture prove undoubtedly that further analyses, further proposals are necessary in relation to farm structure, the efficiency of farms, the age structure and qualifications of farmers, the technical background of production. The analysis of FSS data revealed in Hungary that young farmers, AGRYA could be the "flagship" of innovations and development. In Hungary 13 percent of private farms are managed by farmers under the age of 40. In their case the average size of the farm, qualification, the technical conditions of agricultural production, the efficiency of the production are more favourable than the average. The analysis of this situation led to establish a fruitful cooperation between statisticians and the AGRYA.

The AGRYA in cooperation with Hungarian agricultural statisticians launched 5 years ago a special research program. Using the statistical data available (supplemented by special surveys) statisticians have been analysing the situation, characteristics, innovation of farms managed by farmers under the age of 40. The statisticians and the AGRYA used for this purpose the databases of agricultural and population censuses, regular statistical surveys (including surveys on social issues as well). Two separate publications have been published up to now on the structure of Hungarian agriculture, social and market aspects of production focusing on the most intensive branches of agriculture like horticultural production. The collaboration between statisticians and the AGRYA can be an example of how to support decision makers with statistical data, information.

N. Georgieva | FAO, Statistics Division (ESS) | Rome | Italy
S. Saravia-Matus | FAO Consultant, World Agricultures Watch initiative

DOI: 10.1481/icasVII.2016.c21d

ABSTRACT

Numerous experiences show the value of developing classifications of farms based on structural characteristics to better design and evaluate policy. Specifically, farm typologies provide policy makers a better understanding of the evolving diversity of agricultural holdings to more efficiently target policies. Such tools are widely used in the European Union and the United States but are less common in developing countries. In addition, cross-country comparisons are key to informing dialogue at regional and international levels but require enhanced harmonization of existing information. Session IDCB 5 in the ICAS VI provided an introductory look at how various countries quantify structural change in agriculture. The Global Strategy to Improve Agricultural and Rural Statistics (GSARS) has started to systematically identify the core data that should be available. Beyond this, there is no common theoretical and empirical framework to monitor and analyze the diversity of agricultural holdings and their transformations. Yet, such a framework could provide national policy makers a comparative or relative vision of various local and national contexts, while serving as an evidence-based resource to inform policy dialogue at an international scale. To respond to such issues, the GSARS, together with the World Agricultures Watch (WAW) and international experts, is developing an international framework for characterizing agricultural structure to support countries as they develop comparable typologies to inform policy dialogues and improve monitoring at national and international levels. This paper summarizes the progress to date in working towards an international harmonized typology framework.

Keywords: Farm classifications, Typology, Agricultural Structural Change, Policy

PAPER

1. Motivation and Efforts to Create a Policy-Relevant Farm Typology

Rapid changes are occurring in agricultural supply chains worldwide and are directly connected to transformations in agricultural structures. Changes are impacting the structure of agriculture at all levels of capacity, but oftentimes, structural changes impact the most vulnerable who control fewer assets and have difficulties in managing risks. Rapid structural changes and attention to contemporary issues—such as sustainability, food safety and nutrition, and equity—amplifies the need for policy makers to carefully consider the diversity of holdings and transformations they may experience in the context in which they operate.

Numerous experiences show the added value of developing farm typologies to analyze, summarize and better understand the evolving diversity of agricultural holdings to better design and evaluate policy.[1] Such tools are widely used in the European Union and the United States but are less common in developing countries. In addition, cross-country comparisons are key to informing dialogue at regional and international levels but require enhanced harmonization of existing information. Session IDCB 5 in the ICAS VI provided an introductory look at how various countries quantify structural change in agriculture. The Global Strategy to Improve Agricultural and Rural Statistics (GSARS) has started to identify systematically the core data that should be available (FAO, 2010). Beyond this, there is no common theoretical and empirical framework to monitor and analyze the diversity of agricultural holdings and their transformations. Yet, such a framework that provides national policy makers a comparative or relative vision of various local and national contexts, while serving as evidence-based resources to inform policy dialogue at an international scale is largely missing.

[1] In addition, typologies have been developed for a variety of purposes outside of agriculture. (See Saravia-Matus, et al., 2015, for an extensive review of typology development and methods.)

In order to fill such a gap, the GSARS, together with the World Agricultures Watch and international experts, is developing an international framework for characterizing agricultural structure based on key domains of structure to inform policy dialogues and improved monitoring at national and international levels. The guidelines will also provide reference points for countries, to facilitate progressive harmonization of concepts, classification and reporting systems.

As a first step, an extensive literature review was completed and highlighted a series of domains common to most existing international, national and regional typologies (Saravia-Matus, et al., 2015). In October 2015, an international expert group was formed with recognized experts bringing various technical and geographical expertise to consider key dimensions to be taken into account in the typology guidelines. In January 2016, a first concept paper (Ahearn, et al., 2016) was reviewed by the international Scientific Advisory Committee of the GSARS. Following the meeting, a parallel process has been undertaken to combine the production of an international typology informed by the recent release of the Sustainable Development Goals (SDG), and a country-driven process to develop nationally relevant typologies from a set of relevant policy domains.

In this paper, we outline the progress to date in the development of a harmonized classification system. First we review the major policy issues facing decision makers that are relevant to a classification system. Next we consider the classes of characteristics—or as referred to here, domains—that can best capture the most important policy considerations. Upon these domains, a harmonized system will be developed, including consideration of the critical underlying questions that must be addressed in light of the ongoing and future transformations of farm structure. We then consider the potential for an integrated international and national typology drawing on these domains and showing the challenges and options for such a framework. We also consider a country-driven process, based on a flexible framework targeted to support nationally relevant typologies. Finally, we conclude with the next steps in the development of a harmonized farm classification system.

2. Need for a Typology and Domains of Structure

2.1 Common Critical Policy Issues

The policy challenges are recognized to be multi-faceted, including challenges exogenous to agriculture. In addition, there is a diversity of farms with different challenges, contexts, and contributions, which contribute to their different responses to policies and market signals. Policy objectives and priorities may vary over time and place as a result of this diversity. Due to the multiple and inter-related objectives of policies, there is a corresponding need for a farm typology framework that goes beyond a single dimension—such as farm size measured in hectares of land—for informing those policy maker decisions. The recognition of the integrated nature of multiple objectives has increased the interest—and frankly the need—for policy makers to have the benefit of statistical frameworks that simultaneously consider a variety of measures of farm structure in the development of a typology. In a globalized economy, it is useful to both international and national decision makers to have a common framework in which to consider the diversity of farms. The most recent example of the value of an international perspective is evident in the wide interest in the Sustainability Development Goals (SDG).

2.2 Policy Relevant Domains

The preferred approach to typology development at the international level, and perhaps national, is through a deductive process, rather than a multivariate statistical approach.[2] The deductive approach consists in defining types on the basis of pre-selected domains of characteristics and specified levels, identified by expert knowledge, literature reviews, and/or a specific policy objective/focus. Ahearn, et al. (2016) identified an expansive list of domain characteristics of agricultural holdings and households that could be considered as core concepts in the conceptual framework include the following:

- Legal Status/Management (household or corporate/cooperative/other),
- Dependence of the holding on family labor
- Off-farm Work/Pluriactivity of household member(s)
- Extent of marketing (compared to self-consumption)
- Commodity specialization (could be defined in various ways, e.g., food or cash crop, or based on specific commodity),
- Farm Size (measured in either area or value of production),
- Gender
- Access, and the form of access, to assets or capital
- Origin of the capital and its intergenerational transfer

[2] It may be preferred by some stakeholders that a typology be developed using multivariate statistical analysis, rather than a deductive process. Saravia-Matus, et al. (2015) review alternative approaches.

According to FAO (1999) devising an appropriate typology begins with a declared operational interest: trying to simplify the heterogeneity of the farms through the identification of groups or types defined under a core set of traits and presenting similar potential and experiencing similar problems. Such key traits have been identified above as core concepts but require further organization into domains of interest. For this purpose, we identify thematic domains that may guide farm typology building: Legal Status, Economic Size, Product Mix and Input Use, and Human Capital and Household Characteristics. These domains connect to a series of distinguishing criteria and their policy relevance (Table 1).

Table 1 - Typology Thematic Domains

Thematic Domain	Main Distinguishing Criteria	Policy Relevance
Legal Status/Management Starting point for the international typology. National typologies may also use this domain as starting point, depending on typology objectives.	Legal status is designated and varies across countries	Only a small share of farms are designated as corporate farms even in developed countries, however, they account for a disproportionately large share of output and they have been a growing share over time. Furthermore, this designation is used in the System of National Accounts, and so an indicator is likely to be available at least at a macro level.
Farm Economic Size Recommended as the starting point for national typologies, but may vary according to national policy interests.	Economic value of agricultural output (e.g., including self-consumption and sales)	By considering an economic size indicator which captures total agricultural income generating capacity (including self-consumption and sales), it is possible to compare farms involved in widely diverse agricultural activities. While it is useful to know the extent of self-consumption relative to sales, rather than refining the typology classes, this information may be provided as part of the reporting of statistics by typology group. Farm size distribution measures are generally available for most countries; hence this availability will facilitate monitoring trends.
Production Mix and Input Use Since commodity mix varies significantly by country, aggregations will vary significantly in national typologies, and will be major categories in international types.	Commodity mix, specialization, input use and production practices, and access to land and capital	Production level information is a basic indicator for policy since many farm policies and marketing options are commodity-specific. It also incorporates information on physical capital, technology and agronomic practices. Thus this domain allows for the evaluation of production efficiency and access to factors of production (other than labor, treated in last domain). Input use and production practices are relevant to agri-environmental indicators.
Human Capital and Holder(s) Household Characteristics For national typologies focus on gender and the family farming sector may be of specific relevance.	Farm Labor Usage (Working time on Holding for family & employees) Working time and income from family working off-farm. Total family income from farm and off-farm sources. Market Orientation Gender	This domain is important for policies focused on both farm production and farm family well-being. It brings more visibility to emerging international policy agendas, such as the SDG, and national agendas that focus on specific categories such as: small scale family farms, female-headed households, young farmers and selected ethnic groups. Data to measure specific labor information are at times missing (particularly off-farm working time and income), but due to their policy importance they are now included in core data goals and their availability is expected to increase.

3. Organization of Domains into International and National Typologies

It is important that a typology have a balance between a framework that offers a harmonized classification system and that offers value in differing contexts and under a variety of policy goals. The organization of the domains into typologies for international and national purposes is expected to differ. The international typology will be guided by common agricultural, economic, social, and environmental issues, such as those captured in the SDGs. The national typologies will be guided by unique national priorities, especially those focused on improving the well-being of the population and the farm and household structure.[3] Consequently, the organization of the policy domains will differ, but the goal is to provide a typology organization that can link the many national typologies to the international typology, or perhaps a family of international typologies. A useful transition between national and international typologies would be the regional typology, like for example the typology built in the European Union, allowing for regional comparisons and common analyses.

3.1 International Typology Development

Different challenges in developing a useful typology for agriculture are amplified when the scope of analysis extends to the international context. Although there is significant diversity in agricultural structure across and within countries, basic agronomic relationships and an increasingly globalized marketplace bring some commonality to the challenge. Similarly, there are some socioeconomic characteristics that are common to countries regardless of stage of development. In particular, first, it is worth noting that agriculture in all countries is dominated by family control and management and, secondly, nonfarm employment is important in sustaining family farms across the globe. Finally, the wide acceptance of the SDGs brings agreement to the multiple policy goals that will drive an international typology.

One logical difference between an international typology and a national typology may very well be the starting point, or highest level of classification. In particular, an international typology may logically begin with a distinction based on legal status, that is, non-corporate family holdings and corporate holdings, whereas a national typology may not. This is because, first, large multinational firms increasingly entering the supply chain tend to have a corporate organization. Such a distinction may be less critical for a national typology because of the absence of much market presence by multinational firms. But, understanding the variation and growth of corporate activity spatially across the globe may be of significant interest in an international typology. It is these large holdings that further complicates classification and data collection because they often have a complex organizational structure, for example, to manage risks and reduce taxes. Furthermore, many distinguishing characteristics related to the family of the holding may be irrelevant in a corporate holding. For example, the off-farm income of corporate holdings or the gender of the corporate board would be irrelevant. Hence, in an international typology, it is necessary to recognize that different domains will be employed below the legal status distinction.

Finally, in the interest of consistency with statistical guidelines, the legal status is a useful entry point in an international typology because it is compatible with the U.N. System of National Accounts and is, therefore, commonly available.

3.2 National Typology Development

Since national typologies will be guided by national goals, inclusive multi-stakeholder interaction about the design of a country-specific typology is critical.. However, a likely key entry point in national typologies is an economic size criterion or a total family income criterion. Depending on the overriding policy focus of a nation, the entry level of a national typology could focus on either (1) the farm economic size indicator (based on total agricultural income including sales and self-consumption or similar) or (2) the total family income indicator provided agriculture is considered the main income source. Under either scenario, units will be classified as below or above the selected threshold. Regardless, additional distinguishing criteria are to be integrated in order to identify relevant national types. It is instructive to examine an empirical case for a national typology. In the case of El Salvador (Guanziroli, 2016) In this particular instance, there was a policy interest to distinguish family from non-family farming sectors as a first step, so the universe of farms was first disaggregated in such terms using both legal status and family labor information. In addition, country-relevant thresholds were chosen for selected key indicators of distinguishing criteria within the class of family farms, such as:

- total agricultural income, with four levels – high, medium, low and very low;
- market integration, with 3 levels – Commercial (more than 2/3 of the production is commercialized); transitional (less than 2/3 but more than 1/3 of the production is commercialized) and subsistence.

---

[3] The development of typologies for farm households in developing countries should recognize that different "types" may be relevant for different development trajectories (e.g., see Fan, et al. 2013).

- Specialization, with three levels according to the presence of a main product in total output – specialized (+70%), semi-diversified (30-70%), diversified (less than 30%);

- And technological , with three levels based on the relative usage and proportion of variable inputs: intensive (over 50%), semi-intensive (30 to 50%) and low intensive (less than 30%). This is the first step to engage in crossings of distinguishing criteria that can lead to highly policy specific farm types.

That is, it is possible to identify specialized family farms with high income and technological level on one hand, and the poorest and less marketed integrated family farms with diversified portfolios and reduced used of inputs on the other hand. The advantage is that all farm types in the middle of such a continuum may also be well targeted.

4. Conclusions

International and national typologies are expected to provide new insights into agricultural transformations. For example, it will be possible to assess phenomena related to challenges within the agricultural sector, including agricultural feminization, so-called land grabbing, rural economic diversification, etc. Farm typology development rests on established general statistical frameworks and specialized frameworks focused on agriculture and rural areas.

However, the proposed development faces a variety of challenges, including data availability, complex organizational forms, and capacity building. Furthermore, addition of an agri-environmental dimension faces significant hurdles since natural resources and policy priorities are often specific to local areas, but a typology will benefit from the significant efforts that are being invested for other purposes. More in-depth analysis is needed on the variation in the definition of a farm, land tenure systems, and off-farm work income. It is essential that typology development engage with multiple stakeholders, including those closely associated with policy development, in order to ensure that typologies live up to their potential to become a valuable tool in policy making.

THEMATIC SET

MEASURING THE EVOLUTION OF FARMING PRACTICES

C22

Session Organizer
A. Sorrentino | Università degli Studi della Tuscia | Viterbo | Italy

ABSTRACT

Farming practices play a fundamental role for the promotion of food security and safety and overall agriculture development. Changes in farming practices involve several actors in the food chain, from input producers, farmers, agribusiness and food enterprises to research, extension and rural development services. There is a wide range of technology options available which are often difficult to classify. There is the need to select appropriate measure indicators and identify data requirements and gaps in available statistics. The session will discuss criteria and quantitative indicators related to the development, adoption and implications of changes in farming practices. Specifically, the session will focus on the following areas: 1. Drivers to change agriculture practices: environment and climatic conditions, resource availability, policies and institutional factors, markets and food chain dynamics, access to input and technological knowledge, effects on factor productivity, technological innovation, research results 2. Actors in the development and adoption of new farming practices: research and extension services, NGOs, firms in the agri--food chain, farmers (adopters and involved in participatory research) 3. Implications of farming practices adoption: resources use, climate change adaptation/ mitigation and risk management, substitution effects among inputs, environmental protection (e.g. reduced pollution), farmers income and welfare, food security and safety, rural development. The session will welcome thematic papers focusing on these three areas. Methodological studies concerning constraints and difficulties for farming practices measurement and classifications such as data gaps/needs (data typologies, data collection) and implications for Institutions involved in agriculture statistics will be welcome as well.

Intensity of adoption of agricultural innovations in risky environment: the case of corn producers in West-Cameroon

P. Koncy Fosso | University of Douala, Faculty of Economic Sciences and Applied Management | Douala | Cameroon

DOI: 10.1481/icasVII.2016.c22

ABSTRACT

This study identifies factors that affect the intensity of use of improved maize seed and chemical fertilizer, the main modern inputs used to produce maize in West-Cameroon, by producers in West-Cameroon. The multivariate tobit model is used to take account of correlation between the disturbances. Results mainly indicate that the perception of risks is an impediment to a simultaneous adoption of agricultural innovations such as improved maize seeds and chemical fertilisers by corn producers in West-Cameroon and that, as a consequence, the price of corn has no effect on the intensity of use of modern inputs. We conclude that policies aiming at setting up sustainable risks management could greatly promote the adoption of agricultural innovations by farmers of the western region of Cameroon in general and probably by their peers in other regions of this country.

Keywords: Intensity of use of agricultural innovations; Multivariate Tobit model; Risks; West-Cameroon.

PAPER

1. Introduction

Despite the fact that agriculture is a very risky activity, it continues to be a fundamental instrument for sustainable development, poverty reduction and enhanced food security in developing countries. It is a vital developmental tool for achieving the Millennium Development Goals. However, Africa faces huge food supply challenges due to increasing human population, limited opportunities to increase arable land, and declining yields associated with continually declining soil fertility. Currently, agricultural productivity growth in sub-Sahara Africa lags behind that of other regions in the world, and is well below that required to achieve food security and poverty goals (Morris, 2007). Increasing agricultural productivity in Africa is an urgent necessity and one of the fundamental ways of improving agricultural productivity is through the introduction and use of improved agricultural technologies.

In Cameroon as in most countries of sub-Saharan Africa, although agriculture is a predominant sector, there is a low adoption of agricultural innovations, particularly among producers of food crops (INS/ECAM 3). In this regard, this paper analyses the determinants of intensity of adoption of improved maize seeds and chemical fertilizers by farmers (especially corn[1] producers) in western Cameroon. This is aimed at providing an empirical basis that would guide effective programs to promote agricultural innovations use[2] in Western Cameroon. A study on the intensity of adoption of agricultural innovations being more complete than that which is only limited to the examination of the adoption decision, then, while introducing the risks, this paper analyses the factors influencing the intensity of use of modern inputs by corn producers in West-Cameroon.

Although there is a well-developed literature on the impact of a host of explanatory variables on technology intensity adoption (Eba and Bashargo, 2014; Arslan et al, 2014; Turinawe et al., 2014), there is a dearth of the analysis which provides new evidence on policy relevant variables such as prices (particularly the price of output) and risks. In fact, facing some economic incentives such as the rising price of output, some atypical behaviours of producer (i.e. negative or absence of production/input demand response to output price incentives) in developing countries can be better explained only if risks are introduced in the analysis.

[1] This interest for corn stems from the fact that it is among the main food crops that is most consumed in Cameroon. Indeed, almost 67% of Cameroonians consume corn, about 12 million people; corn is also used in animal feed and in industry (ACDIC, 2008). In addition, maize is consumed in all regions of Cameroon. It should also be noted that today, this product is also used to make energy (corn is a bio fuel).

[2] A survey of 564 corn producers in West-Cameroon indicates that the intensity of the use of agricultural innovations is very low in this region.

Even if Asfaw et al. (2011) and Beshir (2013) take into account risks, they don't take into account the interdependence of adoption of agricultural innovations.

The contributions of this paper are twofold: First, in this study, farmers' perceptions of different types of risk are introduced in the list of factors influencing the intensity of adoption of agricultural technologies. We also introduce prices, particularly the price of output (here, the price of corn) as a driver of adoption. Second, we provide a rigorous analysis of the interdependent adoption of agricultural innovations by using a simultaneous equation Tobit model for estimating the intensity of technologies adoption.

The remainder of the paper is organized as follows: data and methods which are discussed in section 2; section 3 presents and discusses the results and section 4 concludes.

2. Materials and methods

2.1. Study area and data collection

This study was conducted in West-Cameroon, one of the ten regions of Cameroon. This region is known to be the barn of Cameroon since it is the main production area of food crops, especially corn. Corn production in West-Cameroon is estimated at nearly 20% of national production of corn (MINADER, 2012). West-Cameroon is divided into eight divisions among which four distinguish themselves in terms of maize production by their high density of production. These are: Hauts-Plateaux, Koung-Khi, Mbamboutos and Mifi.

According to the divisions of the Central Bureau of Census and Population Studies in Cameroon (BUCREP), regions in Cameroon are divided into divisions which are also divided into subdivisions, which in turn are subdivided into Enumerated Areas[3] (ZD) with known geographical boundaries. It is on the basis of these divisions that we gather our sample.

Data were collected in 2012 using the three-stage sampling technique. At the first stage, subdivisions with the highest density in maize production were selected from the four highly dense divisions in maize production, making a total of seven subdivisions. At the second stage, and on the basis of BUCREP's cartographic maps, we randomly selected from the selected subdivisions and in proportion to the population size, 25 ZD among the 282 ZD in the urban area and 17 ZD among the 291 ZD in the rural area. At the third stage, 11 corn farmers were randomly selected from each urban ZD selected and 17 corn farmers in each rural ZD selected. This choice was made in such a way that the number of producers surveyed should be the same in the rural and urban areas. The sampling process ended up with a sample of 564 corn producers. According to the formula of Cochran (1977), this sample size should be sufficient for this study.

Six students trained for this survey were used for data collection. These students were divided into two teams of three. Every day, each team had to go to one selected ZD and within the ZD, they would select, using the systematic sampling method, households (in each household, the surveyor would interview the farmer with the aid of a questionnaire) by steps of 18 households in urban ZD and by steps of 11 households in rural ZD.

Data were collected on the socioeconomic characteristics of the farmers[4] and their farm, the use of agricultural innovations such as improved seeds and chemical fertilisers, farmer's corn selling price during the year preceding the survey and the perception of risks by farmers.

2.2. Modeling and description of variables

As Arslan et al. (2014), Eba et Bashargo (2014) and Turinawe et al. (2014) we employed the Tobit model to examine the intensity of adoption of various technologies. But, in contrast to these authors, especially the work of Arslan et al. (2014) and Turinawe et al. (2014) which various technologies had been examined as in ours, we took into account possible inter-relationships between the various practices by using a simultaneous equation Tobit model for estimating the intensity technologies adoption. In fact, the adoption decision of the farming household for any one practice does not rule out the adoption of the other available practices, but as noted by Isgin et al. (2008), the adoption of a given technology might not be independent of another since the effects of certain technologies might be complementary.

In this paper, we adopt a multivariate Tobit econometric technique to estimate simultaneous equation Tobit model. The Multivariate Tobit model is estimated by maximum simulated likelihood that uses the Geweke-Hajivassiliou-Keane (GHK) simulator.

The intensity adoption equations for each modern input can be represented by:

$$y_i^* = X_i \beta_i + u_i \quad i = 1, \ldots m \text{ (in our case } m = 2\text{)} \qquad (1)$$

[3] An enumerated area is a geographical area that can accommodate approximately 200 households.

[4] In this study, a farmer is a person who operates a farm (farm owner). A farm owner or a farmer is not necessarily the owner of the land where he cultivates.

where y_i^* is a latent variable representing the intensity of adoption of the agricultural innovation i (y_i), X_i is a vector of exogenous variables (These variables are presented in Table 1), β_i is the vector of parameters to be estimated and u_i is a random disturbance with mean zero and variance σ_i^2. The relationship between the latent variable y_i^* and the intensity of adoption for a modern input i (y_i) can be represented by:

$$y_i = y_i^* \;\; if \;\; y_i^* > 0 \qquad (2)$$
$$= 0 \quad \text{otherwise.}$$

Table 1 - Variables definition and descriptive statistics (N=564)

Variables	Variable names	Measure	Mean	Standard deviation
Dependent variables				
intsam	Intensity of use of improved maize seeds	percent of area planted to improved maize seeds	12.906	28.644
intanch	Intensity of use of chemical fertilisers	quantity of fertiliser (in gram) applied per m^2	10.278	14.996
Independent variables				
riskmala	Perception of risk of illness or death of a key member of the household	1 if a risk, 0 otherwise	0.521	0.500
riskprix	Perception of risk of decline in the price of corn	1 if a risk, 0 otherwise	0.943	0.232
riskphyt	Risk perception of pest-disease infestations	1 if a risk, 0 otherwise	0.568	0.496
riskclim	Perception of climate risk	1 if a risk, 0 otherwise	0.941	0.235
riskfina	Risk perception of default to finance a crop production	1 if a risk, 0 otherwise	0.334	0.472
dist_ch	Average distance from the farmer's home to the farm	Distance in kilometres	11.664	
fem	Gender of farmer	1 if the producer is a woman, 0 otherwise	0.824	0.381
fertilbais	Evolution of the farmland fertility over the past 5 years	1 if the farmland fertility has declined, 0 if soil fertility has not changed	0.237	0.426
fertilhaus	Evolution of the farmland fertility over the past 5 years	1 if the farmland fertility has increased, 0 if soil fertility has not changed	0.248	0.432
primary	Educational level of farmer	0 if no education, 1 if has primary education level	0.420	0.494
secondary	Educational level of farmer	0 if no education, 1 if has secondary education level or higher	0.374	0.484
credit	farmer's credit access	1 if access to credit, 0 otherwise	0.342	0.475
div-act	Exercise of the non-agricultural activity by the farmer	1 if has a non-agricultural activity, 0 otherwise	0.404	0.491
asso	Farmer participation to a producer organisation	1 if adhere to a producer organisation, 0 otherwise	0.688	0.464
propr	Ownership of land cultivated	1 if owner, 0 otherwise	0.894	0.309
experience	Agricultural experience of the farmer	Number of years during which the producer has been engaged in corn production	23.608	14.184
experience2	Agricultural experience of the farmer squared	Number of years during which the producer has been engaged in corn production (squared)	758.175	791.978
tailmenag	Household Size	number of persons in the household	6.596	3.056
dist_mark	Average distance from the farmer's home to usual market	Distance in kilometres	2.026	2.320
super	Farm size	Acreage (in m^2)	11493.010	10652.460
pmoy	Average sale price of a kilogram of maize	Amount in FCFA	140.971	45.757
tauxsal	Cost of labour	Amount in FCFA/week	10508	5994
revenu	The annual income of the farmer	Amount in FCFA	598351	1169125
rural	Area	1 if rural area and 0 if urban area	0.5124	0.500
coutfiente	Cost of 50 Kg of manure	Amount in FCFA	1757.307	431.015

Note: In this study, the farmer is the interviewee.

Regarding dependent variables, we examined in this study two main modern inputs which are used to produce corn in western Cameroon, these are: improved seeds of maize and chemical fertilisers. We noted that in average, farmers used 10.278 gram of fertiliser per m^2 and allocated only 12.906 % of their cultivated land to improved seeds. Among those who used chemical fertilisers on their corn, 15.2 grams on average of chemical fertiliser[5] were applied per m^2 of land; which is well below the average quantity regularly recommended for corn in western Cameroon (i.e. 20 to 30 grams per m^2 (IRAD, 2010)).

Table 1 shows that about 82 percent of surveyed farmers were female[6], 89.4 percent owned their lands[7] and about 50 percent reside in rural zone. 42 percent of survey farmers had primary education level while 37.4 percent had secondary education level or higher. The average size of farm was about 1.15 hectares and the farmer's average annual income was about 598,351 FCFA (about 1,196 US $). In average, maize price was about 140 FCFA, the cost of labour and manure were about 10,508 FCFA and 1,757 FCFA, respectively.

Regarding risk variables, in this study, as in the works of Glynn et al. (2009) and Kurihara et al (2014), the perception of farmers of the importance of events that could have a negative impact on their income will be retained as a means of quantifying the principal risks which farmers face. In fact, this perception of risk by the producer is nothing more than an assessment by him of the risk in terms of probability that risk has a negative impact on his income. So, to capture farmers' risk perception, farmers were asked to score their perception of the importance of events/shocks that could have a negative impact on their income based on previous shocks (on a scale of 1 to 5; where 5 signifies high negative impact on their income).

[5] Chemical fertiliser most used in western Cameroon is the composite variety 20-10-10.

[6] This is in conformity with national estimations which reveal that Cameroonian women accomplish more than 75 % of agricultural work and contribute for 60 % of food production (FAO, 2007).

[7] In the western region of Cameroon most of the land belongs to families and all family members including women claim to be co-owners of land.

This variable is converted into a dummy variable, where 1 indicates that there is a risk perception and 0, the absence of risk perception. Because this method of quantification of risk does not require either knowledge of the probability distribution of the loss of income, nor the values of those potential losses that may be incurred by the producer, this method will be used to capture the main agricultural risks which farmers face.
As regards statistics of the risk perception variables, we noted that farmers that perceived risk was 52.1, 94.3, 56.8, 33.4 and 94.1 percent for risk of illness or death of a key member of the household, for risk of decline in the maize price, for risk of pest-disease, for risk of default to finance a crop production and for climate risk respectively.

3. Results and discussion

The significant effect of the perception of some risks (see Table 2) indicates that the econometric specification in an uncertain environment is most appropriate. Table 2 presents the econometric results concerning variables influencing the intensity of adoption of agricultural innovations by corn farmers in western Cameroon. The likelihood ratio test [chi2(1) = 2.95456, Prob → chi2 = 0.0856] of the independence of the disturbance terms is rejected, implying that multiple technology adoption in West-Cameroon is not mutually independent and supporting the use of a multivariate Tobit model (See Table 2). In addition, the binary correlations between the error terms of the two adoption equations show that these practices are complements (positive correlation).
It appears from Table 2 that the cost of labour has a negative effect on the intensity of adoption of chemical fertilisers. In fact, the use of this agricultural innovation is labour intensive, so an increase in labour costs will decrease its intensity of adoption. Conversely, the high cost of organic fertiliser could drive farmers who want to increase their production to increase the intensity of adoption of chemical fertiliser (which is a substitute for organic fertiliser because it is also added to the soil in order to increase the quantity of nutrient in the soil).

Prices of improved maize seed, fertilisers and pesticides were excluded because there is lack of variation in our data for these variables.

In general, risks perception does not allow the combined adoption of agricultural innovations by corn producers in West-Cameroon (Table 2). Indeed, the perception of climate risk has a negative and positive effect respectively on the intensities of adoption of improved seeds and fertilisers. Similarly, while the perception of risk of financing a crop has a positive influence on the intensity of adoption of chemical fertilisers, it has no effect on the intensity of adoption of improved seeds. According to Feder (1980), these results would be related to the facts that poor farmers in developing countries (including Cameroon) face credit constraints; which leads them to intensify chemical fertilisers more (at the expense of improved seeds). However, the perceived risk of illness or death of a key member of the household (as potential labour) leads these producers (with a binding credit constraint) to reduce the intensity of adoption of chemical fertilisers that are labour intensive and to increase the intensity of adoption of improved seeds. All this shows that the presence of multiple agricultural risks combined with the constraints of credits facing Cameroonian producers do not favour the combined adoption of agricultural innovations; yet, according to Perkins et al. (2008), it is the combined use of these agricultural innovations which ensures higher crop yields.

Table 2 also shows that the intensity of adoption of chemical fertilisers do not continually decreases with the increase of agricultural experience of the farmer. Which indicates that it is only at a certain level of experience in agriculture that the farmer understands the need to intensify the use of chemical fertilizers. The proportion of land allocated to improved seeds only increases with the level of secondary education or higher; it is probably at this level of education that farmers understand the agro-economic potential of the use of improved seeds. Similarly, producer participation in one (or more) organisation(s) has a positive effect on the percentage of land allocated to improved seeds. In fact, it is usually within producer organisations that farmers discuss their work with their peers and share information and their experiences on the advantages of using new technologies. It also notes that the ownership of cultivated plots has a negative effect on the quantity of grams of chemical fertiliser used per 2 m of land. In fact, the farmers who own farmland, aware of the potential long-term negative impact related to the intensive use of chemical fertilisers, therefore use this input less intensely.

Contrary to theoretical predictions, farm size negatively influences the intensity of adoption of fertilisers. This might be due to the fact that farmers with larger farm sizes have the possibility to reconstitute soil fertility by allowing some of their land fallow. However, it influences positively the intensity of using improved seeds. This implies that farm size is an indicator of wealth and a proxy for social status within a community which influences positively the intensity of use of improved seeds. Similarly, as an indicator of wealth, the farmer's income has a positive influence on the intensity of adoption of improved seeds and fertilisers. Moreover, we note that the decreased fertility of cultivated land has a positive influence on the intensity of use of chemical fertilisers and a negative influence on the intensity of use of improved seeds. In fact, in the face of declining fertility of cultivated land, poor farmers (with a binding credit constraint) spend their income to the purchase of fertilisers (at the expense of the purchase of improved seeds). The increase in fertility of cultivated land is an unfavorable factor for the intensity of use of chemical fertiliser. This is quite intuitive because the land being fertile, farmers will no longer need to intensify the use of chemical fertilisers.

4. Conclusion

This study determines the factors influencing the intensity of use of agricultural innovations by corn producers in western Cameroon. Rather than univariate Tobit model which is commonly used, the multivariate Tobit model is employed to take account of correlation between the disturbances. The study shows that, beside the perception of many agricultural risks, multiple characteristics related to the producer or to his farm affect adoption of improved maize seed and chemical fertiliser by corn producers in West-Cameroon. Results mainly indicate that, faced to risks perception, farmers in West-Cameroon tend not to adopt improved maize seed in combination with fertiliser. Yet, according to Perkins et al. (2008), it is the combined use of these agricultural innovations which ensures higher crop yields. Furthermore, the price of corn has no effect on the intensity of use of modern inputs. This result might be linked to the presence of multiple agricultural risks that could make farmers insensitive to incentives of output prices. The implication of this is that the policies aimed at setting up sustainable risk management markets could greatly promote the adoption of agricultural innovations by farmers of Cameroon in general and in the western region in particular where the markets of risk management do not exist or are malfunctioning.

How has farming practices affected the cereal production in Morocco?

A. Mansouri | High Commission for Planning | Rabat | Morocco

DOI: 10.1481/icasVII.2016.c22b

ABSTRACT

The purpose of this paper is to present a new approach to modelling a cereal production function and propose an estimate of farming practices function in Morocco. Cereal production function would be determined by econometric model drawing in particular on the Solow approach (1957), based on five factors- land, water, employment and farming practices. To simplify the model, we aggregate the effects of the three first factors by using a principal components analysis (PCA). We use then the Space state models to provide an estimate for the non observable factor, namely agriculture practices. Such an estimate is a useful tool for examining the farming practices fluctuations and analyzing of its effects on cereal production, in particular, following the Government's adoption of the Green Moroccan Plan in 2008. The data comes from agriculture department and High commission for Planning, from 1991 to 2015. Results show that the improvement by 1% in the agricultural practices leads to a 0.3% increase in cereal production.

Keywords: agriculture, farming practices, cereal, PCA, Kalman filter JEL Classifications: Q1, Q12

PAPER

1. Introduction

The traditional factors determining the agricultural production are labor, capital, land and water. However, the standard approach of modeling the agricultural production generally holds two main factors- capital and labor. The improvements made by the introduction of the third factor land, highlighted by Martin and Mitra (1993), were rare. Most studies have retained the two first factors, assuming constant returns to scale. They have thus used the Solow approach (1957), which expresses the production from factor shares. In this approach, the operating surplus is frequently used to measure the return on capital. However, and taking into account the economic specificities of agriculture in many developing countries, the operating surplus cannot be considered as equivalent to return on capital, but would include also the return shares of land and employment. Furthermore, agricultural practices might also be considered as crucial factor that influences crops output and livestock strength. They play a decisive role in the development of agricultural production, since they achieve higher productivity and contribute to ensure the food security. Overall, the increase of agricultural production could result from the combination of two major sets of factors: the available quantities of traditional factors- land, water, labor and capital and the effectiveness of their contribution associated with the use of agricultural practices.

Agricultural practices consist of all techniques conducted by the farmers to improve crop and livestock productivity. They include irrigation, soil preparation, crop rotation, fertilizers, and pesticides. In Morocco, agricultural practices was continued to progress at a very moderate pace in the 80s and 90s. The fertilizer consumption was limited to 65 kg per hectare of arable land in 2002, instead of 72,8 in Turkey, 164,5 in Spain and 211,3 in France[1]. The number of tractors did not exceed 45 units per 100 square km of arable land. The largest proportion of the crops areas was under rain fed, while less than 15% of cultivated areas were irrigated. The production of rainfed crops, including cereals had not seen a dynamic growth, due to less intensive production system. Thus, the Moroccan government launched in 2008 a new strategy, namely Green Morocco Plan, in order to improve the sector's resilience to climate fluctuations and boost its production and exports through the reorganization of its productive chains, diffusion of good practices at both large and small farms and by adopting a proactive fundraising approach for financing agricultural projects.

This paper aims to present an innovative approach to econometric modelling of cereal production function and propose a new method for estimating agricultural practices indicator in Morocco. The study is carried out over the period from 1990 to 2015. The choice of sample period is related to the availability of data and the fact that the cereal production has been undergoing drastic changes, especially from 2000.

[1] Wolrd Bank Group, 2016

The approach starts with a production function that expresses cereal output as a function of the agricultural practices and the traditional factors. To simplify the model, we have grouped three factors (level and dispersion of rainfall per season, sown areas and employment) using a principal component analysis.

Unlike labor, capital, land and water factors, whose data were collected from the Department of Agriculture and the High Commission for Planning, the agricultural practices factor is a latent variable, which will be recovered by applying the Kalman filter (1960, 1963). An important feature of this filter is to provide an estimate of the unobservable variable "agricultural practices" for the sample period. The second advantage consists on its ability to generate forecasts for the latent variables that can be incorporated in econometric projections. In the next section, we examine the theoretical framework of our econometric model. Section 3 presents an extension of the Kalman filter leading to estimate the unknown model parameters and generate the latent variables. The empirical results will be presented in section 4. We find that agriculture practices and traditional factors are both important in representing changes in patterns of cereal production. Section 5 concludes.

2. Econometric approach

The modeling approach of cereal production has derived from the Solow model (1957). Assuming three production factors (aggregated nature and employment factor, capital and agricultural practices), the cereal production function can be expressed as:

$$Y_t = NL_t^{\alpha} K_t^{\beta} P^{\delta}_t$$

Where Yt is the cereal production, Nl represents the aggregated nature and employment factor, K capital expenditure, and P is the farming or agricultural practices factor. α, β and δ represent respectively the shares of production that remunerate the three factors. These shares should be less than unity. By differentiating the production function with respect to time t, and dividing by Y, the growth rate can be estimated as :

Log(Y)= α log(NL) + β log(K)+ δ log(P)

dLog Y = Y'dNL+ Y'dK+ Y'dP

$$= \alpha\, NL_t^{\alpha-1} K_t^{\beta} P^{\delta}_t + \beta\, NL_t^{\alpha} K_t^{\beta-1} P^{\delta}_t + \delta\, NL_t^{\alpha} K_t^{\beta} P_t^{\delta-1}$$

$$\frac{dlogY}{Y} = \frac{\alpha\, NL_t^{\alpha-1} K_t^{\beta} P^{\delta}_t}{NL_t^{\alpha} K_t^{\beta} P^{\delta}_t} \mathrm{dNL} + \frac{\beta\, NL_t^{\alpha} K_t^{\beta-1} P^{\delta}_t}{NL_t^{\alpha} K_t^{\beta} P^{\delta}_t} \mathrm{dK} + + \frac{\delta\, NL_t^{\alpha} K_t^{\beta} P_t^{\delta-1}}{NL_t^{\alpha} K_t^{\beta} P^{\delta}_t} \mathrm{dP}$$

$$\frac{dlogY}{Y} = \alpha \frac{dNL}{NL} + \beta \frac{dK}{K} + \delta \frac{dP}{P}$$

The decomposition of the production growth shows the contributions of each factor to the growth and their remuneration.

3. Application of the Kalman Filter

The identification of the unobservable variable "agricultural practices" is based on the application of a State Space model. This type of model can distinguish between the specification of observed variables (the signal) and the unobserved variables (known as the state variables). It generally consists of one or more measurement equations describing how the observed variables are explained by the unobserved variables and one or more state equations indicating how these variables are generated from their dynamic of the past and from the residues.

In our study, the state space model highlights a linear decomposition of the dependant variable (cereal production) into three factors (aggregated indicator, capital, agricultural practices). The two first factors are observed and assumed uncorrelated, while the latter is not observable and assumed stochastic. The variable representing the agricultural practices follows a random walk model, taking into account the effects of two exogenous variables (fertilization and seeding use).

The State Space model is expressed as following:

$$\begin{cases} P_t = CP_{t-1} + \varepsilon_t \\ Y_t = A'X_t + B'P_t + \eta_t \end{cases} \qquad \{t \geq 1\}$$

Where Y is the dependent variable determined by the vector of the independent variables X (NL, K) as well as the unobservable variable Pt. The irregular components εt and ηt are uncorrelated white noise. A, B and C are the parameter matrix. $P_0 \approx N(m, \sigma)$

We propose to include two major changes into the state equation. The first concerns the addition of explanatory variables in order to improve the quality of latent variable estimate. Pt equation would give a clear idea of the exogenous variables effects (fertilization and seeding use) taking into account the past effect of the variable changing itself according to random shocks.

The second is related to the dynamic change of Pt assumed following a random walk with drift. This latter change will allow Pt slope to change as a result of random shocks that could affect its level over time.

The new state space model is given by the system of the following equations:

$$\begin{cases} Y = A'X_{1,t} + B'P_t \\ P_t = C'X_{t,2} + P_{t-1} + W_{t-1} + \varepsilon_t \\ W_t = W_{t-1} + \mu_t \end{cases}$$

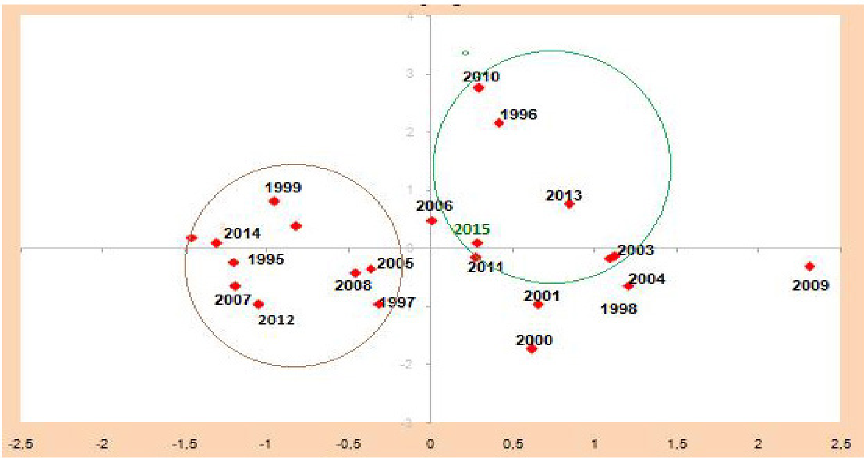
Where ʹt and µt are independent vectors of mean zero Gaussian disturbances variance. ʹt allows to the latent variable P to fluctuate by varying its slope. With the new State Space representation, extraction of the agricultural practices factor would be performed using the Kalman filter, which provides a recursive estimation of the latent variable at time t assuming the conditional distribution of the State vector.

4. Empirical results

In this section, we provide but are not limited to the results of our investigation. It seemed relevant firstly to present the results of principal components analysis conducted on rainfall, employment and areas sown data. The level of rainfall remains a determining factor of cereal production since the irrigated area did not exceeding 9% of the total area sown.

The 7 variables used in the principal components analysis were chosen because of their correlations and contributions to explain the cereal production. This include rainfall level divided into two periods (October to December and January to March) and differentiated in terms of distribution during the winter and autumn season, employment, sown area and the effect of early rains. The results reveal that the two axis resulting from the implementation of the PCA account for about 72% of the variation. The first axis is strongly associated with rainfall dispersion and area sown. Similar years in terms of climatic, land and employment conditions, easily emerge from their proximity from on the plane factor. Overall, and taking into account the first two axes selected by PCA, two homogeneous sets of agriculture campaigns are characterized (poor and good harvests).

Figure1 - similar crop year scatter



Once calculated the aggregated indicator based on rainfall, area sown and employment factors, we estimate the State Space model suggested in the previous section. However, we encountered severe convergence problems suggesting a specification problem. We decided to improve the model by inserting a constant in the equation state. The model is thus expressed as following:

$$\begin{cases} Y_t = \alpha Ag_t + \beta K_t + \delta P_t \\ P_t = a_0 + a_1 engr + a_2 sem + P_{t-1} + W_{t-1} + \varepsilon_t \\ W_t = W_{t-1} + \mu_t \end{cases}$$

The estimation of unknown parameters will be operated from the maximum likelihood method. The results are summarized in the following table:

Table 1 - parameter's estimate

Variable	Coefficient	1991-2015		2000-2015	
		Estimation	Z statistic	Estimation	Z statistic
Aggregated factor	α	0.31	3.37	0.10	2.20
Capital	β	0.28	1.87	0.43	3.42
Practices	δ	0.31	4.73	0.18	3.65
Constant Pt	a_0	-12.8	-0.00	0.18	0.129
Fertilizer	a_1	-6.42	-0.67	-46.36	1.46
Seed	a_2	3.74	1.71	24.57	1.86

The results show that the sign and the size of estimated parameters are consistent with economic theory. An increase of each quantity on the three factors (aggregated indicator, capital and agricultural practices) leading to improved cereal production. The homogeneity hypothesis of production function is also not rejected (the sum of the parameters associated with the three factors is near to unity). However, the results revealed a less prominent role of fertilizers; its z-statistic is not significant. To check the robustness of the parameter, we re-estimated the same model on a more recent period (2000-2015). The results show a fairly significant improvement in the contribution of seed and fertilizer use, especially from the adoption of the Green Morocco Plan in 2008.

The estimate of the Space State model reveals a gradual progress of agricultural practices function, especially during the dry seasons with a significant rainfall deficit. This is particularly true for 2000 and 2007 which were characterized by an important improvement of agricultural practices, in line with the increase of the use of irrigation and certified seeds. Conversely, the campaigns which are marked by good temporal dispersion of rainfall, especially during the winter, were down on the use of agricultural practices, due, in particular, to the large proportion of rainfed areas that do not require irrigation during the wet years.

Figure 2 - agricultural practices indicator

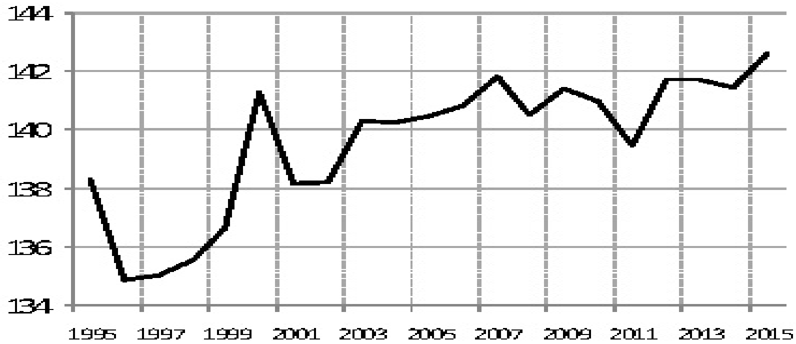


Figure 3 shows the performance of Space Stat models. It reveals a perfect synchronization movement of the original and fitted series on the whole sample period. It shows also the ability of the model to reproduce output fluctuations throughout the sample period. Specifically, the graph shows that the cereal production function cannot be performed from the two only traditional factors- labor and capital, but should also take into account the effect of natural factors, employment and agricultural practices, particularly in countries that are highly exposed to climate disruption.

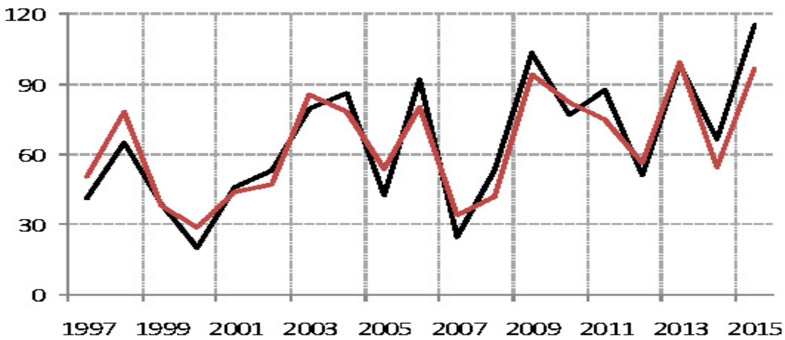
Figure 3 - cereal production(original and fit series)



5. Conclusion

The principal innovation of this paper is to generate empirical measure of the agricultural practices factor as latent or unobservable variable, while providing cereal production function. The results reveal the crucial role of agricultural practices in improved cereal production in Morocco. Agricultural practices focused on the use of inputs have generally achieved a higher crop yield in recent years, but found liable for accelerated pollution of fresh water, soil and a decline in food safety. The increase of restrictive practices and more geared towards the use of natural inputs and a local knowledge of farmers should answer, in part, to the growing demand for sustainable organic agriculture. However, it marks a major shift in agricultural production function that should give a prominent role to the labor factor (knowledge and technical competence) rather than practiceintensive factors. It should be emphasized that this transformation, highly recommended as part of Sustainable Development Goals (SDGs) could be long and difficult in the short term, as it would be difficult to ensure the nutrition of the entire Moroccan population or meet changes in market access at affordable rates. Moroccan Farmers would continue to use intensive agricultural practices and the cereal production function would be thus continued to be influenced by the effect of inputs (fertilizer, pesticides) in the short term.

Evolution of farming practices in the French vineyard The use of pesticides 2006-2013

J. Pujol | Ministry of agriculture, food and forestry Office for Statistics and Prospective
Complexe agricole d'Auzeville | Castanet-Tolosan | France

DOI: 10.1481/icasVII.2016.c22c

ABSTRACT

The French surveys on viticulture 2006, 2010 and 2013 form part of a wide range of surveys on farming practices. One of their primary objective is to evaluate the use of pesticides. A good knowledge of their use is a major challenge for sustainable development because of their relationship with environmental and health risks.The first part of this study identifies the main indicators on the use of phytosanitary products and focuses on the treatment frequency index (TFI). Based on the Danish experience, this indicator is built with the normalized doses of pesticides actually applied by the wine producers. It can be easily expressed on a regional scale or on pesticides subdivision. In France, this indicator varies from 9.2 in Pyrénées-Orientales to 21.4 in Champagne in 2013. The second part raises the question of the climate effect on the TFI variations 2013/2010. The weather with its stimulus role in the parasite development can cause an augmentation of the use of pesticides. In 2013 degraded climatic conditions, the TFI has increased in all vineyards. The use of a fixed effect model leads us to estimate a significant climate effect in 7 vineyards out of 13. The weather variations between 2010 and 2013 contribute from 6% in Bourgogne to 31% in Val de Loire to the TFI increase.

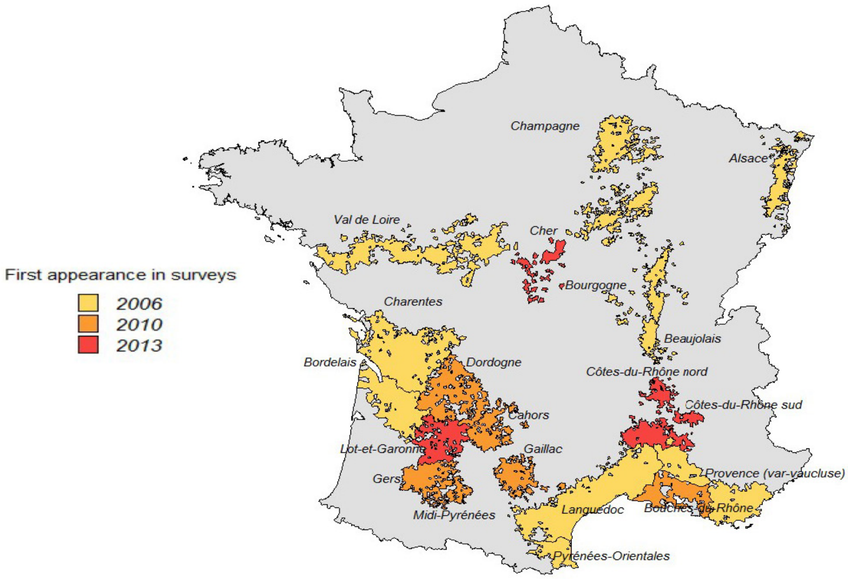
Keywords : pesticides, treatment frequency index, climate effect

PAPER

1. Introduction

Since the mid of the 2000's, the French statistical service has launched a wide range of surveys on agricultural practices. These surveys are a major tool to assess the impact of the French public policy Ecophyto[1] that was developed by the French Ministry of Agriculture in 2008 with the purpose of progressively reducing the use of pesticides while maintaining agricultural performance. The surveys cover nowadays the main crops productions: field crops, fruits, vegetables and viticulture[2]. This paper will focus on the 3 waves of the survey on viticulture implemented in 2006, 2010 and 2013.

Figure 1 - The French vineyards map Farming practices surveys in viticulture 2006, 2010 and 2013.



[1] This public policy is an answer to the Article 4 of Directive 2009/128/EC. A second version of the Ecophyto plan was published in 2015. Among its main objectives is the reduction in pesticides use in two stages: -25% by 2020 and -50 % by 2025.

[2] Wine grapes.

2. Measuring the use of pesticides

The relationship between pesticides and environmental and health risks is beyond doubt and is coming into sharper focus. The permanent crops like vines consume large amounts of pesticides. In 2013, the French vineyard area is about 800 000 hectares and represents a major challenge for the reduction of the use of phytosanitary treatments. To evaluate the practices, several indicators have been developed.

2.1 Number of phytosanitary treatments and sales of active ingredients

A phytosanitary treatment is defined as the use of a commercial product across a cultivated land during a cropping season. A same product applied in two passes counts for two treatments. A mixture of two products applied during a single pass also counts for two treatments. Most of pesticides can be subdivided into the fungicides (against fungi), the insecticides (against insects) and the herbicides (against plants considered to be « weeds »).

The **number of phytosanitary treatments** does not take into account the spread quantities during each pass. Some vineyards can be treated with several passes with low pesticides doses while others are often less treated but with higher doses during each pass. For example, two passes with halfdose count for two treatments whereas a single pass with full dose counts for one treatment. However, the sanitary pressure is the same in the two cases.

An other pressure indicator regularly followed in Europe is the total **quantity of active ingredients** which is sold on a given territory. The main limit of this indicator is the measure of the difference between sale and consumption of pesticides. For example, the storage variations of products from year to year can create a gap between sale and use of pesticides for a given year. Thus, this indicator can decrease even though the pressure on the environment is the same.

2.2 The treatment frequency index (TFI)

The treatment intensity index (TII) is a monitoring indicator of the use of pesticides. It has been developed in Denmark in the middle of the 80's. It is defined at the national level:

$$TII = \frac{\sum_{AI} \frac{SQ_{AI}}{ED_{AI}}}{TCA} \quad (1)$$

SQ_{AI} Sold quantity of active ingredient
ED_{AI} Effective dose of active ingredient
TCA Total cultivated area

In France, the National Institute for Agricultural Research (INRA) and the Ministry in charge of agriculture have developed in 2006 a calculation method based on the Danish experience (Champeaux, 2006 ; Pingault et al., 2009). The French version, the treatment frequency index (TFI), is not built with the active ingredients but with the phytosanitary products. It also takes into account the quantities actually applied by the wine producers instead of the sold quantities. Since 2007, it is implemented as a supporting and evaluation tool for the reduction of the use of pesticides.
For the TFI calculation, the « pesticides » item of the questionnaire allows to identify the applied products during each pass for a given vineyard parcel. For each applied treatment on the vineyard parcel[3], the TFI is the following:

$$TFI = \frac{DA}{ED} * PTA \quad (2)$$

DA Dose actually applied per hectare (from survey)
ED Effective dose for a target (diseases/pests) per hectare (from target framework)
PTA Percentage of treated area (from survey)

Specific cases:

- Some products do not have effective dose (ED). In this case, the TFI is equal to the percentage of treated area (PTA),
- If TFI<0.1 or >2, or if it is a misuse, it will be corrected by imputation (mean based on vineyard and target). Depending on the year, these corrections vary from 2% to 5% of the observations,
- TFI=1 for pheromone dispensers (mating disruption).

Until 2015, the effective dose was defined on a pair (culture, phytosanitary product). When several effective doses were available corresponding to different targets, the calculation method was based on the lowest dose. The methodology has been improved with the use of the triplet (culture, phytosanitary treatment, target) to determine the effective dose.

[3] Rodenticides, repellent products, talpicides are not included.

For the 2006 survey, the target of the used product was not collected. To calculate the TFI, the method has been as follows:

- The pairs (phytosanitary product, target) 2010 were settled.
- The 2010 target was applied to all the 2006 products still existing in 2010. For the 2006 products that disappeared in the meantime, the target has been searched in a reference viticulture basis.

Figure 2 - Examples of the TFI calculation Farming practices survey in viticulture 2013.

Date	Product	Target	Percentage of treated area	Applied dose (KG/HA)	Effective dose (KG/HA)	TFI
2013-03-01	PLEDGE	Herbicide	60	1	1,2	1/1.2*0.6=0.5
2013-05-28	VALIANT FLASH	Mildew	100	3	3	3/3*1=1

The « TFI parcel » is defined as the sum of the TFI.

2.3 Results by vineyard

In 2013, the average TFI varies largely across vineyards ranging from 9.2 in Pyrénées-Orientales to 21.4 in Champagne. The protection of grape wines against microscopic fungi is responsible for around 80% of the phytosanitary treatments. Thus the main source of regional heterogeneity is related to the dispersion of the TFI fungicide.

Between 2006 and 2013, the TFI has increased in all vineyards but in varying degrees. The highest increase has been measured in Bourgogne (+5.6), the lowest one in Alsace (+0.5).

Farming practices surveys in viticulture 2006, 2010 and 2013.

3. Parasite pressure, climate and TFI

Several factors can explain the phytosanitary treatments level: the parasite pressure of the year which is partly related to climatic factors; the farming practices of the wine producers who use more or less pesticides,… The main aim of this paper is to isolate the impact of the parasite pressure on the level and the evolution of pesticides use as measured by the TFI index. The analysis will focus only on the years 2010 and 2013 to use a panel approach and also because some climatic factors, used as a proxy for parasite pressure, are not available for the year 2006. It will be based on 13 vineyards.

3.1 Measuring the parasite pressure

Mildew and oïdium are the major diseases of vine. They develop better with a hot and humid weather. Mildew affects the photosynthesis and causes a lagging maturity and a decrease in the alcoholic degree. Oïdium can cause a decrease in the grape wine quality by reducing the content in phenols and sugar. Repeated attacks of these diseases on leaves and grapes can destroy an entire crop. To evaluate the parasite pressure, two sources are available. The first one relies on quantitative indicators built by a network of regional observers. The pressure level is determined for each vineyard and covers most of the parasites. The second source is based on the farming practices surveys that also collect some qualitative indicators on the parasite pressure (strong/ average/ weak pressure). To answer this question, wine producers rely on their experience about the cultural parcel.

According to the quantitative approach, both « mildew » and « oïdium » pressures have increased between

2010 and 2013 in 2 regions (Charentes and Val de Loire) and both have decreased in one region (Provence). In the other regions, the evolution of parasite pressure is not the same for mildew and oïdium.

Table 2 - Level of parasite pressure 2013/2010

	Parasite pressure 2013/2010		
	More pressure	**Equal**	**Less pressure**
Mildew	Alsace, Bordelais*, Bourgogne, Charentes, Dordogne*, Val de Loire.	Beaujolais, Champagne.	Bouches-du-Rhône, Provence.
Oïdium	Beaujolais, Champagne, Charentes, Val de Loire.	Bouches-du-Rhône, Bourgogne.	Alsace, Bordelais*, Dordogne*, Provence.

**Regional phytosanitary results do not distinguish Bordelais and Dordogne.*
Regional phytosanitary results are not available in 2010 in the following vineyards : Gers, Languedoc and Pyrénées-Orientales. In 2013, "mildew" pressure was described as "average" in Languedoc and "weak" in Pyrénées-Orientales. At the same time, "oïdium" pressure was described as "average" in both vineyards.
Regional phytosanitary results in viticulture 2010 and 2013.

The qualitative approach provides divergent conclusions. Except for Pyrénées-Orientales, the "mildew" is perceived as a growing pressure on average for all vineyards. The "oïdium" pressure also increases except in Alsace, Bouches-du-Rhône, Gers and Pyrénées-Orientales where it is stable. Whatever the level of pressure, the TFI average in 2013 exceeds the one in 2010. Whatever the year, the highest TFI average is obtained when the parasite pressure is felt strong for mildew and weak for oïdium.

Given the difficulty to obtain objective indicators at the parcel level to quantify the parasite pressure effect, we finally opt for an indirect measure: the impact of climatic factors on the TFI. If climatic conditions are not the only determinant for parasite pressure and phytosanitary treatments, they are important parameters in the use of pesticides. In 2013, 44% of wine producers said that weather forecasts and rainfall were the main reasons for the use of pesticides.

3.2 Climatic factors and TFI

The spatialised data base of Meteo-France provides for each parcel the information collected by the nearest grid point (about ten kilometers grid). From April to August, the following monthly parameters can be observed: rainfall (RR), sunshines (INST), average and range temperatures (TMOY, AMPT), wind speeds (FFM) and humidity (HUMOY).

In April and May 2013, the rainfall has increased with respect to 2010 in all vineyards in particular in Bourgogne, Beaujolais and Champagne. During these two months, the average temperatures were significantly lower with important gaps in May (-3°C). In April, the wind was strong in particular in Dordogne and Gers. In May, except in these two vineyards and in Bordelais, it is a reverse trend. In June 2013, the rainfall has decreased and the average temperatures were significantly higher especially in Beaujolais, Bouches-du-Rhône and Provence. In July and August 2013, the weather was very sunny in particular in Alsace, Bourgogne, Champagne and Charentes.

A principal component analysis (PCA) is performed to study the correlation between climatic factors and TFI. The main results are the following:

- Overall, a stronger correlation between climatic factors and TFI for the year 2013,
- A positive correlation between TFI and rainfall and humidity variables,
- A negative correlation between TFI and sunshines, wind speeds and temperatures variables.

Using an ascending hierarchical classification (AHC), we can isolate three large geographical areas in France:

– Mediterranean area: Bouches-du-Rhône, Languedoc, Provence and Pyrénées-Orientales. This area is characterized by abundant sunshine and frequent high winds (in particular in Pyrénées-Orientales). This area has the lowest TFI level and TFI increase between 2010 and 2013 (from 10.7 to 11.9),

– Continental area: Alsace, Beaujolais, Bourgogne and Champagne. This area is characterized by wide temperature variations and abundant rainfall. This area has the highest TFI level and TFI increase between 2010 and 2013 (from 15.4 to 18.7),

– Atlantic area: Bordelais, Charentes, Dordogne, Gers and Val de Loire[4]. This area is characterized by mild temperatures and high humidity. The TFI in this area is a bit lower than in the continental area and its increase between 2010 and 2013 is more moderate (from 14.1 to 16.7).

[4] Val de Loire is classified in the "Atlantic area" but this vineyard is very close to the characteristics of the "Continental area".

4. Measuring the climate effect

The aim of this section is to focus on the impact of climatic conditions on TFI variations in order to obtain a 2010-2013 TFI evolution with controlled climatic factors.

To explain the TFI evolution, the model selects only climatic factors as independent variables. This choice is justified by the fact that farming practices, although important to explain TFI level, do not vary much over time for vineyards. Firstly, the vine is a permanent crop and has fixed characteristics like grape variety, density, no rotation…. Secondly, the main farming practices that can be observed in the surveys like weed control, fertilization, shoot and bud removing, leaf pulling, irrigation vary scarcely over time. Thus, between two years, their impact on TFI variation is rather neutral. Therefore, if the exclusion of farming practices as independent variables could in theory create a bias on the estimated coefficients (omitted-variables bias), their exclusion in the model may be justified for the vineyards.

4.1 Data modeling

The panel is composed of 4 838 parcels. Some atypical data were withdrawn (14 parcels). Several classic functional forms were tested: log-linear, semi-log and linear. Finally, the linear form was chosen.

Multicolinearity and variable selection were treated simultaneously with LASSO (Least Absolute Shrinkage and Selection Operator). Without going into details (Tibshirani, 1996), this method rewords the least squares problem but with an additional coefficient requirement. The coefficients of the most correlated variables are 0. All the average temperatures variables are excluded because of their correlation with the range temperatures variables.

17 variables and 6 cross effects are selected (04=April, 05=May, 06=June, 07=July, 08=August): RR04, RR05, RR07, RR08, AMPT04, AMPT06, AMPT08, FFM04, FFM05, FFM07, FFM08, HUMOY04, HUMOY05, HUMOY07, HUMOY08, INST05, INST07; RR07*INST07, AMPT06*HUMOY06, INST05*FFM05, INST05*HUMOY05, INST07*HUMOY07, FFM04*HUMOY04.

In a first model, we assume that the climatic variables effect is not the same across the vineyards. According to this hypothesis, the model writes:

$$TFI \;=\; \Sigma_{k=1}^{13} \beta_k X \, I_{(Vineyard=k)} \;+\; \beta_{0k} I_{(Vineyard=k)} \;+\; \delta_k I_{(Vineyard=k)} I_{(Year=2013)} \;+\; \varepsilon \quad (3)$$

$I_{(Vineyard=k)}$ Dummy variable for vineyard k
X Climatic factors
$I_{(Year=2013)}$ Dummy variable for year 2013
ε Residual

The number of available observations is however too limited to allow this model to be estimated. In a second model, we relax the constraint of the heterogeneity of the climatic variables effect and we assume that the climatic variables have the same effect whatever the vineyard. Only a vineyard fixed effect remains in the model to take into account specific unobserved variables that affect the TFI.

The second model with fixed effect has the following form:

$$TFI \;=\; \beta X \;+\; \Sigma_{k=1}^{13} \beta_{0k} I_{(Vineyard=k)} \;+\; \delta_k I_{(Vineyard=k)} I_{(Year=2013)} \;+\; \varepsilon \quad (4)$$

$I_{(Vineyard=k)}$ Dummy variable for vineyard k
X Climatic factors
$I_{(Year=2013)}$ Dummy variable for year 2013
ε Residual

The dummy coefficient of vineyard*year gives the TFI difference 2013/2010 corrected by climatic factors.

4.2 Results by vineyard

The estimated model identifies a significant climate effect on the TFI difference in 7 vineyards out of 13: Beaujolais, Bordelais, Bourgogne, Champagne, Charentes, Languedoc and Val de Loire. The weather explains from 6% in Bourgogne to 31% in Val de Loire of the difference between the TFI in 2010 and the one in 2013. For other vineyards, the change in weather conditions between 2010 and 2013 does not seem to have a significant impact on the TFI increase.

Table 3 - Climate effect 2013/2010 by vineyard

	TFI 2010	TFI 2013	TFI difference 2013/2010	Explained part (%) by the weather 2013/2010	Signif. Codes

The TFI vineyards are recalculated with the panel data and are different from that observed in table 1.
Farming practices surveys in viticulture and Météo-France data 2010 and 2013.

5. Conclusion

The measure and the understanding of the use of phytosanitary products is a major challenge. In France, the main indicator is the TFI that is built with the quantities actually applied by the wine producers. With a survey every three years, the TFI evolution cannot be easily interpreted: it may be linked to changes in farming practices but also mainly to interannual climate variability. In order to go further in the understanding of TFI variations, this paper focuses on the impact of climatic factors relying on a rich spatialised meteorological data base. We thus introduce in a model several variables describing the climatic conditions encountered by the sampled parcels with a fine grid point.

A fixed effect model leads us to estimate a measure of the "climate-TFI" relationship, excluding the "farming practices-TFI" link. This approach seems admissible for the vineyards because the farming practices do not vary much over time. Otherwise, it would be necessary to add in the model all the farming practices with significant evolutions and check the linear model assumptions. As a consequence, the corrected evolutions between the two years would take into account both climatic factors and farming practices. In that case, an indicator decomposition method would be necessary to estimate an "only climate effect".

In this article, although significant in half of the vineyards, the climate effect appears somehow moderate and leaves unexplained most of the TFI variations. This may be partly explained by the fact that weather conditions are only a proxy of parasite pressure that may depend of many other unobserved factors. Collecting more data on parasite pressure may be useful to go further in the understanding of the use of pesticides.

ABSTRACT

Climate-smart agriculture (CSA) would enhance the capacity of farming systems to sustainably support food security in the context of climatic changes. CSA practices may constitute an ex-ante adaptation strategy while also generating environmental benefits in the form of climate change mitigation. However, questions arise about the profitability of CSA systems and the possibility of spontaneous adoption at smallholders level. A spatial assessment of benefits and costs of CSA systems as opposed to conventional ones in different agro ecologies in Zambia is proposed here, including opportunity costs of switching from one system to another. Primary data collected through ad hoc household and community surveys have been used. Zambian farmers adopt a wide combination of land management practices, applied to various crops. Isolating the productivity effect of each single practice was complicated by the adoption of various combinations of practices. To assess the extent to which SLM technology packages improve crop productivity and net incomes of Zambian family farms, Minimum Soil Disturbance (MSD) systems was selected as the main distilling factor to compared with „conventional tillage systems for key food and cash crops (maize, groundnuts and cotton). MSD in arid areas of Zambia has shown promising results in terms of land, capital and labor productivity and could represent valid CSA option providing that appropriate choices in terms of labor source (manual versus animal draft power), specific practice (planting basins/potholes versus ripping, legume inclusion in crop rotations and residue retention), crop (maize versus groundnut) and access to fertilizer subsidies are made. SLM technology options can also generate environmental benefits in the form of CC mitigation. To better understand mitigation potential, marginal abatement costs curve have been computed. Results show that negative marginal abatement costs for all MSD options imply synergies between increased farm incomes and climate change mitigation, and represent means of generating "win-win" solutions to address poverty and food insecurity as well as environmental benefit (climate change mitigation). The cost-effectiveness of different land management practices is proposed as synergetic decision criteria allowing policy makers to prioritize support interventions on the basis of the economic efficiency of GHG abatements.

Keywords: Climate change, Food security, Sustainable farming practices

PAPER

1. Introduction

The Zambian agricultural sector has a dual structure which involves 740 large commercial farms co-existing with about 1.4 million scattered smallholder agricultural households, including some 50,000 emerging commercial farmers. Commercial farming focuses on cash crop production including wheat, soybean, tea, coffee, tobacco cotton, floriculture and intensive livestock production, while smallholder farmers mostly cultivate staple crops, including maize, sorghum, rice, millet, beans, groundnuts, sugar cane, vegetables and cassava and practice extensive livestock production. The focus of this research is on the smallholder agricultural households.

Zambian smallholder agricultural producers are mainly asset-poor farmers who use simple technologies (hand hoes and oxen) and cultivation practices (minimal purchased inputs such as hybrid seed or fertilizer). They produce rain-fed maize, groundnuts, roots and tubers, mostly for own consumption on five or less hectares (most smallholders cultivate less than 2 hectares) and productivity tends to be low. Sustainable land management (SLM) technologies could represent an option to increase productivity and develop Zambia's smallholder agriculture untapped potential which can lead to diversified production, increased employment and income, and improved food security.

Various potential SLM technologies are found within crop-livestock farming systems in Zambia. However, while biophysical and land productivity benefits of SLM have been widely investigated (e.g. see Branca et al. 2013), questions arise about the costs and overall profitability of investing in SLM practices, whereby very little empirical evidence exists. Much uncertainty exists about economic costs and benefits, level of inputs use, labour demand and factor productivity of SLM practices compared to direct implementation costs and to indirect opportunity costs deriving from the comparison with „conventional" practices, established as „baseline".

This is essential to understand the barriers and trade-offs of SLM implementation and ultimately its viability in supporting sustainable agriculture intensification at smallholder's level. There are important data challenges associated with this effort. This paper presents the results of a three years field and desk research work carried on in Zambia in the period 2013-15 and aimed at providing evidence about costs, revenues and overall economic performance of both SLM and „conventional" practices for different crops and agro-ecological regions. Results would help in identifying technology options which could potentially be implemented in Climate-smart agriculture (CSA) systems, enhancing the capacity of farming systems to sustainably support food security in the context of climatic changes. Since results may very much differ depending on the agro ecological context - and CSA is not a single recipe but it varies depending on the agro-climatic context and no single blue print technology exist - data collection and analysis has been conducted at an appropriate scale. The study findings would help in CSA adoption decision by farmers residing also in similar ecological conditions where such studies have not been undertaken yet.

Using spatial information about SLM technologies in different agro-ecological regions we look at private costs and benefits of target SLM farm practices in the country; we investigate about the profitability of such practices as opposed to „conventional farming; we verify the potential of SLM to improve crop yields controlling for other determinants; we estimate synergies with climate change mitigation and identify cost-effective abatement options and derive implications for CSA policies and actions.

2. Materials and methods

Agricultural practices targeted for the analysis are „innovative" practices already adopted at farm level (even if only through supporting development projects) and ready to be scaled-up if proven to be economically profitable. Therefore, practices only present in experimental fields and research stations, and not yet implemented at farm level, have been excluded from the research. „Conventional agriculture practices have also been included as profitability of SLM practices will be estimated with reference to a „baseline scenario : it includes ploughing or ridging performed using manual labor and animal or mechanical draft power (tillage system). The list of practices surveyed is reported in Table 1.

Table 1 - Description of target practices

Practice surveyed	Details of the practice
Tillage (conventional)	Ridging with hand hoe
	Ploughing with oxen
	Ploughing with tractor
	Bunding
	Chitemene
	Contour Ploughing
Minumum soil disturbance	Planting basins/potholes
	Minimum tillage (ripping by hand)
	Ripping with oxen
	Ripping with tractor
Agronomy	Crop rotations
	Crop rotations with nitrogen fixing crops (legumes)
	Intercropping (mix cropping)
	Cover crops
Residue management	Crop residues (from the same field or imported from other fields) are left in the field as residue or incorporated with plough & the proportion of remaining residue eaten by animals is less or equal to 30%. No residue burning in the field.
Agroforestry	Trees considered: Musangu (Faidherbia albida), Sesbania, Musekese, Lukina (Leucaena), Moringa (Zakalanda), Masau, Mulubesi
Soil and water conservation structures	Stone bunds, earth bunds, terraces, ditches, grass barriers (e.g. vetiver grass embankments)

Source: own elaboration

Primary data, completed with available secondary information, have been used in the analysis. Ad hoc household (HH) surveys have been conducted. Data have been integrated through key informant interviews and focus group discussions with extension workers and village representatives. Questionnaires have been specifically developed to collect primary data from farming HHs and villages to estimate benefits and costs of agricultural practices and to be used as survey instruments in the country, with reference to 2012-13 cropping season. Only main season and rain-fed crops are considered.

Data was collected at a single point in time through a „one-shot" survey. Multi-stage Stratified Random Sampling (SRS) procedure was used in the study in order to obtain efficient and consistent estimates of the target population. It involved dividing population into Ni homogeneous non-overlapping sub-groups (i.e., strata) and then taking a simple random sample in each subgroup. Each stratum is represented by the group of SLM adopters in each Camp, characterized by homogenous agro-climatic conditions. Since we use different sampling fractions in the strata, we apply disproportionate stratified random sampling. During the first stage, the areas where farmers have been practicing SLM technologies for at least 4 years have been identified. At the second stage, key informants were interviewed in order to obtain information on the location of clusters that have the necessary critical mass of smallholders who have adopted the relevant CSA practices. Third stage involved selection of single HHs to be interviewed. Actual respondents have been randomly selected to be interviewed. Results will be considered as representative of the HHs in the stratum. Crop and livestock production data (socio-economic, agronomic, farm management) have been collected for 1,264 fields cultivated by 695 smallholders over 17 camps located in 8 districts (Mumbwa, Chibombo, Katete, Chipata, Chinsali, Mpika, Kalomo, Choma) in agro ecological regions IIa and III.

Information collected during preliminary field activities confirmed that farmers adopt SLM practices on some fields, and keep practicing „conventional" agriculture on other fields. In the same HH data on both SLM and „conventional" agriculture practice can be collected and comparison between SLM and „conventional" practices is conducted at the field level within each household. For each sampled household, a field managed through SLM was selected as well as a conventionally managed field. This eliminated any potential household characteristics that might influence household productivity but are unrelated to CSA. The direction and success of diverse agriculture practices (SLM vs. „conventional") will therefore not depend on HH structural characteristics (family and farm size, land use, age and educational background, level of capital assets, resource ownership), business organization, skills of farmers and their ability to employ those skills in optimizing the use of available resources. In this way, it can be expected that only the specificities of target practices will influence both the likelihood and potential success of agriculture practice diversification. This controls for the potential bias in observations between adopters and non-adopters. A sub-sample of non-adopters was also selected for being interviewed.

A four-step methodology is adopted for the empirical analysis. First, food security increase of the selected „improved" practices with respect to „conventional" farming has been estimated by using partial budgeting technique and following equations:

$$GM_{jT} = TR_{jT} - TVC_{jT} \qquad (1)$$

$$TR_{jT} = P_j Q_{jT} \qquad (2)$$

$$TVC_{jT} = \sum_{i=1}^{n} P_{xi} X_i \qquad (3)$$

$$GM_{jT} = P_j Q_{jT} - \sum_{i=1}^{n} P_{xi} X_{iT} \qquad (4)$$

Where:

GM_{jT}=gross margin (\$/ha), for crop j and technology T

TR_{jT} = total revenue (\$/ha), for crop j and technology T

TVC_{jT}=total variable costs (\$/ha), for crop j and technology T

Q_{jT}=crop yield obtained under different technologies (Kg/ha)

P_j=farm-gate price of crop j (\$/kg)

X_{iT}=quantity of input i (per ha) used in production of crop j, under technology T

P_{xi}=farm-gate price of input i (\$/kg).

Second, Ordinary Least Squares (OLS) regressions have been run in order to control for the impact of other variables on crop yields and isolate the effect of farming practices. The following log-linear Cobb-Douglas function is considered:

$$lnQ = lnB_o + \beta_1 lnX_1 + \beta_2 lnX_2 + \beta_3 lnX_3 + \cdots + \varepsilon^{\mu_i} \qquad (5)$$

where:

Q=crop yield

Xi=the following variables have been considered: field size (ha), total labor (days), quantity of chemical fertilizers (kg), quantity of herbicides (lt), dummy variable for use of improved seeds (1=yes), dummy variable for adoption of MSD technology (1=yes), dummy variable for AEZs (1=yes).

Third, the potential of climate change mitigation of target practices has been analyzed through a mitigation option model (MOM) developed by Vetter et al. (2014). MOM is based on empirical models and emission factors to calculate the mitigation potential spatially. This analytical modelling work was conducted to determine appropriate "Tier 2" greenhouse gas (GHG) mitigation estimates for a range of cropland mitigation options. Technical mitigation approaches in the MOM were mainly based on the methodology for field related nitrous oxide emissions using Stehfest and Bouwman (2006), an adapted application of IPCC (2006) and further complementing methodologies[1].

Fourth, cost-effectiveness of each technology option is estimated (in terms of $/t CO2e abated). This will represent the marginal abatement costs of each option computed on the basis of the unitary abatement potential and estimated against what would be expected to happen in a „business as usual" (BAU) baseline (Branca et al. 2015). MAC curve for target technologies is built using net incomes from the cost-benefit analysis and the mitigation potential estimated using the MOM model. It reports the incremental costs with respect to baseline scenario (i.e. „conventional" tillage system). MAC curve reports costs of different abatement measures (per unit of CO2e abated) on the vertical axis and the GHG volumes abated (annual emission savings generated by adoption of the measure) on the horizontal axis, showing a schedule of abatement measures ordered by their specific costs per hectare and unit of CO2e abated. The curve is upward-sloping, showing how marginal costs rise with the increase of the abatement effort, therefore indicating which solutions are most efficient. Moving along the graph from left to right worsen the cost-effectiveness of technology options since each ton of CO2e mitigated becomes more costly. Negative abatement costs are found for cost-saving technology opportunities, i.e. the adoption of such measures will increase profits.

3. Results

Tillage practice (MSD or Tillage) is considered the discriminator between SLM and „conventional technologies, the latter representing the baseline scenario of the analysis. This will state the point of view from which costs and benefits will be assessed. MSD is somehow „improved" and represents SLM systems. Since the questionnaires allowed reporting multiple practices applied on the same field, many different combinations of practices have been found and a classification in terms of absolute and relative frequency has been made in order to select only most represented technologies (table 2). Zambian farmers adopt a wide combination of land management practices, applied to various crops. Most farmers rely on conventional agriculture for crop production but are testing SLM technologies on some fields, with the support of government and non-government projects and programs.

Different crops and agro-ecologies are taken into account in the analysis. However, here we report only results related to maize, which is most important grown crop in the country. We find: MSD increases yields in AER IIa where both MSD and „conventional" practices are recorded; maize yield under „conventional till system in AER III is much higher than under MSD; yield results do not substantially change when we look at specific Till and MSD management technologies, i.e. hand hoeing/ridging and ploughing with oxen (till) on one side, and planting basins and ripping with oxen (MSD) on the other. Such results are compatible with the agronomic principles of MSD (and CA in particular), aimed at maintaining soil moisture, with effective benefits in dryer areas. Conservative soil practices provide benefits in terms of increased soil moisture, which are mostly beneficial to yields where water is a limiting factor. Cash costs for fields under MSD are higher than under tillage (conducted adopting conventional hand hoe/ridging practices); they are at about the same level as fields ploughed with oxen; MSD requires more herbicides (used to control growth of weeds which may be a problem when tillage is not practiced) and fertilizers than the alternative „conventional" and manure. Other inputs (manure, seeds) do not show significant differences among technologies. Cash input costs are higher for practices making use of external hired labor (animal draft power for ploughing and ripping with oxen). In dry areas, gross margins are slightly positive for conventional hand hoeing/ridging and MSD. However net incomes are negative for all technologies. Ripping with oxen technology gains better results than till soil management, due to higher revenues gained through better yields. Family labor costs are particularly relevant for planting basins making the technology less profitable than ripping. In any case maize cropped in humid areas is found to have better results (higher revenues and positive net incomes). It is interesting to note that net incomes for hand hoe/ridging and ripping with oxen become positive when farmers benefit of the subsidized fertilizer price. This is the meaning of the column „net income subsidized" in figure 1. It is found that 56% of farmers purchase top dress fertilizers[2] at subsidized price; and 43% purchase basal fertilizer at subsidized price[3].

[1] The covered GHG emission and carbon stock change impacts include: soil organic carbon stock changes on agricultural land, carbon stocks in biomass, direct field emissions of N2O and NO (from fertilizers and crop residues), volatilization of ammonia, Nitrogen leaching and runoff, fertilizer and agrochemical production and application. Different typical fertilizer intensities, crop yields and associated residue quantities are considered as identified through the HH survey data. Target agriculture practices were assessed for their potential to lead to significant mitigation benefits utilizing spatial explicit data with regards to initial soil carbon stocks and further soil input variables at a resolution of 30 arc-seconds using the Harmonized World Soil Database (Vetter et al. 2014).

[2] This fertilizer category includes: Urea or (calcium) ammonium nitrate.

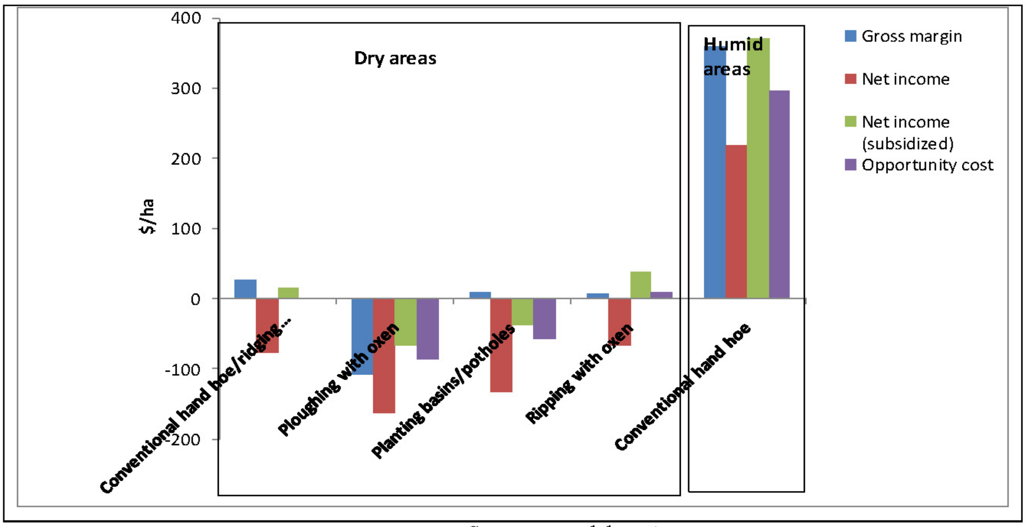
[3] This fertilizer category includes: Compound D, Compound X, Compound R, Compound S, Triple Super Phosphate (TSP), Single Super Phosphate SSP).

Table 2 - Classification of the practices in appropriate technology packages (MSD vs. Tillage systems) and diffusion among farmers in the sample (national level)

			Freq.	Percent
Tillage	T1	+ crop rotation no legumes + residue retention	290	23
	T2	+ crop rotation no legumes	254	20
	T3	+ residue retention	21	2
	T4	+ other combinations	73	6
	T	**Total conventional**	**638**	**50**
MSD	M1	+ crop rotation no legumes + residue retention/cover crop/intercropping	314	25
	M2	+ residue retention	83	7
	M3	+ crop rotation no legumes	114	9
	M4	+ crop rotation legumes + residue retention/cover crop/intercropping (CA)	23	2
	M5	+ agroforestry + other combinations	73	6
	M6	+ other combinations	19	2
	M	**Total MSD**	**626**	**50**

Source: own elaboration

Figure 1 - Maize; gross margins and net incomes, by technology and AER



Source: own elaboration

Albeit the small sample size, productivity analysis confirms the key role of inputs (capital and labor) as well as SLM practices (MSD, residue retention, and crop rotation with legumes) on crop yields in the AER IIa. Results of the OLS estimation of the log-linear production function for maize are reported in table 3. Across SLM practices, however, only MSD (which is defined as either planting basin/potholes or minimum tillage or ripping with oxen or ridging) is significant. However, higher CA yields could also depend on higher fertilization level. In order to check this possibility, we introduce an interaction term between MSD adoption and the amount of inorganic fertilizer used (column 2). The results still show a positive effect of MSD practices on yields (i.e. MSD is effectively increasing yields). Results also show diminishing returns to scale, as expected. We also control for weather variables but results are not significant. Looking at household characteristics, the age of the household head is negatively related to productivity, whereas wealth (measured by a wealth index computed using Principal Component Analysis) is associated with higher maize yields.

Table 3 - Regression results, maize, AER IIa

	Log of maize yields (kg/ha) AER IIa	
	(1)	(2)
SLM practices		
MSD (1=yes, 0=no)	0.172**	0.178*

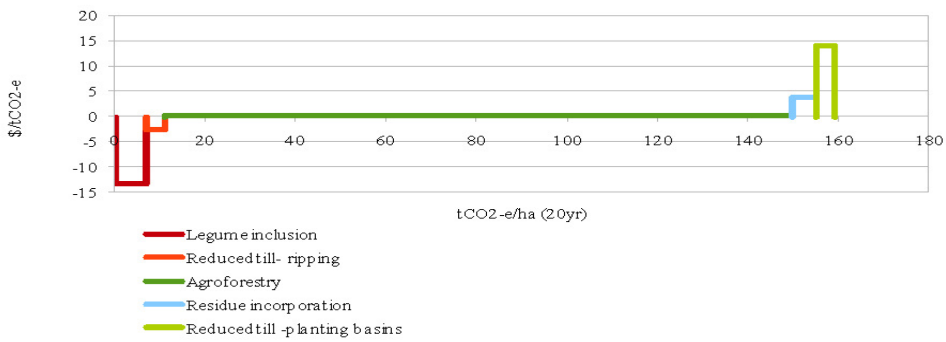
Source: own elaboration

MAC curve is derived as a histogram where each bar represents a single agriculture technology option. The width of the bar represents the amount of abatement potential (ton of CO2e saved as measured on the x axis). This amount is computed as difference between the mitigation potential of the technology and the mitigation potential of the „conventional technology (baseline). The height of the bar indicates the unit cost of the action (unit cost of abatement measured in US$ per ton of CO2e saved as measured on the y axis). The area (height * width) of the bar shows the total abatement cost of the technology (measured in US$). Land reference unit is 1 hectare and each bar refers to that land unit. The bars have been placed in order of increasing unit cost. Technology with the lowest abatement cost is put as the first option, while the technology with the highest unit abatement cost is put as the last option. In this way the MAC curve shows the range of possible technology options that should progressively be implemented according to a criterion of cost-effectiveness. MAC curve is reported in figure 2.

Figure 2 - Marginal Abatement Cost Curve for maize production in Zambia, AER IIa



Source: own elaboration

MAC curve shows that legume inclusion provides the most cost-effective form of mitigation, followed by MSD (reduced till through ripping with oxen). By contrast, more labour intensive technologies, such as reduced tillage through planting basins or residue retention (mulching) are less cost effective, which is due to their higher cost implications. Agroforestry is able to sequester biggest CO2 quantities bust is less cost-effective than cheaper solutions like legume inclusions and MSD with animal draft power (ripping with oxen). Policy makers should promote the adoption of MSD technology options first, in order to act in a costeffective way and gain efficiency. Marginal abatement costs are negative for cheapest options (-13.2$/t and -2.4$/t for legume inclusion and MSD-ripping, respectively). Adoption of these practices will generate higher benefits than under conventional agriculture, therefore showing a synergy between rural development (increased food security) and climate change mitigation (abatement potential). Marginal abatement cost for agroforestry amounts to only +0.12$/t. This means that costs offset the benefits. This technology requires bigger production costs (seedlings production and planting, labor). Also, they are characterized by a longer implementation period where the costs are borne in the first years (building infrastructure and planting trees), while the benefits are gained in the medium-long term, therefore generating a negative flux of net benefits in the short-term (like the time frame of the present analysis). In terms of the mitigation potential per hectare (width of the MAC curve) AF systems provide a structurally higher potential than all other systems. MSD-planting basins is found to have a positive abatement costs (+14.1 $/t) due to labour intensity related to this practice. Although technologies are alternative options, the areas where such options are implemented can be added together. By summing up the areas of the bars it is therefore possible to derive the total abatement cost of a cumulative abatement target, measured in US$.

4. Discussion and Conclusions

A wide variety of SLM practices characterize smallholder agriculture in Zambia and isolating the productivity effect of individual practices is complicated by the adoption of combinations of practices. We assess the extent to which SLM technology packages improve crop productivity and net incomes of Zambian family farms. Results are compatible with other studies in the area (e.g. see Burke et al. 2011).

Maize grown using MSD technologies in dry areas is found to gain better yields than maize cropped under „conventional" ill methods. This is in line with the agronomic principles of MSD which can generate most benefits in dry areas, improving soil properties, increasing soil moisture and overall organic substance. When controlling for fertilizer and other inputs, MSD still has positive effects on the yield. Maize yields in humid areas (only „till systems") are much higher than yields in dry areas, no matter the technology adopted.

However, overall production costs for maize MSD are higher than for „conventional till". MSD is found to be more capital-intensive than „conventional" agriculture. This is because of the higher use of fertilizers and herbicides to control weeds. MSD is also more labor intensive, especially for some time-consuming practice (e.g. planting basins). Cash cost and labor availability could therefore represent a barrier to adoption and well-resourced farmers are better positioned than low-resourced ones in adopting MSD. Use of improved seed varieties is found not to have a specific role in SLM productivity, as their use is reported to be at the same level as „conventional" farming. MSD gains better incomes when animal draft power is considered (ripping with oxen). MSD represents an improvement with respect to conventional hand hoeing/ridging as it shows higher labor productivity.

SLM implementation has important implications in terms of food security, climate change adaptation and mitigation and should be considered in investments aimed at increasing Climate-smartness of agriculture systems. Supporting farm incomes growth is a way to address food security in Malawi. This requires, in the first instance, an increase in productivity of land and labor in the farming sector. Increasing the productivity of farm labor typically requires the introduction of new technologies (Paarlberg 2010).

MSD in arid areas of Zambia has shown promising results in terms of land, capital and labor productivity and could represent valid CSA option providing that appropriate choices in terms of labor source (manual versus animal draft power), specific practice (planting basins/potholes versus ripping, legume inclusion in crop rotations and residue retention), crop (maize versus groundnut) and access to fertilizer subsidies are made.

This is consistent with the expected agronomic benefits of CA pillars (minimum tillage, crop rotations with legumes and residue management), i.e. improved soil moisture and fertility conditions, with evident adaptation benefits. MSD represents a feasible option to face drought risk for resource constrained smallholders and synergies between food security and CC adaptation (e.g. see Delgado et al. 2011; Kaczan et al. 2013) are highlighted . Such option would be cheaper, of easier adoption and better accessibility than more costly alternatives, e.g. irrigation. However irrigation requires high investments, and is questionable for smallholders with limited access to markets. SLM is a much better option as it requires fewer on-farm and off-farm investments.

Climate-smartness of SLM practices is considered also as concerns CC mitigation. MSD technology options also generate environmental benefits in the form of CC mitigation. Agroforestry has highest mitigation potential per unit of land. Negative marginal abatement costs for some MSD options (legume inclusion and ripping with oxen) show synergies between increased farm incomes and climate change mitigation, and represent means of generating "win-win" solutions to addressing poverty and food insecurity as well as environmental issues (climate change mitigation). The cost-effectiveness of different land management practices is proposed as synergetic decision criteria allowing policy makers to prioritize support interventions on the basis of the economic efficiency of GHG abatements.

Results of the analysis have also interesting social implications: better returns makes profitable to hire labor with positive results in terms of increased food security for HH and Communities. Also, better economic results can drive the transformation from smallholder to emergent farmers. The use of herbicides instead of weeding implies less work for women, with important gender implications.

Adoption of MSD technologies in the field is driven by several factors, e.g. access to inputs, labor availability, profitability and returns, equipment availability . Also, organizations and projects which provide some form of support to farmers willing to participate (e.g. tree seedlings for Agroforestry).

Difference in MSD diffusion has to do not only with climate (MSD is effective in keeping soil moisture, therefore more effective useful in drier areas) but also with policies – in Zambia most CA/CF projects have been focused in AER IIa (next to the railway line and Lusaka area); and in the sample MSD fields are found only in AER IIa.

Farmers are testing the innovative technologies. Given the cost barrier, this support - as well as support provided through the FISP-fertilizer subsidy program - is key. Although it can be argued that production costs can be offset by higher gross margins realized under MSD systems, incurring additional capital costs can be a disincentive for MSD adoption for majority of smallholders in SSA and Zambia in particular.

Several implications at policy and institutional level can be highlighted here. National statistics in Zambia do not systematically collect and record information related to the different farm technologies, land management. The present work represents a contribution in this direction. Classification of practices/ technologies, economic and environmental indicators and data collection methodology could be useful for Institutions involved in agriculture statistics.

Policies to promote appropriate CSA technologies should be differentiated in order to take into account values of land, capital and labor productivity indicators associated to technology uptake in different agro ecologies and climates. For example, higher production costs of MSD could be addressed by policies aimed at making herbicides and mechanization (e.g. rippers) more affordable to farmers; reduce transactions costs throughout the value chain (e.g. real-time market information). Coherent messages should be conveyed through rural extension services.

The results are affected by the way the definition and identification of crops and practices/technologies in the field has been made and data have been collected. The survey has also revealed that many farmers claim to practice residue retention (i.e. they leave crop residues on the soil after harvesting) without any specific management and protection from free grazing. Probably only a few farmers adopt proper „mulching" following agronomy rules developed in experimental fields. Leaving crop residues in the field is one of the three CA pillars. Mulching is a further step that involves crushing the residue and using it to cover the surface of the soil. This is done mostly for tobacco and horticulture on a smaller scale. Few farmers would mulch on a field crop because they would need significant quantities of residues. It is also well known that in Zambia keeping residues in the field is difficult due to some traditional practices (e.g. free grazing, mice hunting and burning). More research is needed on this issue. There are many implications in terms of land tenure, community rules and titling enforcement which are not taken into account here.

Cover crop use is very limited in the sample and it's not used in its proper agronomic function. Intercropping is present and included in MSD, however the comprehension of this question in the survey is doubtful. Agroforestry data have been collected either at plot level (if available) or for the overall HH, depending on what the farmer was reporting. In the latter case, costs have been approximately imputed at field level on the basis of HH size. Soil and water conservation practices are excluded from the analysis due to lack of sufficient data. Cassava was excluded from the analysis, although data were recorded but considered not reliable because of the difficulty in estimating yield and allocating labor and inputs to the crop.

Given the base data collected through a one-shot survey, the analysis adopts a static approach, ignoring the year to year difficulties associated with the transition from one system to another (which may be important in case perennial species are grown, e.g. with Agroforestry). Agronomists argue that switching from „conventional" to MSD technologies (e.g. from till to CA) increases crop yields after a few years of declining or stable yields. Also farmers may need a few years of experience to acquire the additional knowledge and management skills necessary for more diversified operations. Most farmers adopt alternatives gradually. In the sample, an average a number of 3-4 years of adoption is recorded which agronomists consider not enough for „conservative" practices to generate expected benefits. Unfortunately due to lack of data this piece of information is not statistically significant, and was not possible to make a distinction in terms of years of adoption (e.g. up to 2 years and above 3 years). These aspects are not sufficiently taken into consideration here.

The one-shot survey and recalling approach may also affect the results discussed here. This is particularly true for some variables such as labor costs. Although the survey has been conducted at the immediate end of the cropping season, in order to minimize the recalling bias; both recalling and market labor approaches are used in the HH and Community questionnaires respectively; medians are used instead of means; results have been validated using available secondary information; overestimation/ underestimation of some variables may be occurred.

ABSTRACT

The Directive 2009/128/EC establishes a framework for Community action to achieve the sustainable use of pesticides. It also establishes that Member States shall adopt National Action Plans for the sustainable use of plant protection products (NAP), which shall also include indicators to monitor the use of plant protection products (PPP) containing active substances (AS) of particular concern. In Italy, within the framework of the NAP, adopted by Interministerial decree of 22 January 2014, a set of 15 indicators has been selected and formally assumed by the Interministerial decree of 15 July 2015. Indicators aim should be assessing progress in reducing the risks and impacts of PPP use on human health, on the environment and on biodiversity. In this paper an overview of the indicators will be presented, underlining those based on data collected in accordance with Regulation (EC) No. 1185/2009 concerning statistics on pesticides.

Keywords: pesticides statistics, Directive 2009/128/EC

PAPER

1. Introduction

The paper presents a set of innovative indicators, selected for measuring and evaluate the results of the National Action Plan for the sustainable use of plant protection products (NAP) adopted in Italy. Section 2 describes the NAP and the corresponding actions, while section 3 presents the methods and criteria used to select the set of indicators. An overview of the indicators will be presented, underlining those based on data collected in accordance with Regulation (EC) No. 1185/2009. In section 4 a brief discussion follows.

2. The National Action Plan and the measures for assessing progress achieved under its implementation

The Directive 2009/128/EC (enacted into national law with Legislative Decree of 14 August 2012, n. 150) stated that a specific action plan needed to be adopted in order to reduce the risks to human health, environment and biodiversity, associated with the use of pesticides. The NAP has been adopted in Italy by Interministerial Decree of 22 January 2014. Main actions proposed by NAP in Italy concern:

1. *Training and requirements for users, sellers and advisors*, regarding specifically the risks associated with the use of plant protection products (PPP);

2. *Information and awareness*, specifically addressed to the public, on potential risks associated with the use of PPP;

3. *Control of equipment for the application of PPP*, and in particular monitoring, regulation and maintenance;

4. *Aerial spraying*, in respect of its ban except for derogations in specific cases;

5. *Specific measures to protect the aquatic environment and drinking water and to reduce the use of PPP in specific areas* (rail and road, areas frequented by the population, protected areas – Natura 2000 sites, parks, etc);

6. *Handling and storage of PPP and treatment of their packaging and remnants*;

7. *Integrated pest management (IPM) and organic farming*, with the goal to increase agricultural area carried out with voluntary and mandatory IPM and organic farming.

Furthermore one specific task regards the identification of a set of indicators, whose aim, in addition to encourage dissemination, is to verify the achievement of the objectives of the NAP and to measure and monitor the results and the effectiveness of actions takeni. A working group (WG) coordinated by the Institute for Environmental Protection and Research (ISPRA) has defined the proposed set of indicators. Article 22 of the Legislative decree no. 150 of 14 August 2012 specifies that the set of indicators should be aimed at "assessing progress in reducing the risks and impacts of PPP use on human health, on the environment and on biodiversity" (ISPRA, 2014).

Most indicators regard, directly or indirectly, farming practices. The application of the NAP hopefully should determine significant improvements in sustainability of farming practices. The overall objective is to reduce the PPP use and especially the risks and impacts in the plant protection treatments. This will require a greater spread of voluntary integrated pest management and organic farming, the decreasing use of traditional aerial spraying, an even better performance of the equipments and treatment methods, an improved skill of operators in carrying out treatments, a greater diversification of the cropping system (higher number of crops grown, more efficient crop rotation criteria, presence and duration of cover crops, use of non-chemical alternatives), etc..

3. The set of indicators: work method and criteria for the selection

The NAP assessment relies on information built on good quality data and indicators. Indicators are selected and/or aggregated variables derived from datasets linked to assessment issues and related to policy objectives or targets.

The WG considered as "indicator" „a measure, generally quantitative, that can be used to illustrate and communicate complex phenomena simply, including trends and progress over time – and thus helps provide insight into the NAP".

The WG selected the indicators according to OECD criteria (OECD, 1993), that are:

a) relevance of information;

b) measurability in terms of immediate data availability and upgradeability;

c) scientific soundness.

Other important criteria for the selection of indicators were existing links to the official statistics. Adherence to principles of official statistics can ensure that the indicator provides objective information, has a scientifically defensible foundation, is consistent over time and from country to country and meets pre-defined quality standards (EEA, 2014).

The indicators were analyzed according to two procedures:

1) compilation of indicators fact sheets (ISPRA, 2010);

2) implementation of a web application to process and fill in the compilation of the indicators fact sheets.

This application program is open to consultation by potential users on/at the ISPRA site: http://indicatori-pan-fitosanitari.isprambiente.it.

The set of 15 indicators has been selected and formally adopted by the Interministerial decree of July 15, 2015. These indicators cover as much as possible the NAP objectives and actions and reflect policy priorities (Table 1). More specifically, the set of indicators is structured into seven main actions which match up the objectives of the NAP (Pallotti A. et al., 2013). However, currently, only five actions are represented by the **specific indicators** processed. The specific indicators are also integrated by **key indicators** and **cross indicators** (Graphic 1).

The selected indicators take into account and exploit existing monitoring programs and databases. Several institutions provide the data and the information and share the responsability for the processing of the indicators (Table 1). In accordance with the Interministerial decree of 15 July 2015, ISPRA, in cooperation with the Italian National Institute of Statistics (ISTAT), the Council for Agricultural Research and Economics (CREA) and the Italian National Institute of Health (ISS), is incharged to coordinate a new WG and to manage the above mentioned web page. According to the NAP updates, single indicators can be improved and the set of indicators can be integrated with new ones, above all with harmonized risk indicators that will be defined at Community level under Directive 128/2009/EC.

The availability of the data and information for the processing of the indicators is not homogeneous. Three main situations are described:

a) the data are available and directly accessible;

b) the data are potentially available, but they need more time and resources to be collected, harmonized and processed;

c) the availability of data depends upon the start and/or the continuation of specific monitoring and survey activities, which require specific programs implementation and adequate financial support.

Some indicators are immediately processable and therefore considered "active", being database already available; others, considered particularly relevant and with appropriate scientific soundness, there will be in the medium and long term whether feedbacks from the NAP actions implementation will be available and/or specific actions will be undertaken.

Futher information on scope and limits of single indicators can be found in Table 1 while detailed general information is available on-line and in the web page dedicated to the information system.

Table 1: *The set of indicators for assessing progress achieved under the NAP, in Italy*

Indicator	Indicator brief description	Institution calculation	Institution data	Indicator status
PPP placed on the market for consumption in agriculture	It allows to assess the amounts of PPP and AS yearly placed on the market for consumption in agriculture, as well as to compare the trends over time and on territorial (regional) basis. Data on placing on the market are considered to be a proxy of PPP sold and used in the field. They do not allow to (a) quantify their use in the various agricultural crops, (b) consider the environmental factors that affect their use in agriculture and (c) analyze their impact on the environment and human health.	ISTAT	ISTAT	*Active*
Use of PPP in agriculture	It provides information on the intensity of use of PPP and AS in individual crops in terms of quantity/ha and potential environmental impact.	ISTAT	ISTAT	*Active*
Release of qualification and update courses certificates for advisors, sellers and professional users	It expresses, in absolute value, the number of brand new certificates and those resulting from updating courses released to advisors, sellers and users of PPP. It allows to assess training achievements trends but does not reflect the effects on human health and the environment, i.e. the effectiveness of training.	MiPAAF	MiPAAF, Regions	*To be activated*
Intoxications caused by PPP	It is based on the number of surveyed/observed incidents and on related poisoning episodes of agricultural workers and general population.	ISS	ISS	*Active*
Inspection / technical checks / calibration of PPP application equipment	It expresses the number of technical checks and calibrations performed in the year. It measures the efficiency of PPP application equipment.	MiPAAF	MiPAAF, Regions, ENAMA	*To be activated*
Frequency of detection and concentration of AS in waters at national level	It provides detection frequency and concentrations of PPP residues in surface and ground waters as well as a national overview of contamination status. It allows to follow the evolution of the contamination due to the use of pesticides and, ultimately, to monitor the effectiveness of specific actions taken for mitigating risk.	ISPRA	ISPRA, Regions / ARPA-APPA	*Active*
Frequency of detection and concentration of specific AS in waters	It measures the contamination of surface and groundwater by residues of "specific/selected" AS.	ISPRA	ISPRA, Regions / ARPA-APPA	*Active*
Buffer strips and other permanent mitigation measures to reduce the risk for surface waters	It estimates the surface area change over time (percent) of the buffer strips (not cultivated vegetated strips and other ecological infrastructure) located along water bodies in order to limit pollution due to runoff, percolation and drift.	MiPAAF	MiPAAF	*To be activated*
Population of birds potentially damaged by PPP	Intended to detect the effects of agricultural practices on biodiversity, it estimates the trend of population of nesting species in agricultural habitats. It is calculated considering the specific ornithological area of the plains, where it is assumed that the use of PPP is more intensive.	CREA/LIPU	MITO 2000	*Active*
Integrated pest management (IPM) on a voluntary basis	It describes the utilized agricultural area (UAA) and the tons of crops produced according to integrated pest management (IPM) on a voluntary basis.	MiPAAF		*To be activated*
Organic farming	It describes the utilized agricultural area (UAA) cultivated according organic farming techniques. It is calculated as the ratio of the organic farming area and the total UAA.	MiPAAF	SINAB	*Active*

Indicator	Indicator brief description	Institution calculation	Institution data	Indicator status
Measures regarding the management of PPP in Natura 2000 sites and nature protection areas	It provides information on the number and type of measures (regulatory, administrative or contractual) on the use of PPP included in Natura 2000 sites Management Plans and in the protected areas (parks, etc.) Plans. It allows to assess over time the implementation of the measures in sites and areas characterized by a percentage of UAA ≥ 20%. It does not detect the environmental effectiveness of the measures taken.	ISPRA	MATTM	*To be activated*
Bee mortality caused by PPP	It shows the number of bee mortality cases attributable to PPP throughout the country. It tries to detect agricultural practices and specific PPP responsible of bee mortality. The mortality data/reports come from SPY-BEENET project (MiPAAF) and the National Health Service (MINSAL).	IZS LT	MiPAAF, MINSAL	*Active*
Pesticide residues in food matrices	It allows to assess the proper use of PPP and to monitor the risks to consumer health associated with food intake. It detects the residue levels of pesticides in or on food of plant and animal origin. Every year 10 vegetables, both from organic farming and conventional agriculture, 2 foods of animal origin and one baby food are sampled.	MINSAL	MINSAL	*Active*
Cropping systems sustainability	It aims to highlight the adoption of preventive measures and non-chemical means. It assumes that the greater is the diversity of cropping system the lower is the presence of organisms harmful to crops. The evaluation of this diversity is based on: number of crops grown, rotation type and presence and duration of cover crops. A further aspect is the use of non-chemical means. Data source is mainly Farm Accountancy Data Network (RICA).	MiPAAF, S.S. S. Anna	CREA	*To be activated*

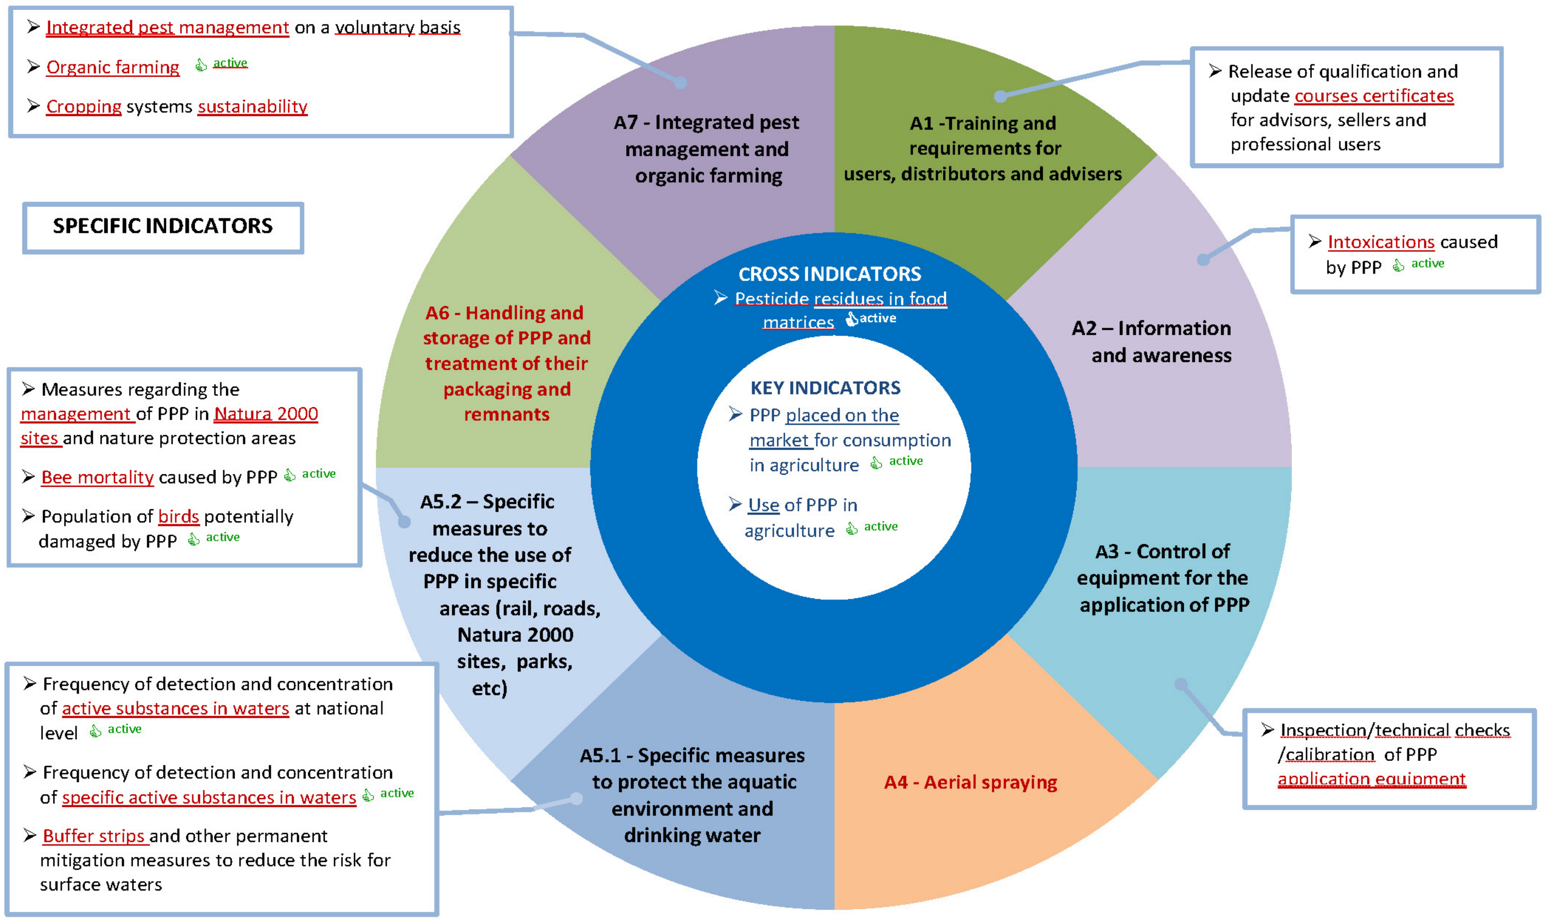
Graphic 1: *The set of indicators structured into the seven main actions of the NAP*



Special attention deserve the first two indicators in Table 1, as they concern statistics on pesticide.

The Regulation (EC) No. 1185/2009, concerning statistics on pesticides, establishes a common framework for the systematic production of Community statistics on the placing on the market and use of pesticides on specific relevant crops.

The Regulation points out that the statistics shall serve the purposes of Directive 2009/128/EC, in particular, to monitor actions implemented through the application of the NAP.

Harmonised and comparable Community statistics on pesticide are essential for the development and monitoring of Community legislation and policies in the context of the Thematic Strategy on the Sustainable Use of Pesticides.

At EU level, the need for harmonised data, specifically on pesticide use, has been clearly recognised (EUROSTAT, 2008). Once the regular collection of usage statistics on PPP use has been established, it is possible to monitor changes over time in the use on particular crops or in the use of specific pesticides.

As stated by Legislative decree no. 150 of 14 August 2012, these data will be also used for the compilation of the indicators and will make an essential contribution in detecting "trends in the use of certain AS with particular reference to the type of crop, treated areas and pest management practices."

The statistics produced in Italy by ISTAT are essential for assessing policies of the EU on sustainable development and for calculating relevant indicators on the risks related to pesticide use (Table 2). ISTAT produces two types of statistics on pesticides:

- Statistics on the annual amounts of pesticides placed on the market.
- Statistics on the annual amounts of pesticides used on specific relevant crops.

Table 2 - The first Indicator - PPP placed on the market for consumption in agriculture: products and traps, and active substances, distributed for agricultural use, for category (in Kg) - Year 2014

Source: ISTAT, Survey on the distribution of pesticides for agricultural use

The usage statistics allow to estimate active substances (AS) contained in pesticides used on each selected crop. Moreover they allow to monitor changes over time in the use of AS on crops, since information for each individual crop are collected periodically and compared with the preceding years. In Italy crops are selected taking into account the most relevant cultures for the NAP. Crops currently surveyed are: grapevine, maize, durum wheat, tomato and potato. Usage statistics are collected through samples of farms and provide information on the pesticides used on two or three crops each year, estimating the total amount of any specific pesticide and the area of crop treated with those pesticides. The data are collected through telephone interviews directed to a representative sample of farmers and growers. The phone calls are preceded by an information letter and are performed by trained personnel. Telephone surveys are used to reduce the cost of the surveys. These surveys are in fact similar in structure to personal interviews, but they avoid travel time and costs. However, for each call it is preferable to cover a single crop per farm.

Some useful information can be obtained from the statistics on the annual amounts of pesticides placed on the market which are compiled by companies and can be used as a proxy for pesticides use data. ISTAT produces an annual census survey and data (totals) are released at NUT3 level. Sales figures may be used to adjust and improve surveys on the use of pesticides. One of the advantages is these statistics are much cheaper to collect as they are compiled directly by companies and not by farmers. The data are generally accurate, as chemical companies normally know the amount of each product placed on the market and are able to provide annual figures. However, due to commercial reasons, these statistics can give rise to confidentiality issues and restrictions on the release and use of data. In fact, when published, data are grouped, masking the specific AS.

4. Discussion and conclusions

The initial objective of the activity was to define a set of innovative indicators for measuring and evaluate the results of the NAP adopted in Italy. The work continued with the revision, consolidation and optimization of the indicators list published in the Interministerial decree of 22 January 2014, regarding the adoption of the NAP. The ultimate achievement on the indicators was the proposed set of 15 indicators, adopted with the Interministerial decree of July 15, 2015.

At present ISPRA, in strict cooperation with ISTAT, ISS and CREA, is coordinating a new WG whose main task is to process the selected "active" indicators and manage the website *http://indicatori-pan-fitosanitari.isprambiente.it*.

The WG also aims, in accord with the NAP updates, to improve the definition and performance of the indicators and to integrate the set of proposed indicators with new ones, above all with harmonized risk indicators that will be defined at Community level by Directive 2009/128/EC. It is expected also that most of the indicators named "to be activated" (e.g. "Release of qualification and update courses certificates for advisors, sellers and professional users", "Inspection/technical checks/calibration of PPP application equipment", "Integrated pest management (IPM) on a voluntary basis", "Measures regarding the management of PPP in Natura 2000 sites and nature protection areas" and "Cropping systems sustainability"), will be processed in a reasonable time, since the data will be soon available partly as a consequence of the NAP actions implementation.

The WG expects a discussion and cooperation with other experts and scientific bodies, in particular universities and research institutes, that have specific expertise in this field and that so far the WG was not able to involve suitably in the work.

Interesting information and proposals are arising, for example, from the assessment of the effectiveness of laws, e.g. environmental monitoring of the Rural Development Plans or evaluation of the measures implemented by the regions according to Directive Habitats and Directive Birds.

At this time, experts are loading the available information on indicators in an information system, accessible via the above mentioned link. A first review of active indicators will probably be on-line early 2017. By the end of 2017, Member States shall submit to the European Commission a report on the achivement of the objectives and targets established in the NAP. The report should take in account also the information and evaluations arising from indicators processing. But, even more relevant, not further the beginning of 2019 (that is within 5 years from the NAP adoption) Member States shall revise NAP and propose a possible review and, if necessary, reformulation of the actions previously implemented.

The information system will represent the opportunity for stakeholders and policy makers of assessing results of NAP actions implementation and progress in reducing the risks and impacts of PPP use on human health, on the environment and on biodiversity.

The selected indicators represent a useful tool for researchers to evaluate the evolution of farming practices and measure the spread of good practices aimed to reduce PPP impacts and risks and to reach more efficient and sustainable crop production systems.

ABSTRACT

Public and private investment in agriculture is of special interest in developing countries for its crucial contribution to the enhancement of the production capacity of the sector through productivity increases. In particular, investment in smallholder family farming is essential for poverty reduction and food security improvement.

Investment in a sustainable agricultural production and productivity includes the improvement in physical capital formation and land, water, and other natural resources; the development of human and social capital; and the environmental protection.

Public investment sets the conditions for private investment. However, innovative public financing models and partnerships between the public and private sector finance in agriculture and in the overall supply chains should be identified.

Moreover, financial markets have come to play a role in many dimensions of food systems and are evident in the phenomenon of foreign direct investment in land.

Suggested topics concerning data gathering and analysis may include:

- Investment and agricultural productivity;
- Investment along the agro-food chain;
- Comprehensive agricultural investment measures;
- Innovative public-private partnership in investment in agriculture;
- Innovative public finance models to increase allocation in agriculture;
- Foreign direct investment in land;
- Role of financial markets in land ownership, credit provision, food distribution systems.

ABSTRACT

A guidance note to lead countries on the public expenditure analysis in the agriculture sector has been formulated in order to reach the target of 10% of the share of national budget to agriculture, expressed firmly at Maputo, in 2003. The ambiguousness in the methodologic guidance carried a lack of precision in the estimations of progress accomplished in the achievement of this target of 10%. Thus, agency of NEPAD and Africa Commission Union are engaged in a process to revised the guidance note, in partenership with others partner groups in order to reinforce the analysis and the following of the level and the quality of public expenditure in the Africa's countries. It is in that frame work that the main goal of this study permits to enhance comparative analysis of results from COFOG and COFOG revised methodology in the case of TOGO from 2011 to 2013. This permits to appreciate better the impact of both tools for monitoring the quality of agriculture expenditure which provides more indications on the assessment of the efficiency and efficacity of budgetary expenditure in agriculture sector, in accordance with the Malabo declaration in 2014 on the following the quality of agriculture expenditure. The analysis of agriculture public expenditure with COFOG methodology reveals that the share of public expenditure of agriculture sector in the total expenditure of State increased from 5,7% in 2011 to 6,6% in 2012 and 8,2% in 2013. With the guidance note in 2014 relative to COFOG revised the Maputo rate move to 7,3% in 2011 to 8,5% in 2012 and 9,3% in 2013. It appears that the inclusion of expenditure on service roads, expenses concerned out budgets and excluding debt service payments from the Guidance Note from a the methodology revised COFOG shows better performance in achievement of objectives 10% of the national budget to the agricultural sector. However, a reduction of weight of procedures of financial technical parteners at the level of differents projets in the implementation of National Agriculture Investment and Food Security (NAIFS) will improve more the absorption capacity of agriculture sector. Special attention must be given to the level of public expenditure coming from the official development assistance for the agriculture to better identify and measure their impact.

Keywords: COFOG, Investment, Agricultural

PAPER

1. Introduction

The primary sector namely agriculture is at the heart of economic and social development and national development strategies are built taking into account agriculture. Thus, Togo, several policies have been implemented and are contributing to a successful implementation of PNIASA. It is estimated that a thorough evaluation of agricultural and food security programs must precede any credible process of investment planning also making use of key analyzes, such as analysis and monitoring of agricultural public expenditure continued to inform and guide the implementation of the CAADP process. In the context of recovery of the agricultural development in Togo, to facilitate access to analyzes of the highest quality policies to manage the necessary knowledge in the formulation and implementation of its policies, with technical support IFPRI, and the financial ReSAKSS the International Fund for agricultural development (IFAD) since 2014 a strategic analysis tools is the review of public expenditure in the agricultural sector for the monitoring of agricultural expenditure, the measurement of efforts and progress respecting the Maputo commitment by the Government of TOGO in 2003.

Economic growth in Togo has continued to increase from 4.8% in 2011 to 5.4% in 2013 (GDP Committee, 2014). This macroeconomic performance remains one of the strongest economies in West Africa. This dynamic is drained by the agricultural sector with an average growth of 4.13% between 2011 and 2013. This result is explained by improved macroeconomic management but also by the bonds of investment in infrastructure, the revival agricultural development with emerging economies. Agricultural expenditure is one of the strategic decision-making aspects for the development of the agricultural sector, leading in 2014, the leaders of Africa, at the summit in Malabo to reaffirm their commitment to respect the commitments made in Maputo, especially their commitments in the efficiency of the allocation of a minimum of 10% of public expenditure to agriculture. In this context, national macroeconomic performance will likely be affected by growth and accelerated transformation of agriculture for shared prosperity and better living conditions. The relationship between the analysis of agricultural expenditure according to the methodology of classification of the functions of public administrations (CFAP or COFOG), national development strategies and sector objectives have attracted increasing attention of technical and financial partners, academic researchers such the World Bank, the African development Bank, the United Nations development Programme, the French Cooperation (2006); Maurice Taondyandé, MbayeYade (2013); and others. To this end, there is a lot of research on the analysis of public spending on agricultural support and supply link with national development strategies. The study of the World Bank's Public Expenditure in the agricultural sector in Togo in 2012 found that although agricultural expenditure according to COFOG single methodology increased significantly from 2002 to 2010, they remain below the commitment Maputo. The similar study for Chad for the period 2003-2012 shows that agricultural expenditure represented 5.7% of total public expenditure; 4.1% of agricultural GDP and 1.1% of total GDP (World Bank, 2014). In 2013, the study of the World Bank for Senegal shows that agricultural growth recorded an average performance with a rate of 4.6% between 2005 and 2009. The agricultural sector is small increase its share Total public expenditure financed from own resources, from 9.8% to 10.9% between 2005 and 2009.

The area of monitoring and analysis of agricultural expenditure in Africa is composed of major initiatives which, although different, all have objectives related to the promotion of agricultural development, economic and social development in Africa. The procedure was defined by the African Union and the NEPAD vision has been realized through the results framework of CAADP. In this context, much of the attention of policy makers has been devoted to identify initiatives that verify whether the target of Maputo / Malabo 10 percent of total public spending on agriculture is reached. Thus, among the initiatives, a wide range of definitions and classification methods are used to calculate this indicator. The system of CFAP was regularly employed but with groups of categories CFAP inconsistent from one measurement to the other. In addition, as many African States do not use the CFAP, which also prompted many analysts to aggregate expenditures by specific categories into national accounting systems. However, the target of Maputo / Malabo 10 percent of total expenditure on agriculture is only a tool for achieving a set of development goals (eg CAADP 2003 and UA 2003, 2014). As stated in the Declaration of Malabo 2014, these objectives include the improvement of investment in agriculture, accelerating agricultural growth and agricultural productivity, poverty reduction, mitigating the impact of climate change and mutual accountability. Therefore, the level of agricultural expenditure should be taken into account by policy makers and practitioners of agricultural public spending and development stakeholders, in combination with the quality and composition of expenditure and the ability to analyze their impact [(1)]. To this end, the United Nations highlight the availability of data, along with the statistical and analytical capacities as one of the main driving forces for the political decisions to support the Millennium Development Goals (UN, 2014 p. 6-7). In the scientific literature on agricultural expenditure, that "national governments, particularly in sub-Saharan Africa, have limited budgets and are forced to make difficult funding decisions concerning the provision of social services and support agricultural programs "(Allen et al., 2012, p. vi) is regularly reported, pointing here and there the importance of knowledge systems that can effectively guide policy. The study by the Food and Agriculture Organization of the United Nation (FAO) on the comparative reviews and analysis on "monitoring initiatives and analysis of agricultural expenditure in Africa," it appears that there no single way to monitor and analyze agricultural expenditure, and that policy makers need to consider the contribution of each initiative to the overall objectives of CAADP. Some initiatives focus on building capacity and production analysis on specific policies at the national level while others provide expertise to improve public financial management systems, or publish aggregated benchmarks on spending agricultural public regional or global level. Thus, there are limits to the possibilities of harmonization of monitoring and analysis initiatives in agricultural expenditure. Although agreeing on a common definition of agriculture is certainly possible for a number of initiatives, it would be only part of the solution to improve monitoring and analysis of agricultural expenditure in Africa. In fact, all monitoring initiatives and analysis of agricultural expenditure in Africa are experiencing considerable difficulties in obtaining reliable, updatable data and classifiable under a system like the CFAP. Standards and definitions are shared, of course, necessary.

Thus the aim is to provide clear guidelines and common to the Member States of the African Union (AU), in monitoring public expenditure in agriculture and increase the effectiveness of budget management in the agricultural sector.

---

[1] It is widely accepted that the establishment of monitoring and analysis of reliable and sustainable national agricultural systems of public spending is essential to support the development of the agriculture sector through the formulation of policies based on reliable information. For example, the African Union sees the planning based on reliable information as a fundamental strategy for the implementation of the CAADP (CAADP 2010).

This is facilitated monitoring the country's levels and the AU on the share of public expenditure in agriculture compared to total public expenditure in order to establish the status of progress made by countries concerning target of 10% and strengthen the investment based on the evidence and the political justification for levels of appropriate expenditure and the efficiency and effectiveness of agricultural expenditure in order to assess the quality of public expenditure in the agriculture to enhance the value for money. Thus these principles address some key methodological issues on common accounting standards, agriculture defining the functions of government classifications, the distribution of spending in other sectors, as well as consistency and the harmonization of data on the numerator and denominator in estimating the ratio of Maputo. The framework for monitoring the quality of agricultural expenditure implementation provides guidance on assessing the efficiency and effectiveness of budget spending in agriculture, under the terms of the Declaration of Malabo on monitoring the quality of agricultural expenditure. Thus, CAADP continues to provide an agreed framework to promote and support agricultural development in Africa. Thus, the status of implementation of commitments and emerging issues show that since the Maputo Declaration (2003), progress has been made by African countries towards an expenditure in the sector farm of at least 10% of total budget allocations. The experience gained from the implementation and emerging issues related to the target of 10% of expenditures allowed to draw policy lessons. It is in this context to better understand all the contours of the study on "What real interest in evaluating the quality and effectiveness of agricultural investments between simple COFOG methodology and revised COFOG? Case of Togo 2011 to 2013. "It is important to provide some answers to these different questions: between 2011 and 2013, what is the behavior and evolution of government expenditure in the agricultural sector by between single COFOG methodology and the revised COFOG? What is the comparative evolution of the ratio of Maputo by the two approaches? The rest of this article is as follows. Section 2 presents the methodological approach to analysis of agricultural expenditure by COFOG single and revised COFOG NEPAD and the African Union. Here we define the approach of estimation of agricultural expenditure and expenditure of the state in the country, the ratio of Maputo. In Section 3, we present the main results in the empirical application and presents summary statistics of our estimates of agricultural expenditure. Section 4 concludes.

2. Methodologicalreview

2.1. Definition of agriculture public expenditure

The roles of the AU, NEPAD and FAO in the establishment of a monitoring system for agricultural expenditure were asked to develop, pilot and implement a system to monitor compliance with this resolution. In order to introduce the monitoring system for agricultural expenditure, the AU member countries, a number of consultations were held and the first steps were taken. In 2004, FAO, as a specialized partner of the AU and NEPAD in agriculture, organized technical meetings with the participation of the World Bank, the International Monetary Fund (IMF), the African Development Bank (ADB) and NEPAD. It was agreed that the agriculture sector should be defined according to accepted standards internationally based on the Classification of Functions of Government (COFOG), revised by the United Nations in 1989, and incorporated in the IMF Manual Statistics of Finance of the State (GFS) for 2001. However, it was recognized that some exceptions, African governments do not use the COFOG in their budget classification structure, which implies a dimension and a unified definition of the agricultural sector does not exist in the budget and thus, in all countries accounting systems, and a reliable exercise requires the incorporation of such a classification in the budgets of member countries [2].

2.2. Simple COFOG methodology from United Nation, Africa Union

In the calculation and monitoring of agricultural expenditure is recognized as expenses indicator of 10 percent of total government expenditure in agriculture aims to establish a base platform for agricultural expenditure both in terms of absolute amounts as a percentage of total government expenditure, and monitor their movements on time. Actual expenditures (not budget) are subject to the expenditure tracking system. The definition of COFOG is maintained and confirmed again that a broader definition based on COFOG, as previously proposed by the AU member countries in April 2005, and will be used to determine the agricultural sector and spending it covers.

[2] Although considered the ultimate solution, it is allowed the replacement of existing budget classifications by the COFOG system in member countries of the AU require substantial resources and time. Since the introduction of the COFOG system should cover all ministries and public offices, it should change the structure of the allocation and the general accounting plan of the State, and therefore the budget code system and accounts public. The note will be a tool facilitating and unifying the country reports in the calculation of the share of agricultural spending in total government expenditure.

Data collection must be from more than one department. In many countries, data on the agricultural sector starting from the COFOG are budgeted and accounted for on behalf of more than one department or organization. The Ministries of Finance should be actively involved in this exercise with the cooperation of the ministries concerned [3]. In addition, if a university or research center performs work related to agriculture, they should also be included in the agricultural sector. Finally, the multi-sector projects if a mega - project has multisectoral objectives, including irrigation for agricultural purposes, expenses must be included in the agricultural sector if 70 percent or more of the project costs are related to agriculture. Otherwise, they must be included in the sectors responsible for the supply of water or energy, which poses no problem in this exercise.

2.2.1. Estimation of agriculture public expenditure

Let $i, j, k, n, m \in \mathbb{N}$; $i \in \{1, \ldots, n\}$; $j \in \{1, \ldots, m\}$;

M_{ji} = Ministry Spending i involved in agriculture for j;

M_{ji}^{I} = Sectorial expenditure i on internal resources for the year j;

M_{ji}^{E} = Sectorial expenditure i on external resources for the year j;

H_{jk} = Expenditure outside the budget partner k agriculture for the year j;

N_j = Agricultural expenditure for the year j;

$$(1) M_i = M_i^I + M_i^E$$

$$(2) N_j = \sum_{i=1}^{i=n} M_{ji} + \sum_{k=1}^{k=m} H_{jk} = \sum_{i=1}^{i=n} \left(M_{ji}^I + M_{ji}^E\right) + \sum_{k=1}^{k=m} H_{jk}$$

2.2.2. Estimation of total state spending in the country

I_j^I = *Capital expenditure for the year j on internal resource;*

I_j^E = *Capital expenditure for the year j on external resource;*

T_j = *Transfer expenditures of the year j;*

F_j = *Operating Expenses of the year j;*

P_j = *Personal spending the year j;*

I_j^{EH} = *Investment spending on external resources outside of the budget for year j;*

D_j = *Total state spending in the country for year j;*

$$(3)\ D_j = I_j^I + I_j^E + T_j + F_j + P_j + I_j^{EH}$$

2.2.3. Estimation of Maputo ratio

Let year j,

$$(4)\ R_j = \frac{N_j}{D_j}$$

[3] It should be noted that agricultural education at the university level and the level of formal secondary education system under COFOG falls within the education sector, but the training of specialized and lower levels should be within each sector, namely agriculture. It should also be noted that rural development in the system of COFOG is not an independent sector butits operations are distributed among many other sectors, including health, education, transport, etc. Special attention should be given to this issue to include only activities related to agriculture of a Ministry of Rural Development. Similarly, it should be noted that in some countries, the ministries of public works or their equivalent who perform construction projects related to agriculture, should also be involved.

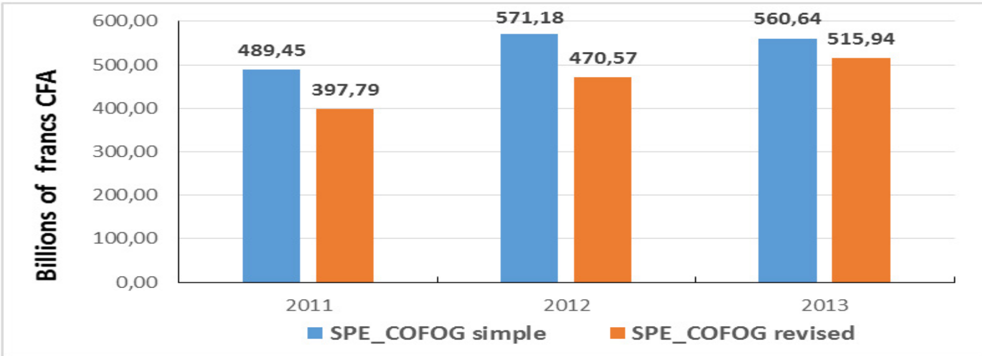
2.3.Méthodology of COFOG révised of NEPAD and African Union

The following guidelines are proposed for the identification, measurement and distribution of the most relevant components to be integrated in the estimated expenditure (numerator and denominator) according to the Guidance Note document of the African Union and NEPAD on the revised COFOG methodology. Indeed, it is with regard to the road serving the important indicator to consider is the proportion of inhabitants and beneficiaries residing in the sphere of influence of the road service for which agriculture is the main source of livelihood. Debt service payments are excluded, the debt service (payment by the state of the interests of its domestic and foreign borrowing) or annuities paid to the state budget are, in principle, of a statutory nature or discretionary spending say no, and states have no control over them. It is therefore proposed that no payment of debt service is included in the total expenditure for agriculture (DEA). For the purposes of this Guidance Note for expenditure outside the budget concerned, it is requested the inclusion of major expenses of Public Aid for outside speaker concerned budget development in the agricultural sector are identified and estimated for both the numerator (total amount of a multisectoral activity) as the denominator (total expenditure of the State). This integration is also consistent with the mutual accountability framework promoted in the CAADP maintenance program [4]. There is a growing demand for institutional accountability, as part of strategic key to improving the quality of expenditure for agriculture and its results as stated in the Declaration of Malabo.

3. Main results and implications

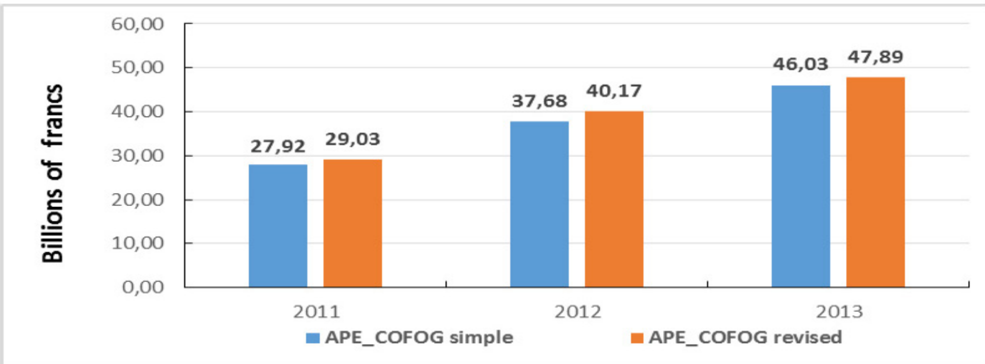
The analysis of the comparative evolution of the budgetary expenditure of the state in the country shows that the level of single COFOG expenditure according methodology is higher than that under the revised methodology COFOG in 2014 of the African Union and the NEPAD. Indeed, the level of state spending as easy COFOG respectively and revised COFOG was established in 2011 to 489.45 against 397.79 billion CFA francs; in 2012 to 571.18 against 470.57 billion CFA francs in 2013 to 560.64 against 515.94 billion CFA francs.

Figure 1 - Comparative evolution of budgetary expenditure in the country



The analysis of the comparative evolution of agricultural expenditure shows that the level of expenditures by COFOG methodology revised slightly higher than under the single COFOG methodology of the African Union and NEPAD. Indeed, the level of agricultural expenditure by COFOG single respectively and revised COFOG was established in 2011 to 27.9 against 29.03billion CFA francs; in 2012 to 37.68 against 40.17 billion CFA francs and in 2013 to 46.03 against 47.89 billion CFA francs.

Figure 2 - Comparative Evolution of agricultural expenditure



[4] In addition, it is important to ensure that the definition and measurement of the ratio of government spending in favor of agriculture and the total expenditure of the state in the country include appropriate adjustments to both numerator and denominator to avoid inconsistent and misleading estimates to contribute also to calculate robust and comparable expense ratios. The Maputo Declaration emphasized the level of expenditure. Recent years have seen an increasing demand from key stakeholders to promote and monitor the quality of expenditure on Agriculture (DEA), including its composition and adding value regardless of its level and its share total expenditures.

The synthesis of the analysis of the main macroeconomic and agricultural development indicators according to the two methodologies reveals differences. Note that the calculation of the agricultural public spending and government spending helped to establish the ratio of Maputo and the relevant ratios. These calculations allowed to turn to international comparisons: (i) on the strict basis of COFOG expenditure; and (ii) on the Maputo target and other targets.The analysis of the comparative evolution of the Maputo ratios shows that the level of the revised ratio according to COFOG methodology is above that falling within easy COFOG methodology of the African Union and NEPAD in the period. Indeed, the ratios of Maputo as single COFOG respectively and revised COFOG was established in 2011 to 5.7% against 7.30%; in 2012 to 6.6 against 8.5 in 2013 to 8.2 against 9.3 billion CFA francs. The index of Togo's agricultural orientation [5] between 2011 and 2013 according to the two methodologies shows disparities. On average over the period, the Agricultural Orientation Index (IOA) as the single COFOG methodology is estimated at 0.17 against 0.21 as the methodology revised COFOG.

Table 1 - Comparative analysis of the agricultural orientation index (IOA)

Rubrique	2011	2012	2013	Moyenne (2011-2013)
COFOG simple				
Ratio of Maputo (A)	5.7	6.6	8.2	6.83
Agriculture DGP (Billionsof francs CFA)	714.87	840.93	800.74	785.51
National DGP (Billions of francs CFA)	1772.58	1989.49	2064.86	1942.31
Agriculture DGP*100/National DGP (B)	40.33	42.27	38.78	40.46
IOA (A/B) simple	0.14	0.16	0.21	0.17
COFOG revised				
Ratio of Maputo (A)	7.30	8.54	9.28	8.37
Agriculture DGP (Billionsof francs CFA)	714.87	840.93	800.74	785.51
National DGP (Billions of francs CFA)	1772.58	1989.49	2064.86	1942.31
Agriculture DGP*100/National DGP (B)	40.33	42.27	38.78	40.46
IOA (A/B)revised	0.18	0.20	0.24	0.21

4. Conclusion

In the CAADP framework, the analysis of agricultural expenditure under the single COFOG methodology and revised COFOG shows that on average the ratio of Maputo between 2011 and 2013 is set at 6.84% to 8.34% against single COFOG revised COFOG. It appears that the inclusion of expenditure on service roads, expenses concerned out budgets and excluding debt service payments from the Guidance Note for the methodology revised COFOG shows better performance in achievement of objectives 10% of the national budget to the agricultural sector.

[5] The agricultural orientation index is the ratio between the share of agricultural investment in public investment and the share of agriculture in GDP, lets see how government spending on agriculture reflect the importance of the sector in the economy. When the index is less than unity, then public spending in the sector are not up to what it brings to the economy. The higher the index, the higher the expenditure on agriculture are the share of agriculture in GDP.

ABSTRACT

THE AIM OF THE PAPER IS THE ANALYSIS OF THE "CONSUMPTION" OF RURAL DEVELOPMENT POLICIES (RDP) AS THE RESULT OF ENTREPRENEURIAL BEHAVIOURS ADOPTED BY FAMILY FARMS. THE UNDERLYING HYPOTHESIS IS THAT FAMILY FARM'S CHARACTERISTICS INFLUENCE THE CONSUMPTION OF RURAL DEVELOPMENT POLICIES. BY PUTTING FORWARD A FAMILY FARM PERSPECTIVE, WE SUPPORT THE IDEA THAT ANY BOUNDARY BETWEEN PRODUCTIVE AND REPRODUCTIVE WORK IN THE FARM HOUSEHOLD IS ARTIFICIAL AND CONDITION FARM STRATEGY AND APTITUDE TO INVEST. THEREFORE, A RELEVANT ASPECT TO BE EXAMINED CONCERNS FAMILY SIZE, LOCALIZATION IN LIFE CYCLE, AND THE PRESENCE OF ASSISTANTS WITHIN THE FAMILY FARMS. THE RESULTS OF OUR ANALYSIS PERMIT TO EMPHASIZE THE IMPORTANCE OF FAMILY CONTEXT IN THE ACCESS TO RDP AND THE RELEVANCE OF THE FAMILY ASSISTANTS ON FARM'S PROPENSITY TO GET FUNDED.

Resumé:

Cet article analyse l'adoption des politiques de développement rural en l'articulant sur la base des typologies de familles agricoles, de la phase de leur cycle de vie et sur la base de la présence d'assistants familiales dans l'activité agricole. Les résultats confirment cette association, en adressant des suggestions des stratégies de politique économique.

Keywords: Family Farms, Rural Development Policy

PAPER

1. Introduction

This paper is centered around family farms and their capabilities of getting funded by Rural development policies (Rdp). Family farms may be labelled as the backbone of the European agriculture (Crowley, 2013); as a consequence, recent rural development policies are specifically targeted to this special type of business, characterised by the strict overlapping between the productive and reproductive sphere (Errington and Gasson, 1993). Against this background, the unit of analysis of our paper is the family farm business. The aim of the paper is to analyze the adoption of Rdp on behalf of family farms and eventual discrepancies in the access to rural policies, based on demographic, economic and territorial variables. The underlying hypothesis is that family farm's characteristics influence the consumption of rural development policies. By putting forward a family farm business perspective, we support the idea that any boundary between productive and reproductive work in the farm household is artificial and condition farm strategy and aptitude to invest. That means the analysis of access to Rdp on behalf of family farms involves the analysis of a collective decision-making process. Therefore, a relevant aspect to be examined concerns family size, localization in life cycle and perspective of generational renewal.

Against this background diversified strategies (portfolio strategies) are at stakes: differentiation of agricultural products, diversification of farming activity into non-farming activities, along either a supply chain or a territorial strategy. Investments are necessary to maintain farm's profitability and its persistence over time. In order to cope with an even more competitive scenario and to grant family farm's resilience, a mix of strategies has to be carried out (Darkhoner, 2010).

From a methodological point of view, the paper tries to match two different statistical sources, the Italian census of agriculture and a regional database containing information on the adoption of rural development policies in the region Lazio (Italy). This attempt may be considered as innovative, due to the lack of numerous studies in literature on this topic. By crossing the two statistical databases we will try to excavate the socioeconomic characteristics of farms consuming/not consuming rural policies and, as a consequence, we will discover possible cases of policy failures.

2. Theoretical background

As Offutt (2002) points out, *since farm households are demonstrably diverse, analysts would seem obliged to investigate hypotheses about differential response and impact*. One of these differences concerns demographic variables: family contexts are particularly favorable to set up a farm venture (Jervell 2011): an abundant economic literature has emphasised the strict connection between farm household strategies and style of farming (among others, Whatmore, 1994), by demonstrating the persistency of family farms (Sabbatini 2011). Their ability to survive over time witnesses the relevance of F-connection[1] in fostering lower levels of transaction costs and a higher aptitude to adapt (Ben Porath, 1980; Pollack, 1985).

In the last decades, family farms have been characterizing European agricultural landscape: in this types of farms: *the principals are related by kinship or marriage, business ownership is usually combined with managerial control, and control is passed from one generation to another within the same family* (Gasson et al., 1988). The strong relevance of family farms at European level has fostered tailored policies within the framework of the Common Agricultural Policy (CAP) policies. For example, a set of measures is addressed to stimulate generational renewal, income support, farm diversification, quality certification schemes (Davidova, Thomson, 2014). At the beginning of the new programming phase for 2014-2020, new opportunities for farms have been provided, in order to encourage farm's development. The capability to exploit these opportunities may be considered as a question of entrepreneurial capability, in that the access to investment measures involves entrepreneurial skills of farmers (Rudmann, Vesala and Jackel, 2008).

Against this background, our first hypothesis is that life cycle of family farms could influence the strategic choice of measures. Moreover, the eventual presence of family assistants may envisage a collective decision-making process which affects the adoption of Rdp. A second hypothesis to be tested is the territorial discriminant that is the possibility of a differentiated access on behalf of family farms in various rural areas. Finally, possible barriers to Rdp may be related to farms' economic dimension, in that the probability to apply for Rdp may be reduced in cases of farm's low economic dimension.

Even though family farm business has been deeply explored in literature, few analyses have been conducted on the consumption of Rdp, by discriminating life cycle of family farms, role of assistants and farm's territorial localization. This paper tries to fill this gap in literature by providing a first analysis of the access to Rdp on the basis of family composition.

Materials and method

In this paper we define as "consumption of policy" the farmer's ability to obtain funds from rural development policies. Family farms are the object of our analysis, marked out by following methodological steps. The first one concerns a socio-demographic classification of family farms taking into account farm activity and the composition of family work: key-elements of the classification are family composition, its localization in the life cycle and the emphasis on the role of farm's assistants either exclusively employed within the farm (p/e: prevalent or exclusive) or not (np: not prevalent). This is a novelty in the analysis of family farms: the role of farmer's assistant has not yet been explored in recent literature.

As far as the family cycle is concerned the age of reference is 40 years, because it is the threshold to gain access to rural development policies for generational change. Following table illustrates the structure of the family farms, according to their life cycle.

Family farm typology		
Young farmer and a not young assistant *(Y+not Y ass.)* - p/e - np	Mature farmer and a young assistant *(M + Y ass.)* - p/e - np	Older farmer and a young assistant *(O + Y ass.)* - p/e - np
Young farmers with other (assistant may be young or may be not) *(Y + other)*	Mature farmers with other (assistant may be old, mature or may be not) *(M + other)*	Older farmers with other (assistant may be mature, old or may be not) *(O + other)*

The second methodological step tries to link family types and access to Rdp, by focusing attention on the consumption of rural development policies in the region of Lazio (Italy). The measures under observation belongs to the three main axes of regional rural program for the last programming period 2007-2013:

1. competitiveness of the agricultural sector;
2. environment and landscape;
3. quality of life and diversification in rural areas.

[1] Family, friends and firms.

Our analysis concerns the first and the third axes, including measures of investments, through which an authentic entrepreneurial activity is realized. As a matter of fact, the second pillar of the CAP provides for multiannual support to family farms by delivering different types of measures articulated on four axes. Second axis includes surface measures, which offer annual allowances based on farmers' commitments to adopt sustainable agricultural models. In this case, farmers are subsidized for lacking revenues, due to their commitments. Axes I and III comprehend investments measures, aiming at sustaining territorial development. Differently from the previous types of measures, investment measures are strictly linked to an entrepreneurial activity, which foresees risk-taking.

A matching procedure between the regional database and the national census of agriculture has been carried out, by making reference to the fiscal code of the farm. This lets the composition of the funded family farm to emerge.

Information and data are downloaded from the database of region Lazio: more precisely, funded farms are linked to farms from the data warehouse of the last census of Italian agriculture, in order to classify them on the basis of family composition. Therefore, three main aspects have been investigated:

- demographic aspects that is the incidence of family composition on the consumption of Rdp;

- territorial aspects: information concerning number of applications and funds obtained have been gathered and articulated on the basis of family types and farm's territorial localization according to the national strategic plan which distinguishes following homogeneous areas: A) urban poles, B) areas with intensive and specialized agriculture, C) intermediate rural areas, D) rural marginal areas.

- economic aspects, that is the eventual relevance of the economic dimension of the farm (expressed by the standard output) in gaining access to Rdp.

Results

Table 1 shows the results of our analysis, as consequence of the match between regional database and the national census of the agriculture 2010. Table articulates the results on the basis of family composition, consumed measures per axis and type of rural area. On the whole 2.368 farms gained access to rural development policies for the period 2007-2013, 2.41% of the amount of farms located in the region Lazio. Therefore, a very small percentage of farms succeed in getting funded.

The results are articulated on the basis of either demographic profiles or type of consumed measure and standard output of applying farms.

As far as demographic profile is concerned, the majority of funded farms are located in the younger and mature phases of life cycle. Almost 54% are young farmers with various assistants, while 42% are mature families. As expected, elderly family farms evidence a reduced propensity (4%) to adopt rural policies for farm investments. Another reflection is inspired by the higher access to policies on behalf of "other" types of farms, with double percentage in the younger phases of life cycle, and triple in the mature and older phases. However, by observing the average contribution obtained in each typology of farms (tab.1b), the relevance of family farms with young helpers emerges, which doubles in the elderly phases of life cycle.

As far as types of rural areas are concerned (tab.1c), intermediate rural areas and area with intensive agriculture attract the highest share of funds (respectively, 56.8% and 21.9%), while rural marginal areas and, above all urban areas retain lower percentages of funds. By crossing demographic and territorial variables, an interesting element regards the relevance of younger farmers applying in rural marginal areas, where the percentage of application in young farms rises up to 64%. This is an important result in terms of generational renewal in difficult areas. As far as type of measure adopted and Rdp area are concerned, measures of the first axis are privileged, while access to measure for farm diversification (third axis) are not so much consumed[2].

[2] For the evaluation of policy consumption under Axis 3 it is necessary to precise that a part (often considerable) of the resources allocated to this axis is not devoted to farmers, but to other entities, both public and private.

In order to test eventual association among the previous variables, a chi-squared test has been put forward. Results are illustrated in table 2

Table 2 – Chi-squared test

	DF	*Value*	*Prob*
χ^2	8	33,77	<.0001

The analysis of contingencies (table 3) provides useful insights related to the propensity to consume measures on the basis of the territorial location of the farms: as a matter of fact, a clear "attraction" between farms in rural areas (both intermediate and marginal) and measure of the third axis emerges. Similarly, a certain association between the youngest phases of the life cycle and the propensity to invest on farm structural adjustment and farm diversification is evident.

Mature families seem privilege diversification in not farming activities while elderly one, evidence preferences towards "traditional" measures of investments aiming at stimulating farm competitiveness.

Table 3 - Contingencies

3.a rural areas	*axis 1*	*axis 3*	*axis 1+3*
A	18,79	-7,35	-11,44
B	13,19	-1,57	-11,62
C	-20,93	4,50	16,43
D	-11,05	4,43	6,62

3b type of family	*axis 1*	*axis 3*	*axis 1+3*
Y + not Y	-2,5	-9,0	11,5
Y + other	9,7	-15,4	5,7
M + Y	-2,3	3,8	-1,5
M + other	-6,4	17,9	-11,5
O + Y	1,4	-0,6	-0,7
O + other	0,1	3,3	-3,5

A final element of reflection regards an economic discriminant, concerning farms' economic dimension and access to Rdp. Table 4 points out the differences among farms by relating standard output to farm with no application to Rdp. As a matter of fact, table points out relevant differences between economic dimensions of farms without application to Rdp and farms applying to policies, divided into farms with rejected or not application

From the table a systematic higher level of standard output characterizes farms with consumption of Rdp, which raise up in cases of farms with application and accepted investment projects (table 4b).

Table 4 - Standard output in relation to farm without application to Rdp (%)

4a - Farms with rejected application

Conclusions

The role of the Common agricultural policy in fostering family farm's resiliency has been deeply underlined in recent literature (Koutsou, 2011; Davidova, Thomson, 2014). Nonetheless, a set of factors, generally labelled as transaction costs of policy adoption, brings about a low access with respect to the potential demand. This paper has tried to emphasize how some key aspects may condition the consumption of policy: three discriminants, territorial, demographic and economic, emerge:

- as far as territorial variables are concerned, the prevalence of some areas seems evident in terms of both average perceived contribution and percentage of adoption; rural marginal areas, for example, get low shares of funds, despite marginal rural areas need significant investments to revitalize farms and rural territories. Nonetheless, the good percentage of young farmers applying for rural policies may be an encouraging signal;

- demographic variables involve the life cycle of the family farm business and, as our analysis demonstrates discriminates between younger and elderly phases. This is not a novelty in literature, but, as our analysis demonstrates, the consideration of the role of assistants may provide further elements of evaluation by enlightening the relevance of the young assistants in performing access to Rdp;

- finally, an economic barrier seems to filter the access to rural policies with farms with high standard output getting funded. This may cast some doubts on the aptitude of Rdp to add up and targeting funds in a "democratic" way, so letting problems of result paradox to emerge: the less you need, the more you get (Bartoli, De Rosa, 2011).

To conclude, the analysis of adoption of rural policies should be carried out within a complex and articulated perspective, which endogenize either territorial, or economic or demographic variables, by endogenizing, whose relevance should be taken into account at political level.

ABSTRACT

Economic literature shows that credit constraints have a negative impact on farm performance. The problem of credit constraints is particularly severe for the Italian agricultural sector given the structure and the legal status of most farms. The difficulties in providing collateral is even greater in the case of sole holders who represent almost 96% of whole Italian farms due to the direct link between farm and private capital. Credit market performance may be affected by judicial efficiency that guarantees the enforcement of contracts. We use court judicial efficiency as an instrument and exploit the great heterogeneity in efficiency of Italian courts across time and provinces to estimate the causal impact of credit constraints on farms' productivity. We find that less credit constrained farms have a higher Total Factor Productivity. We also find that Italian farms, when faced with a less efficient judicial system, are less credit constrained, probably because banks tend to grant mainly subsidized loans.

Keywords: Total Factor Productivity, credit constraints, judicial efficiency

PAPER

1. Introduction

Our study fits into two important current policy debates in Italy: credit constraints and judicial efficiency. In particular, we investigate the impact of the credit market, through judicial efficiency, for the Italian farming sector. As far as we know, there is no study investigating the relationships between judicial efficiency, availability of credit and economic performance of agricultural holdings.

Many contributions to the economic literature deals with the negative impacts that credit constraints have on farm's investment (Carter and Olinto, 2003; Petrick, 2004b), output (Petrick, 2004a), profit (Foltz, 2004; Fletschner et al., 2010) and productivity growth (Guirkinger and Boucher, 2008). Other studies argue sometime, due to some peculiar settings, credit constraints may have a positive effect on farm productivity (Sabasi and Kompaniyets, 2015) and technical efficiency (Maietta and Sena, 2010).

Other studies analyse the debt structure according to debts length and reach contrasting results (Lambert and Bayda, 2005; Mugera 2012). While another important part of the agricultural economic literature aims at measuring and empirically analysing the presence of credit constraints (Petrick, 2005; Blancard et al, 2006). As far as agricultural credit market institutions are concerned, in Italy the main creditors are commercial banks, regulated by the National Central Bank. Data for Italy show that the cost of credit for the agricultural sector is higher than for other sectors and varies geographically, being higher in the central and southern regions.

Previously in Italy farm credit was regulated by special regimes that allowed for better conditions of credit access to farmers and amounted to genuine agricultural policy instrument. With several interventions, among which the Legislative Decree 385/93, the introduction of Basil rules and Legislative Decree 141/2010, those special conditions were greatly reduced and the guarantee scheme became more relevant in the relationships between farmers and the credit system (Adinolfi and Capitanio, 2008).

Italian farms are mostly characterised by small size and sole holder, a legal status for which it is difficult to distinguish between farm and private capital, and are generally not required to publicly disclose their financial situation. This is a problem since, due to the de-specialization process of the Italian banking system aforementioned, the rules for the determination of farm credit worthiness are mainly based on financial statement information[1].

[1] The importance of credit access for the Italian agricultural sector is confirmed by two recent Protocols of Agreement signed in 2016. The first one was signed in January by the Italian Ministry of Agriculture and Bank Intesa Sanpaolo, a leading bank in Italy and the second one was signed in March between Italian Ministry of Agriculture and the Italian Banking Association. The issue of farm credit has also been investigated by a recent cognitive survey carried out by the Agricultural Commission Chamber of Deputies, Camera dei deputati XIII Commissione Agricoltura (2015).

In Italy, the lack of collateral is also reported to be one of the main reasons for rejecting farms' credit applications along with poor credit history of the applicant and insufficient farm business income (Jansson et al, 2013).

Credit market performance is affected by judicial efficiency[2]; an efficient judicial system that guarantees the enforcement of contracts is crucial for the smooth functioning of the credit market, while an inefficient judicial system increases transactions costs and reduces the efficiency of the credit market.

With Italian data, Jappelli et al (2005) showed that improvements in judicial efficiency reduce credit rationing and increase the volume of lending. With an investigation at firm level within the European Union, Maresch et al (2015), show that the better the judicial enforcement system and the higher the creditor protection, the lower the probability that the firms are credit constrained. Fabbri (2010) investigates performances of judicial districts in Spain and finds that differences in the length of civil trials affect the cost of lending.

The mentioned economic literature on the impact of judicial efficiency on credit market does not take into consideration specifically the agricultural sector, for which the Italian bankruptcy law cannot be fully applied (Caiafa, 2012). Moreover, the surveys conducted by the Bank of Italy on the management of debt collection procedures by the biggest Italian banks do not allow to analyse specifically the case of non-performing loans granted to farmers (Generale and Gobbi, 1996 and Carpinelli et al, 2016). Bearing in mind the aforementioned limits, for Italy, the incidence, in terms of amounts, of judicial procedures carried out by banks to recover non-performing loans is estimated around 60% of the 2011-2014 average, the rest being conciliations in extrajudicial settings (Carpinelli et al, 2016).

In this paper, we will use court judicial efficiency as an instrument and exploit the great heterogeneity in the judicial efficiency of Italian courts across time and provinces to estimate the causal impact of credit constraints on farms productivity.

Indeed, Italy provides a good environment to test this causality because the same laws apply across the entire territory but judicial efficiency vary widely across courts.

2. Data and Empirical strategy

The main dataset we use in this paper is the Italian Farm Accountancy Data Network (FADN) for the period 2008-2013. FADN[3] is an annual sample survey carried out in EU Member States for evaluating the incomes and business operation of agricultural holdings and the impacts of the Common Agricultural Policy. Italian farm accounts survey contributes to EU FADN with the major proportion of total Farm Returns and collects also additional information. We restrict our sample to farms specialised in the following general type of farming (TF): field crops, horticulture, permanent crops and grazing livestock.

As the aim of the paper is to investigate the relationship between credit constraint and farms' productivity, we use the Total Factor Productivity (TFP) as measure of farm performance.

In the estimation of production functions one of the critical points is that labor and other inputs cannot be treated as independent variables. To address this issue we employed the estimation procedure suggested by Olley and Pakes (1996) and further developed by Levinsohn and Petrin (2003). We estimated TFP at the level of principal TF using value added as output, and labor, land and fixed tangible assets as inputs[4]. Following the approach of Musso and Schiavo (2008) for identifying and measuring the degree of financial constraint, we built a synthetic index using eight dimensions: size (total fixed assets and total current asset), profitability (return on total assets: operating income over total assets), liquidity (total current assets over current liabilities), self-financing capacity (net income over total assets) and solvency (net worth over total liabilities). Moreover, following Adinolfi et al (2012), we considered the peculiarity of agriculture and added three other dimensions: total utilised agricultural area, land/area (agricultural land, buildings and forest over total utilised agricultural area) and investments/land (new investments over agricultural land, buildings and forest). For each of these dimensions, we computed the distance of the value of farm from the average of all the farms belonging to the same TF, and then, we placed the value of the distance in one the quintiles in which the corresponding distribution is divided. Hence, for each farm we obtained eight scores from 1 to 5, where 1 refers to the smallest values and 5 to the highest ones.

Finally, we sum these eight scores and we obtain a synthetic index where higher values of the index are associated to lower degree of credit constraint. The index ranges from 9 to 38. In order to achieve a better interpretation of our results we standardized the score.

---

[2] The judicial efficiency has been widely discussed and several studies have been undertaken by the Italian and international scientific community - for a recent review see Ippoliti 2014.
In Italy the debate on judicial efficiency is particularly current as a result of the territorial organization reform dealing with Ordinary Tribunals, Public Prosecutor's offices and Justices of the Peace offices that aimed at reducing the number of courts, suppressing of 220 courts' detached offices and almost 480 Justices of the Peace offices (Law no. 148/2011 of 14 September 2011 and implemented by Legislative Decrees n. 155, n. 156/2012, n. 14/2014).

[3] The current FADN legal base is Council Regulation (EC) No 1217/2009.

[4] The intermediate inputs used in the estimation of the Levinsohn and Petrin method are proxied by total specific costs and intermediate overheads arising from production. It includes, among others, seed, fertilizer, animal feed, water, electricity, and fuel.

For civil and criminal justice, the Italian territory is divided into judicial areas (Circondari) which define the territorial jurisdiction for each tribunal and public prosecutors' office. These areas mainly coincide with the corresponding provinces' area (NUTS 3) with some exceptions.

Within these areas, the courts of first instance tribunals, 165 ante and 140 post territorial organization reform implemented in 2012, administer both civil and criminal justice. The 26 Courts of Appeal are the second instance courts for civil and criminal cases, their territorial jurisdiction (Distretti) are wider than those of tribunals. We use data provided by the Ministry of Justice and in order to cover the two main degrees of justice, we computed the number of trials pending divided by incoming cases (pending/incoming) both for tribunals (at the level of circondario) and Court of Appeal (at district level). In addition, to avoid potential problems that might arise due to jointly determined choices, we use one year lagged variables. Looking at the judicial efficiency, we find a great amount of geographical heterogeneity, confirming that the degree of efficiency vary greatly among circondari and generally seems to be higher in the North of Italy than in the South. The pending/incoming for tribunals range from 2.6 for Bari to 0.56 for Trento, and the pending/incoming for Courts of Appeal range from 5 for Reggio Calabria to 0.8 for Trento. We finally standardized our two indexes of court efficiency.

One of the key econometric problems when estimating the effect of financial stress on farm performance is its endogeneity, because a high level of financial stress is non-random and depends on farm unobservable characteristics. In order to solve this issue, we used an Instrumental Variable (IV) approach. A good instrument should be exogenous with respect to farm performance but, at the same time, should strongly affect the level of credit constraint. We use our efficiency variables as an instrument and exploit the great heterogeneity in the judicial efficiency of Italian courts across time and provinces to estimate the causal impact of financial constraints on farms productivity. As far as we know, an IV approach has never been used in investigating this relationship. We relied on a classical IV estimation strategy, and tried to define a measure of credit constraints and provided evidence of its effect on productivity. We estimated the following fixed effect model:

$$Y_{ijt} = \alpha + \beta_1 CC_{ijt} + \beta_2 X_{ijt} + \mu_i + \theta t + \varepsilon_{ijt}$$

$$CC_{ijt} = \delta + \gamma_1 Z_{jt} + \vartheta_j + \rho t + \sigma_{ijt} \quad (1)$$

Where Y_{ijt} is the (ln) total factor productivity of farm i in district j in year t, X are a set of farm size[5] dummy, CC_{ijt} is our measure of credit constraints, μ_i is a farm fixed effect, θ_t and ρ_t are year dummies and εijt is a standard error term. In the first step equation, Zjt is a measure of court efficiency of district j in year t, while Z_j are district fixed effects.

The fixed effect method has the advantage of controlling for any latent or not observed constant over time variable that characterizes the unit of analysis (farm and circondari). In our case, for example, the estimated fixed effects model helps to eliminate distortions caused by a possible effect of concentration of technology in the "best farms", those who have the best farm holder or which are located in the more productive areas. However, this approach does not allow us to control for changes in these same characteristics that have occurred in a farm over the period under analysis. With the year dummies, we are able to control for shock common to all the farms in the sample.

3. Results

Table 1 reports the results of the effect of credit constraint on farm productivity. In the column (1), obtained using fixed effect estimator and treating the credit constraint variable as exogenous, the results show that the coefficient of credit constraints is positive and significant: the lower is the credit constraint the higher is the performance of a farm in terms of TFP.

In column (2) we show the reduced form of our estimated equation. We find that an increase in the court inefficiency affects positively the TFP, in other words, an improvement of the civil court efficiency is associated with a decrease in the farm's productivity, and this evidence regards especially the efficiency of the Courts of Appeal.

[5] From the accounting year 2010 farm's size is defined in terms of total Standard Output (SO) of the farm expressed in euro (Reg. (EC) No 1242/2008), previously, until the accounting year 2009, the economic size is measured as the total Standard Gross Margin (SGM) of the farm expressed in European Size Unit (Decision 85/377/CEE). Size is therefore a time varying characteristic. Using farm size we grouped the farms into three classes: Small: SGM <= 19.200 OR SO <= 50.000 which accounts for 34.6% of the sample; Medium: 19.200< SGM<=48.000 OR 50.000< S0 <=100.000 which accounts for 26.2% of the sample; Large: SGM > 48.000 OR SO > 100.000 which accounts for 39.3 of the sample.

Table 1 - Fixed effect, reduced form and IV estimations of the effect of court efficiency on farm productivity. Court efficiency measure: the number of trials pending/incoming cases of court in each circondario and Courts of Appeal (CA). Italy, 2008-2013.

To control for all forms of endogeneity between TFP and credit constraint we use an IV approach. The results of the two stages of our estimations are reported in columns (3) and (4). In the first stage of IV we find that a standard deviation increase in the court inefficiency of tribunals is associated to around a 0.02 increase in our credit constraint index, i.e. the level of financial stress is reduced. In the same fashion, a standard deviation increase in the inefficiency of the Court of Appeal raises the credit constraint index of about 0.034. Therefore, the higher the court inefficiency the lower the credit constraint. This result is counterintuitive, but we may expect that farms could be quite peculiar in their access to credit market. In column (4) we confirm a positive relationship between the loosening of the credit constraint and the productivity of the farms. All columns include, other than farm fixed effects, size dummies and year dummies.

Overall, our results have two important implications. First of all, they confirm a positive role of the loosening of the credit constraint on the performance of the farms. Secondly, an increase in the court inefficiency reduces the credit constraints faced by each farm. This result may be a puzzle, but we have to consider that the farms are quite peculiar in their debt structure. In order to find a plausible explanation for this counterintuitive result, we explored the official data about subsidized loans to agriculture delivered by the Bank of Italy for the period 2008-2013. These loans are supported by specific incentivizing laws that granted interest rates lower than the market's ones. We divided each regional amount of subsidized loans by the number of farms in each region[6]. We then run a fixed effect regression at the circondario level, and found that whenever the judicial system becomes less efficient, the amount of subsidized loans increases. It seems that in those areas where the courts are less efficient, and subsidized loans are available, banks tend to lend money using this channel instead of the unsubsidized ones. Farms benefit from the subsidized loans that are cheaper and their productivity increases.

4. Conclusion

Our study fits into two important current policy debates in Italy: credit constraints and judicial efficiency. In particular, we investigate the impact of the credit market, through judicial efficiency, for the Italian farming sector. As far as we know, there is no study investigating the relationships between judicial efficiency, availability of credit and economic performances of farms. We exploit the heterogeneity in the judicial efficiency of Italian courts across time and provinces to estimate the causal impact of financial constraints on farms productivity. We find that the loosening of the credit constraints increases the performance of the farms. Secondly, an increase in the court inefficiency reduces the credit constraints faced by each farm. This result may be a puzzle, but we argument, with caution, that probably a relationship between the judicial system and the structure of farms debt does exist. Whenever the inefficiency increases, and subsidized loans are available, banks tend to lend money using this channel instead of the unsubsidized ones. Farms benefit from these subsidized loans, that are cheaper, and their productivity increases. This puzzle deserves further investigations and future research should try to discover if this relationship varies according to type of farming, farm size or owner characteristics. We also believe that further progress in solving this puzzle could provide a better understanding of the relationship between credit and agriculture and shed light on agricultural policy implications.

The inverse farm size productivity relationship: some new evidence from sub-Sahara African countries

P. L. Scandizzo | University of Rome "Tor Vergata" | Rome | Italy
S. Savastano | University of Rome "Tor Vergata" | Rome | Italy

DOI: 10.1481/icasVII.2016.c23d

ABSTRACT

The inverse farm size productivity relationship (IR) for short implies that diseconomies of scale characterize agriculture systems for several possible reasons, including the failure of land and labor markets to equalize production efficiency across farm size distribution. From the policy perspective in turn, should smallholders be found to be more efficient, policies to facilitate the redistribution of land from large towards the small farms would be justified not only on equity but also on efficiency grounds. While many consider IR as a "stylized fact" of rural development and a guiding principle of the major land reform in the former Soviet Union, and the Eastern European countries, others find it difficult to accept without further questions for several reasons. These include the fact that in most empirical studies IR appears as smooth tendency for land productivity to decline with farm size and thus is not limited to a different pattern of resource uses between large and small farms. While different reservation wages could account for family versus non-family farms, this would not explain why land productivity appears to decline within small family farms as well. Some empirical evidence also suggests that land quality and farm size are inversely correlated, so that ignoring this relation may be the cause of a basic specification error. Finally, several studies have indicated that total factor productivity does not show any negative correlation with farm size.

In this paper, we investigate the relationship between productivity and farm size from the point of view of the option value of land and its relation with management quality and efficiency. We use LSMS-ISA national representative datasets of five sub-Saharan African countries, which provide standardized location details of sampled communities allowing the data to be linked to any other geo-referenced data . We are thus able to control for many exogenous common and comparative geo-spatial measures of land quality, infrastructure and access to markets, climate conditions, soil and topography. We also use an estimation strategy, based on quantile regressions at the household level, that allows us to test IR existence and verify signs' switches across the entire distribution of farm size, and between countries located in different agro-ecological zones. Our findings indicate that, as suggested by a model combining land option values and farm size related management quality, while IR may be important for certain ranges of farm efficiency and size, it is by no mean an ubiquitous characteristic of agriculture. Whether the relationship between productivity and size is positive or negative may thus depend crucially on other factors, including soil quality, agro-economic zones, and the efficiency of farm management.

Keywords: Farm size productivity relationship, quantile regression, sub-Saharan Africa

PAPER

1. Introduction

The finding that land productivity and size of the land operated (both owned and rented) appears are related negatively has been historically established by a variety of studies starting in the late 70s (e.g. Berry and Cline, 1979, Kutcher and Scandizzo, 1981, Binswanger et al., 1993).

The literature has emphasized different explanations for this empirical regularity:

1. factor market imperfections in land and other market such as credit and modern inputs;
2. omission of soil quality measurements that are inversely correlated with farm or plot size but positively associated with yields;
3. measurement errors in self-reported area and quantity of crop production typical of household survey agriculture data;
4. risk and uncertainty.

The finding, however robust across many studies (Bharadwaj, 1974, Carter, 1984, Feder, 1989), seems at the same time puzzling, for several reasons. First, it is not limited to small versus large farms, but in most studies, there is a smooth tendency for land productivity to decline with farm size. This result seems to contrast to the equalization of factor prices predicted by market equilibrium theory and not simply explained by lower reservation wages for family farms, because land productivity appears to decline within all ranges of family as well as non-family farms. In this respect, Feder's (1985) alternative explanation appeals to a more general transaction effect, reminiscent of Coase's theory of the firm. According to this explanation, smaller farms are based on more intense use of family labor, because of its higher efficiency and motivation than hired labor and the fact that supply of working capital is directly related to farm size. Srinivasan (1973) explains the inverse relationship by yield risk, by defining utility over income , and imposing restrictions on the coefficients of risk aversion and on how risk enters production, under constant returns. Hazell and Scandizzo (1974) provide a rationale for producers to reduce planned production in response to the negative correlation between supply and prices, and Barrett (1993) shows that IR can emerge from price risk if farmers are net buyers of the crop produced, since in this case, risk aversion implies labor overemployment to protect consumption.

As Savastano and Scandizzo(2009) have shown, a relationship between productivity and operated area may arise because of the investment required by the decision to increase one's farmland . Under dynamic uncertainty, in fact, the amount of land operated by a farmer will depend on the timing of the exercise of the option to invest in land development. With decreasing returns to scale, this will imply a non monotonic relationship between revenue per ha and operated land. If land is available on the market in fixed quantities (i.e. supply of plots for rents or sale , or entire farms of discrete size), and/or investment is lumpy, small farms will exhibit lower revenue thresholds for investment, and thus lower revenues per ha than larger farms. This implies, in particular, that the relationship between productivity and size may exhibit turning points, as farmers switch from one type of investment to another (e.g. from land improvements to irrigation) as their operating land increases as a result of previous investment decisions.

Some empirical evidence (Bhalla, 1979, Bhalla and Roy 1988, Benjamin, 1995, Dyer, 1997), suggests an inverse correlation between land quality and farm size, so that ignoring this relation may be the cause of a basic specification error. This implies that if various characteristics of land such as fertility, water and nutrient availability, soil structure and composition are taken into account, the negative correlation between average land productivity and size might be drastically altered or disappear. In an insightful study on the impact of Kenya extension service, Evenson and Mwabu (1998) found that productivity response to acreage, measured through quantile regression, was not significantly different across quantiles, but displayed a concave shape, first rising and then falling with the size of the cultivated area.

More recently, other studies suggest that correcting for land and crop quantity measurement errors strengthen the IR (Carletto et al., 2013; Deininger et al., 2012). Finally, several studies have indicated that total factor productivity does not show any negative correlation with farm size, and results, if anything, seem to suggest a tendency toward increasing with the scale of the enterprise.

The contribution of our paper to the existing literature is threefold:

1. We analyze the existence of the IR in a cross-country context making use of comparable national representative surveys.

2. We avoid the problems posed by the endogeneity of key farm variables, by using a number of exogenous variables available in the geo-referenced dataset of the LSMS-ISA project. For example, instead of controlling for soil quality self-reported information of farmer, we use exogenous soil quality variables.

3. We control for other omitted variable bias and measurement errors in self-reported area of farmers by using the GPS information of land area collected by the enumerators.

Our results , using evidence for five sub-Saharan African countries (Malawi, Niger, Nigeria, Tanzania and Uganda) suggest the following conclusions:

- Consistently with findings of the existing literature, land quality and its components appear to be significant explanatory variables of land productivity, and so are several other exogenous variables linked to urban and market influence, such as distance from the roads, temperature and rainfall.

- Effects of farm size on average land productivity remains significant across all specifications.

- However, this relationship is both nonlinear and switches signs across farm size groups. More specifically, average land productivity (ALP) exhibits an inverted U-shaped relation with farm size for the first three deciles of the land productivity distribution, with ALP first rising and then falling after a threshold farm size. Vice versa ALP shows the opposite pattern of a U-shaped relationship for the rest of the distribution, first decreasing and then increasing after reaching a lower threshold.

- This pattern is confirmed by quantile regression and by testing the ALP – farm size relationship within and across quantile groups.

- Farms in the lower tail of the ALP distribution thus experience IR only once they have reached a critical size. Vice versa, farms at the upper end of the distribution experience IR only if they are below a critical size, which, in general, tends to be larger (and some time much larger) than the critical size of the lower end farms.

- Thus, small and large farm behavior tend to diverge, since farms in the lower deciles of the land productivity distribution experiment the IR for a smaller range of farm sizes than farmers of the higher deciles.

2. Conceptual Framework

The agricultural enterprise poses two different problems to the theory of the firm. First, contrary to reasonable expectations on the division of labor and the role of capital, in most cases the family farm appears to be the dominant form of organization of the productive unit in agriculture. Second, similarly, but more dramatically than for the other types of firms, the existence of profit represents a puzzle for the family farm, since its determination as a residual in a highly competitive market does not follow a clear economic logic . Perhaps the best discussion of this twofold question, within a more general framework of the fundaments of the theory of the firm is the treatment by Demsetz (1995), who discusses the issue of the existence of the firm by contrasting Coase's transaction theory with its own. Demsetz aptly starts its treatment by noting that rather than with the existence of the firm, the early literature was concerned with a related, but separate event, the existence of profit in a perfectly competitive market. Given that profit existed, the institutional theory tried to find a justification in the entrepreneur. In two significant cases, that of Frank Knight (1925) and Ronald Coase (1937). Both these authors laid the foundation of a productivity theory of the firm, based on the idea that the reason for the firm's existence was to increase productivity by providing managed coordination, thereby reducing risk in the case of Knight and reducing transaction costs for Coase. Demsetz's own theory is based on two related concepts: specialization and interdependence, where the development of a business firm is seen as a process of specialization that separates production from consumption, thereby creating interdependence with other firms and households.

For Boserup (1965), Binswanger and Rosenzweig (1986) , and Binswanger and McIntyre (1987), the process of agricultural development is characterized by population pressure which brings about the family farm system, chiefly because of hired labor transaction costs that create diseconomies of management. The family farm, in other words, while equally productive in reducing other transaction costs external to the firm (a la Coase) is superior in increasing productivity by internalizing labor supervision costs without increasing transaction costs internal to the firm. According to the family farm theory (Roumasset, 1995), in particular, it is the very organization of the farm that is determined by labor transaction costs, rather than by any technical economy of scale. On the other hand, Eastwood, Lipton, and Newell (2010), henceforth ELN, on the basis of a simple maximization model, with homogenous farmers, claim that development will bring about an increase in family reservation utility and thus in equilibrium farm size, but the increasing availability of cheaper capital and technological progress can go either way. Moreover, removal of any of the hypothesis of the simple model (e.g. infinite supply of family farmers, homogeneity of land etc.) tends to open the way for different results, pointing to the impossibility of a unique prediction on the effects of development on the farm size. A similar conclusion can be reached for the relationship between efficiency and farm size, with a plurality of possible outcomes, depending on the various components of scale economies and diseconomies, including indivisibilities and transaction costs, that may directly and indirectly interest the farm.

While the outcomes of increasing farm size may be many, it seems legitimate to ask whether there is a fundamental tendency, as postulated by Coase (1937), for the farm to grow in response to the need to reduce market transaction costs and, if not, why or because of which fundamental constraints or counter-tendencies. This question is dictated by the general issues considered by Coase , but also by the seemingly ubiquitous finding of an inverse relationship (IR) between land productivity and farm size. The answer to the above question, however, requires an answer to a more general question, namely: is the farm , and the family farm in particular, defined by its relationship with transaction costs, within the bigger picture of the relationship between the firm and the market? In this respect, most of the literature cited, with the partial exception of ELN, appears to regard transaction costs as an element of possible scale diseconomies in determining the optimal size of the farm, and not as a constitutive element of the productivity mission of the firm as an institutional agent, as claimed by the institutional economic literature . Rather than asking whether small farms reduce transaction costs, for example, Pingali (2010) focuses on the opposite question on whether and how to reduce the transaction costs faced by small farms. On a different note, ELN note that there is no theory that predicts optimal farm size to minimize unit transaction costs, because of multiple equilibria, deriving from non convexities of the transaction cost functions. They claim that these multiple local optima may give rise to sudden jumps from self cultivation to much larger forms of operations, in effect , because labor transaction costs become less important than capital transaction costs.

These arguments seem also to exclude a tendency toward an optimal farm size, but rely on a particular interpretation that essentially assimilates transaction costs to the costs of accessing factor markets and managing factor usage. A more general interpretation, however, considers transaction costs all costs related to ex ante and ex post exchange , including the choice of the trade partners, bargaining, monitoring and enforcing the related contracts. For Coase (1972), the firm acts as an agent capable to reduce these costs by substituting a structure of command and control to the decentralized structure of the market , and by appropriately standardizing the contracts themselves.

Within this interpretation, as a nexus of contracts, the family farm presents different organizational features from a commercial farm which may indeed reveal a tendency to settle around an optimal size , that , if not reached , or once reached, may give rise respectively to scale economies and diseconomies . The organization of the family farm , in fact, is based on a structure of implicit contracting grounded in familiarity (in the literary sense) , trust and mutual exchange, with community monitoring and enforcement, a strong role for tradition procedures, routines and rights, and equal importance of utilitarian exchange and ritualized gift giving. As Demsetz (1995) argues, furthermore, the family farm is also typically organized in a way that promotes a certain degree of self-sufficiency, and thus tends to substitute the contracts between producers and consumers with a standard in house arrangements, which often include family and non family labor.

Family farms may thus be more effective in enhancing productivity, than other types of organizations, especially when market transaction costs are high, and they pursue their mission with a panoply of instruments, characteristic of traditional societies, some of which survive within "familistic" cultures also in more advanced and indeed non agrarian urban contexts (Putnam, 1967). We should expect their contribution to productivity increases , however, to be uneven, and led by different drivers, depending on the features of the environment that they face, their different objectives, and the relative importance that the instruments at their disposal assume . Management ability is certainly a component of a successful performance, but a number of family characteristics may conjure up to determine winners and losers including the human and non human capital (Sen's re-known "capabilities") with which the family is endowed.

Classes of different performances may thus emerge across the spectrum of family farms , depending on the fact that they may have diverse subsistence and marketing goals and because of characteristics that may be at the same time too many and too subtle to observe. Within each class, a tendency to optimize may be present, with several local optima that determine local IRs in different intervals of productivity and farm sizes. In more dynamic terms , the implications of development and transaction costs for the family farm may be rather different than those of the firm. In both cases an increase in market transaction costs (MTC) may increase the incentives to internalize the production of goods and services, but while this typically means a more vertically integrated enterprise for the firm, it will simply tend to enhance the push for self sufficiency for the family farm and thus increase its optimal size. Symmetrically, an increase in internal transaction costs (ITC) , such as information and supervision, will reduce the incentive to integrate the value chain for a firm that is already well positioned in the market, while it may reduce optimal farm size by increasing specialization and market dependence for the family farm.

Decisions about family size are also likely to be affected by transaction costs, so that the family farm, unlike the firm, may react to changes in MTCs and ITCs with two instruments, i.e. the number of people in the family and the scale of operations. Thus increases in the ratio between MTCs and ITCs may be expected to encourage larger family sizes, because a higher degree of self-sufficiency requires larger operating sizes, higher diversification and more general skills, with factors somewhat trapped within the farm or its quasi market circle of mutual help of extended family systems . Here, we should expect first a direct relationship between productivity and farm size and then IR emerging in response to excessive increases lead by the forces unleashed by the harder drive toward self sufficiency. Vice versa a decrease in the MTC- ITC ratio will encourage smaller and more specialized enterprises, higher integration with the market and higher factor mobility, with IR pushing toward a contraction of farm sizes along these lines. Thus, even though consistent with the Coasian premises, the process of de-agrarianization may be itself a cause of the IR, since it is to some extent the opposite of the process originally described by Coase, with many different types of smaller farm- firms emerging from the rather homogenous population of traditional family farms to exploit the reduction in market transaction costs made possible by development.

Because the family farm has low supervisory costs from higher motivation of its members (Feder, 1985) and of the gratuities that they can experience as parts of an extended family business, the reduction in external transaction costs may be expected to have different effects on differently performing farms. For highly productive family farms, that are performing better than their peers because of higher quality management or other non observable farmers' abilities, increases in marketable surplus and development of commercial agriculture may be a chance to be exploited immediately, even before undergoing a transformation to more specialized units, operating exclusively for the market. While increasing farm size may be necessary to exploit the new market opportunities, increasing internal transaction costs (ITC) should be expected with negative effects on productivity until a certain threshold of successful transformation into commercial farming has been achieved.

For the less productive family farms , on the other hand, the opportunities created by lower MTCs may be met with size expansion without major increases in supervision costs at first, either because of underemployed family labor, or because of other benefits from MTC reduction, such as access to modern inputs, extension and better prices. Beyond a certain threshold of expansion, nevertheless, it is reasonable to expect that ITCs will become prevalent again and that larger farm sizes will be associated with lower productivity.

These considerations also suggest that farmers may operate in different ways, especially in the extreme distribution of farm productivity residuals, due to unobserved cognitive and physical abilities (Evenson and Mwabu, 1998), previous experience with investment or other performance- related characteristics. Thus, for example, at the low extreme of the productivity distribution (or the distribution of its residuals after accounting for the exogenous variables), productivity could increase as farmers take advantage of larger operating areas to overcome other performance disadvantages due to low endowments of skills and knowledge. At the high extreme, on the other end, supervision costs may become more important and larger sizes may reduce the competitive advantage of abilities and motivation of family farmers (Feder, 1985).

If factor productivity is distributed normally, with a constant variance, aside from identification problems, OLS will generally provide an estimate of the relationship based on mean response. In other words, OLS will allow us to estimate a response coefficient that will quantify the average response of the dependent variable (e.g. land productivity) to farm size increases. If the distribution of the response around the mean , estimated according with OLS, is not satisfactorily described by a single variance, however, quantile regression (Koenker and Basset, 1978) promises a more robust and appropriate estimate, especially if variance is systematically related to the increase in the response variable (heteroscedasticity). We can also conjecture that the relationship between productivity and alternative measures of size (land available, land under cultivation etc.) may be considerably different for farmers who, for various reasons that cannot be captured by the econometric model, have to operate at low productivity levels, with respect to farmers that operate at high productivity levels.

3. The Option Model

We follow Savastano and Scandizzo (2009) and assume that landowners hold the option to invest in additional land i q at a given rate $r^* = \frac{r}{\rho}$. Yield is assumed to follow a Brownian process as identified by the equation:

$$(1)\quad dy = \alpha y dt + \sigma y dz$$

Assume that the farmer contemplates the possibility of investing in farmland q_i, Farm operating profit from developing land, π, is determined according to the following equation :

$$(2)\quad \pi_i = \frac{y}{\delta} f(q_i; m_i) - \frac{c}{\rho} f(q_i; m_i)(1 - e^{-\rho T})$$

In (2) , $\delta = \rho - \alpha$, and without loss of generality, we set $\frac{c}{\rho}(1 - e^{-\rho T}) = r$ and consider only land a decision variable. Revenue per unit of output, i.e. the random variable y is supposed to follow a geometric Brownian motion as described in (1). In addition, $f(q)$ is a neoclassical production function with the standard properties $f_i > 0$, $f_{ii} < 0$, $i = q, m$, with management m positively related to both average and marginal productivity : $f_{qm} > 0$, $f_{qqm} < 0$. We also make also the following assumptions: (1) the production function is linear homogenous in the two inputs of land and management ability, (2) management is exogenously given for the farmer, (3) the farmer can develop land at the cost c , which includes all on farm investment. This cost is sunk and the investment is irreversible, (4) the operating profit flow is such that the farmer does not have the option to suspend or abandon the cultivation.

The objective of the farmer is to maximize the expected present value of profit. The discount rate is given and equal to ρ . The farmer cultivates his own original plot of land, given his endowment of management capabilities, and has to decide whether to develop land on the basis of costs and benefits of cultivating additional pieces of land.

Given these conditions, as shown more generally by Dixit and Pyndick (1994), the optimal policy is described by an upward-sloping threshold curve $y = y(q,m)$. In the region above the curve, it is optimal to develop more land in a lump to move immediately to the threshold curve. In the region below the curve, inaction, and therefore, cultivating the previous amount, is optimal. The farmer waits until the stochastic process of y moves vertically to $y(q)$, and then develops land just enough to keep from crossing the threshold. Assuming that there is a continuous supply of land, the farmer cultivates his own initial level and has the option of develop additional pieces of land. As shown by Savastano and Scandizzo (2009), the threshold value of production at which the farmer will invest in additional land development is:

(3) $$\frac{y^*}{\delta} = \frac{\beta_1}{\beta_1 - 1}\frac{r}{f_q(q_i;m)}$$

The parameter $\beta_1 > 1$ derives from the solution of the dynamic problem of the farmer under uncertainty and is an inverse function of the variance of the process in equation (1). Thus, equation (3) simply states that the threshold of investment will be at a level of marginal productivity of land that significantly exceeds its development costs.

Since the production function is homogenous of degree one, we can write:

(4) $f_q(q_i;m_i)q_i + f_m(q_i;m_i)m_i = Q_i$

(5) Thus, average land productivity (ALP) for the new developed area can be computed as follows:

(6) $$ALP_i = \frac{Q_i}{q_i} = [f_q(q_i;m_i) + f_m(q_i;m_i)\frac{m_i}{q_i}]\frac{y}{\delta}$$

Substituting (3), we obtain:

(7) $$ALP_i = \frac{\beta_1}{\beta_1 - 1}\frac{ry}{y^*} + f_m(q_i;m_i)\frac{m_i}{q_i}\frac{y}{\delta}$$

From this equation we can directly derive the following results:

(8) $$\frac{\partial ALP}{\partial y^*} = -\frac{\beta_1}{\beta_1 - 1}\frac{ry}{y^{*2}}$$ (8) $$\frac{\partial ALP}{\partial q_i} = \frac{y}{\delta}[f_m\frac{1}{q_i}(\frac{\partial m_i}{\partial q_i} - \frac{m_i}{q_i}) - |f_{mm}|\frac{\partial m_i}{\partial q_i}]$$

ALP will thus be lower the higher the threshold value, but it will increase or decrease with operating size depending on the balance of the diffent effects of management quality. As operating size increases, in fact, if management and farm size are positively related (that is, larger farms tend to have better managers or $\frac{\partial m_i}{\partial q_i}$>0) management will be spread over a larger farm, thereby reducing its impact, but the overall effect may still be positive because of the positive marginal effect that increasing operating size will be in attracting better managers. In general, the fact that the threshold and the management effects may display opposite tendencies to increase or decrease as farm size rises suggests two conclusions:

(1) ALP will display respectively a negative (the IR) or a positive correlation with farm operating size, depending on whether the threshold effect (the higher incentive for larger farms to hold undeveloped land as an option) prevails or is overwhelmed by the management effect (the tendency of ALP to increase with farm size since larger farms attract better managers).

(2) Depending on the functional form of their relationship, the two tendencies may equal each other , once a threshold of farm size is reached, after which the net effect on ALP will be reversed.

(3) Both tendencies and the level of the threshold will depend on the management quality and thus can be expected to vary across farmers, depending on the distribution of management quality and the extent to which a market for managers succeed in allocating them to larger farms.

These conclusions support the idea that the IR relationship may indeed be present in many farming systems, but we should expect it to be neither ubiquitous nor monotonic. In particular, if farmers face dynamic uncertainty by holding a waiting option for land development and unobservable management quality is positively correlated with farm size, both a reverse and a direct effect of operating size on average productivity may be present at any one time. This in turn implies that the net impact of increasing operating size on land productivity will depend on whether a threshold is crossed where the two effects exactly balance each other.

4. The Estimation Problem

Consider the relationship between land productivity and farm size in the stylized form:

$$\frac{y_i}{x_i} = \beta_0 + \beta_1 x_i + \gamma Z_i + \epsilon_i \qquad (9)$$

where y_i is some measure of production for the ith farm, x_1 is a correspondent measure of farm size (e.g. operated area), z_i a set of exogenous variables, and e_i a random disturbance. It is important to underline the fact that equation (9) is not a production function, but the result of farmers' choices, on the basis, inter alia, of an underlying technology. If we assume that farmers have adjusted production (either through optimization or through any other common behavioral rule) to the circumstances outside their control, including exogenous variables, states of nature etc., the coefficient β_1 in (1) should be zero. In other words, all systematic differences in production per acre between farms should be accounted for by differences in the z_i variables or in the random term εi. A β_1 different of zero, on the other hand, would imply the existence of systematic differences across farmers that are not accounted for in the equation: these differences could be due to different behavioral rules, different abilities in following the same rules or different levels of information or other omitted variables that are correlated with farm size.

It is also important to notice that a non zero β_1 may be caused by discontinuities in the behavioral function that underlies farmers' adjustment to the exogenous variables. These discontinuities are implied by most of the explanations of the inverse productivity relationship based on anthropological differences between "family" and " non family" or systematic divergence in behavior between "small" and "large" farms (e.g. Feder, 1989; Cornia, 1985). However, if IR is the result of these discontinuities, it should only concern the differences across the two extreme groups of farmers, and not the differences within the groups themselves.

In order to test for the existence of either an inverse or a direct relationship (IR) between land productivity and farm size , we use both OLS regression models and quantile regressions (Koenker and Bassett , 1978). While OLS focuses on modeling the conditional mean of the response variable without accounting for its distribution, the quantile regression model accounts for the full conditional distributional properties of the response variable (or is residual after accounting for the exogenous variables) thereby differing on the assumptions about the error terms of the regression model.

In the case of equation (1), the OLS model is based on the assumption that the error term is normally distributed with zero mean and constant variance: $\epsilon_i \sim \text{i.i.d.}\, N(0, \sigma^2)$

The consequence of the mean zero assumption of the error term implies that the model fits the conditional mean, namely $E[y - \gamma Z|x] = \beta_0 + \beta_1 x_i$ which can be interpreted as the average value of productivity, after accounting for the effect of the exogenous variables Z, corresponding to a fixed value of the covariate x (i.e. farm size). The linear regression model describes how the conditional distribution behaves by utilizing the mean of a distribution to represent its central tendency, a choice that appears appropriate under the assumption o homoscedasticity , namely of constant variance for all values of the covariate x.

The quantile-regression model (QRM) estimates the potential differential effect of a covariate (farm size) on various quantiles in the conditional distribution. A conditional quantile is a statistic corresponding to the probability level of a given distribution, according to a function (the quantile function) defined as $q(p) = \{y: \Pr(Y \leq y) = p\}$. By considering the different quantiles, the QRM estimates how the effect of a covariate varies with the distribution of the response variable and accommodates heteroscedasticity. The QRM corresponding to the LRM in Equation (9) can be expressed as:

$$y_i = \beta_0^{(q)} + \beta_1^{(q)} x_i + \gamma^{(q)} Z_i + \epsilon_i^{(q)} \tag{10}$$

The parameter vector, $[\beta_0^{(q)} \beta_1^{(q)} \gamma^{(q)}]$ is obtained by minimizing the sum of absolute deviations from an arbitrarily chosen quantile of a farm yield across farmers. In the case of Equation (2) this sum can be expressed

as:

$$\text{Minimize: } \sum_i \left| y_i^q - [\beta_0^{(q)} + \beta_1^{(q)} x_i + \sum_j \gamma_j^q Z_{ij} \right| \tag{11}$$

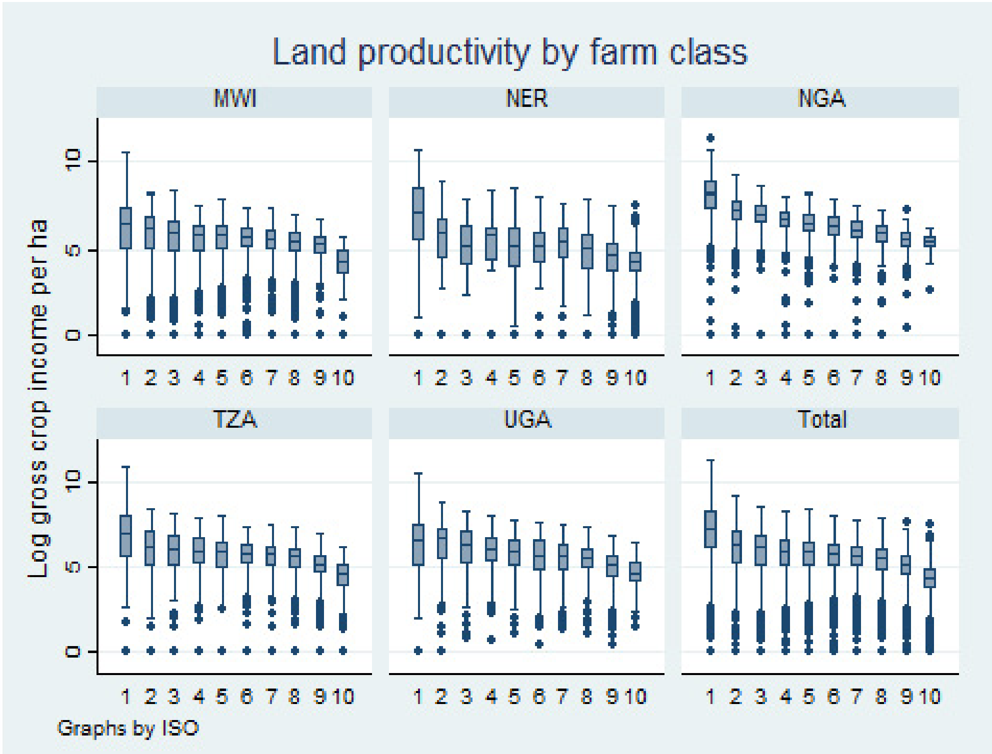
where y_i^q = average productivity for farmer i at quantile q, (i =1, ...n); x_i= farm size Z_{ij}^q = covariate j for farmer i (j = 1,....K).

The solution to Equation (11) is found by rewriting the expression as a linear programming problem over the entire sample (see Chamberlain, 1994) and solving for he values of the parameters. Both the squared-error and absolute-error loss functions are symmetric, as the sign of the prediction error is not relevant. While OLS can be inefficient if the errors are highly non-normal, quantile regression is more robust to non-normal errors and outliers. QR also provides a richer characterization of the data, allowing to consider the impact of a covariate on the entire distribution of y, not merely its conditional mean.

Figure 1 summarizes key aspects of our sample data on land productivity and farm size into a single form. On the horizontal axis farm size classes are reported by increasing size, while the vertical axis measures average land productivity. The top of the rectangular box shaded in the figure marks the 75th percentile of the data range, while the bottom "hinge" marks the lower 25th percentile. The "whiskers" extend another 1.5 times the interquartile range of the nearest quartile. The horizontal line in the middle of the box marks the median of the data for each group. Intuitively, the range of the box delineates observations that are typical. The whiskers contain values that are somewhat atypical relative to most observations, while the dots mark observations that are extreme, with a large number of suspiciously small values with a tendency of dispersion even if we are in the log scale of crop income.

The diagram appears to show a clear tendency for productivity to decline with increase in farm size. This effect is accentuated if we consider the upper and lower tails of the productivity distribution. This crude correlation, however, may be misleading for two reasons: first, it does not consider the effects of the other covariates that are expected to influence farm productivity; second, in the same diagram, dispersion appears to be decreasing with farm size, with a much wider range of values for the smallest size. By characterizing the entire distribution of crop income for each farm class, even for the simple correlation, the plot thus suggests that the relationship between productivity and farm size may not be the same for different levels of productivity, and that group means or medians do not necessarily represent group behavior .

Figure - Log gross crop income (land productivity) by percentiles of land operated



5. Data and Descriptive Statistics

We use data from LSMS-ISA surveys in Malawi, Niger, Nigeria, Tanzania and Uganda, all collected in 2010-2011. These are large multi-purpose household surveys, national representative, with detailed information on agricultural production. Table 1 reports some descriptive statistics from the surveys, showing mean values of broadly comparable magnitude across countries, except for Nigeria, which appears to have a much smaller average operated area and larger yield and labor intensity than the other countries.

Descriptive statistics for the surveys in our sample provide a number of insights pointing in particular to a wide distribution of land ownership, but similar level of crop intensity, difference in rural population density and market access, large productivity gaps across producers, sizable variation in infrastructure, and agro-ecological conditions.

In terms of area operated by farmers (defined by area owned, plus area rented in, and net of area rented out and under fallow), we note that the average across the five countries is 2.1 ha, with the lowest in Malawi (0.73 ha), and the highest in Niger (5.21 ha). With 267 and 218 person per sq. km, Uganda and Nigeria are, respectively, the two countries with the highest rural population density. Somewhat surprisingly, Uganda, with an average rural population density four times the level in Tanzania, has an average operated area quite close to Tanzania's 2.3 ha. While a larger farm size could be expected to compensate for lower population density, labor constraints prevent farmers to make the necessary investment (mechanization, tractor plowing or anima draft), to increase farm endowment. In terms of agriculture intensification, we observe that the majority of the countries have reached a stage of permanent agriculture, as the crop intensity (defined as gross cropped area divided to net cropped area) is larger than one.

The geo-referenced structure of the LSMS-ISA datasets allow us to link geo-variables matched by staff at the World Bank to the external datasets of the *FAO's Harmonized World Soil Database v.1.2* (soil nutrient availability) and use soil quality controls in our regressions. The soil database is the result of a collaboration between the FAO with *IIASA, ISRIC-World Soil* Information, Institute of Soil Science, Chinese *Academy of Sciences* (ISSCAS), and the *Joint Research Centre of the European Commission* (JRC)[1].

[1] The Harmonized World Soil Database is a 30 arc-second roster database with over 15 000 different soil mapping units that combines existing regional and national updates of soil information worldwide (SOTER, ESD, Soil Map of China, WISE) with the information contained within the 1:5 000 000 scale FAO-UNESCO Soil Map of the World (FAO, 1971-1981). The resulting database consists of 21600 rows and 43200 columns, which are linked to harmonized soil property data and display the composition in terms of soil units and the characterization of selected soil parameters (organic Carbon, pH, water storage capacity, soil depth, cation exchange capacity of the soil and the clay fraction, total exchangeable nutrients, lime and gypsum contents, sodium exchange percentage, salinity, textural class and granulometry). http://www.fao.org/fileadmin/user_upload/soils/docs/HWSD/Soil_Quality_data/Rooting_conditions.jpg

Among all the variables tested, two variables are mostly significant in the regressions to indicate lack of soil quality. They are: (i) a dummy constraint oxygen availability equal to 1 if the categorical variable "Oxygen availability to roots" is equal to severe and very severe constraints and zero otherwise; (ii) a dummy "Constraint excess salt", equal to 1 if the categorical variable Excess salts is equal to severe and very severe constraints and zero otherwise.

We use urban gravity and distance to the nearest market or the major road as proxy for urbanization and access to infrastructure respectively. To compute urban gravity we use light intensity data produced by the defense Meteorological Satellite Program (DMSP) of the National Geophysical Data Center, and we convert them into urban gravity using the same approach of Binswanger and Savastano (2015). The proxies for market access are taken from the geospatial dataset of the LSMS-ISA surveys, which include average households' distance to the nearest market and major road[2]. We note large disparities in terms of market access, with an average household distance to reach the nearest market of 35 km for the five countries, with a minimum of 8 km in Malawi to a maximum of 86 km in Tanzania. Also, as a proxy for urbanization, we note that urban gravity is the largest in Malawi and Nigeria and the lowest in Niger and Tanzania.

Table 1 - Descriptive Statistics (Averages)

ISO	MWI	NER	NGA	TZA	UGA	Total
Gross crop income per ha (US$/ha)	507.57	265.2	2229.82	478.52	468.2	733.58
Land operated (owned+ rented in-rented out-fallow) (ha)	0.73	5.21	0.8	2.33	1.45	2.10
Rural population density (pers./sq. km) (2005)	182.5	60.4	218.3	59.9	266.9	157.6
Gross cropped area (ha)	0.74	5.8	1.6	2.03	2.4	2.514
Net crop area (ha)	0.67	4.9	1.3	1.95	1.0	1.964
Crop intensity	1.02	1.19	1.23	1.07	1.89	1.28
Annual Precipitation (mm)	1085.54	375.94	1369.17	1089.87	1225.23	1064.8
Annual Mean Temperature (°C * 10)	218.28	282.03	263.59	227	218.82	233.61
UG: travel time negative exponential, with borders restriction to cities with 500K	142.49	41.36	113.23	49.96	53.59	105.23
HH Distance in (KMs) to Nearest Market	7.96	62.72	71.33	82.67	31.21	35.85
HH Distance in (KMs) to Nearest Major Road	9.69	12.92	17.21	21.73	7.31	12.41
Dummy constraints to oxygen availability to roots[1]	0.1	0.15	0.17	0.12	0.28	0.14
Dummy Excess salts[1]	0.04	0.09	0.03	0.06	0.04	0.05
Pastoral farming system[2]	0	0.49	0.03	0	0.01	0.06

Source: Authors' computation from LSMS-ISA household surveys. [1] Dummy for oxygen availability and excess salt have been computed from the continuous geospatial variable of the LSMS-ISA. A dummy is equal to 1 for higher constraint to soil fertility. Both raw data are derived from the FAO's Harmonized World Soil Database v.1.2 (soil nutrient availability): The dummy for pastoral farming system is drawn from the Harvestchoice dataset, and follow the classification of the farming Systems in sub-Saharan Africa according to FAO's methodology and based on Dixon, J. and A. Gulliver with David Gibbon, Principal [3]Editor Malcolm Hall. Improving Farmers' Livelihoods in a Changing World. FAO/World Bank. 2001

Using both OLS and Quantile regression we estimate the following function at the household level:

$$\ln \frac{Y_i}{v_i} = b_0 + b_1 \ln x_i + b_2 \ln Z_i + u_i$$

where $\frac{Y_i}{v_i}$ represents an indicator of farm productivity (gross crop income per ha , in which case $x_i = v_i$, or total labor productivity) for each household i, x_i is the total area operated, Z_i denotes a vector of exogenous geo referenced households characteristics such as variance of precipitation and temperature, urban gravity, distance to the major road or market, soil quality controls and u_i is an error term.

Table 2 presents the main results from the estimation for the pooled sample. The OLS estimates show a significant negative elasticity for the relationship between gross income per ha and land operated, with a value not significantly different of one and no significant quadratic response. The first (10%) quantile regression estimates, however, "deconstruct" this result as corresponding to the combination of a positive, more than proportional, linear response and a negative, smaller than unity quadratic response. For the other three quantiles considered (the 25^{th}, the 50^{th}, and the 80^{th}), a similar, but reversed sequence, of a negative linear and positive quadratic response is estimated. Moreover, both the quadratic and the linear coefficients increase across the quantiles.

[2] The source for the variable distance to the main road is OpenStreetMap-Tranroad, while the source for the distance to the nearest market is USAID – FEWSNET.

[3] The quantiles represent intervals of the probability distribution of land productivity

The IR hypothesis, therefore, appears to be rejected for all but the very first quantile, where, however, it is reversed after a threshold of operating size is reached. Vice versa, for the other three quantiles, productivity tends to decrease with the cultivated area, according to the IR hypothesis, but also this relationship is reversed, and the threshold of reversal is larger and larger as we move from the 25^{th} to the 80^{th} quantile.

In this regression, the elasticity of productivity with respect to the urban gravity index is low and essentially the same (between 0.01 and 0.03) for all quantiles, except the 20th for which it is not significant. The estimates of the weather impact are somewhat surprising with a large negative effect of the variance of temperature and a smaller positive effect of rainfall variability with both effects tending to vanish for the top quantiles. The elasticities with respect to the distance from the market and the main road are variable and larger. They follow a quadratic relation with a positive linear (in the logs) and a negative quadratic coefficient. The presence of pastoral farming systems appear to impact negatively on average land productivity, only for the lower half of the quantiles, while appears to have no effect in the quantiles in the top 50%. In sum, the results show that performance classes differ significantly in their response to key exogenous variables and that this response from productivity to infrastructure (UG, road and market distance), tends to be nonmonotonic.

Estimates on individual countries confirm the results (see Tables 3-7), which are summarized in Table 8 . They suggest distribution dependency of both the form and the intensity of the productivity response to the increases in operating area. We find that productivity effects of acreage increases are different at different levels of productivity and are highest, but with opposite signs, at the extreme ends of the distribution of yield residuals, with very similar patterns of decline, for the linear terms, and increase for the quadratic ones over the distribution (see Figure 1, 2 and 3). This may be due to various causes, such as, for example, that unobserved farmer ability acts as a complement for land increases at low level of yield residuals and as a substitute at higher yield residuals. More generally, it could be because the endowments of critical, unaccounted, components of human and non-human capital are correlated with productivity increases.

Tables 9 and 10 and Figures 2-6 show that the disparities in the coefficients estimated for the individual countries correspond to much smaller differences in the ranges over which the IR relationship holds for low performers and to huge differences for medium and high performers. These differences, on the other hand, appear to depend also on the other control variables. In the case of soil quality, for example, they are especially effective in the case of the lower performers of Malawi and throughout the quantiles in Uganda[4]. In general, however, for the lower performant farms of the first two quantiles, IR appears to take over at about the same level of operating area for values not significantly different of each other and from the pooled sample estimates. This means that land productivity for low performers tends to increase with operating area up to about a level of 2-5 has and then to decline according with the IR traditional evidence. For the highest performers (farms in the top three deciles of the productivity distribution), the results are the opposite, with productivity declining up to an operating size level of 5 to 80 has and above, after which increasing returns to scale appears to settle. The much wider range of the switching levels of operating area appears to depend on the range of the operating size variable that is much larger than the average for Niger and Tanzania.

The U shaped pattern at the lower tail of the productivity distribution suggests that a larger operating size may be a positive factor for low performers, but only up to a point after which the other causes of the IR relation become prevalent (i.e. only if farm size does not become "too large"). For the upper deciles, on the other hand, the IR relationship appears to hold over a much wider range, although in many cases appears to reverse itself for moderately large operating areas. As Tables 9 and 10 and Figures 4-6 show, the size of the operating area at which the IR relationship prevails for the first two deciles is small, although often above the average, depending on the country. For the upper tail of the distribution, on the other hand, the land size at which the IR relationship reverses itself is only moderately larger except for a few outlayers, so that most large farms essentially do not display any IR.

---

[4] Note that the soil quality variables represent negative qualities and their coefficients have generally the expected negative sign. However, because of the possible correlation with farm size, their signs could also be positive or zero, as the following shows. Consider in fact the model:

(1) $y = b_0 + b_1 x + b_2 z + u$

Where y is average land productivity (LP), x is operating size (OS) and z a soil quality (SQ) variable. The OLS estimates of the coefficients are:

(2) $b_1 = (s_{zz}s_{xy} - s_{xz}s_{zy})/(s_{xx}s_{zz} - s_{xz}^2)$

(3) $b_2 = (s_{xx}s_{zy} - s_{xz}s_{xy})/(s_{xx}s_{zz} - s_{xz}^2)$

(4) $b_0 = \bar{y}$

If both OS and SQ are positively correlated with LP, while OS and SQ are negatively correlated with each other (i.e. larger farms have poorer soils), b_1 and b_2 will be both positive. On the other hand, if SQ is positively correlated with LP and OS ($s_{zy} > 0$, $s_{xz} > 0$), then the signs of the two coefficients become ambiguous.

6. Conclusions

The inverse relationship (IR) between land productivity and land size has been the object of a voluminous literature , raising both objections and explanations. In this study, after a brief review of some of the main arguments, we have presented evidence from five recent farm surveys that in part rebut and in part confirm the existence of the relationship. The survey data used are from detailed household interviews and contain a number of accurate georeferenced information on farmers' location, distance from the markets, distance from the main road, and land quality. In order to test the IR hypothesis, we have used a specification entirely relying on exogenous variables and estimation procedures according to the quantile regression model.

The results of our analysis, show that for all countries, except Nigeria, and for the pooled sample, IR holds only for the top 6-7 quantiles of the productivity variable (the yield residual once we consider the effect of the exogenous variables), while for the bottom quantiles a positive relationship tends to hold. These results appear to hold across different specifications and both for the pooled sample and the individual countries. They suggest that at the two ends of the yield residual distribution, farmers' performance is influenced by land size in a markedly different way. As already noted, although in a different context by Evenson and Mwabu (1998), this may be due to the fact that individual management factors do matter and that in the two areas of the distribution, different complementary and substitute relations may exist between land sizes and unobserved human capital variables, such as farmers' abilities, skills and experience. In turn, these results are consistent with a revised version of Savastano and Scandizzo (2009) option model, where management quality is supposed to be positively correlated with farm size.

Our results also suggest the existence of a U shaped relationship between productivity and farm size. This relationship implies a turning point for the lower quantiles of the yield residual distribution at which a positive relationship becomes negative and one for the upper quantiles where IR becomes positive. Both turning points are for small to medium farm sizes, but the ones of the lower quantiles tend to be smaller than those for the upper quantiles. Thus, while there is some significant negative relationship between productivity and operating size for low performers over a relevant range of farm sizes, higher performers tend to display IR only over a range from small to medium farm sizes.

In sum, our results confirm that IR may be an ubiquitous relationship, as found in much of the literature, but indicate that its form, shape and importance may significantly differ across the spectrum of farm productivity performance. At the low end of the yield distribution, IR appears to prevail, once a minimum threshold of farm size is reached, while at the higher hand, IR only appears to be mainly a characteristic of farmers with operating sizes not exceeding medium size thresholds. The literature on transaction costs and the role of the firm suggests that these differences will require a deeper analysis of some of the critical factors determining the performance of the farm as a "productivity agent" and of the role played by management and capabilities in shaping farmers' choices.

STATISTICS ON WATER RESOURCES AND WATER USE EFFICIENCY

Session Organizer
B. Rater | USDA National Agricultural Statistics Service | Washington, DC | USA

ABSTRACT

Today's water-related challenges depend on timely, detailed water data and information. Quantifying water applied to agricultural areas for irrigation and for watering livestock by use and source is a long-standing challenge. Raising information-gathering capacity and improving data quality on agricultural water management will contribute to improving water-related policy making affecting cost, water quality, profitability and environmental effects. This session will present practical approaches or techniques to surveys that contribute to improvements in water statistics. It will provide examples of how technological advances can be used to facilitate the job of survey data producers and enhance the experience of data users.

Livestock water accessibility index and its linkage to household welfare

S. Ligane Massamba | IFPRI | Dakar | Senegal

DOI: 10.1481/icasVII.2016.d24

ABSTRACT

In this paper, we introduce the concept of Water Index for Livestock. In fact, water accessibility for livestock is as much important as drinking water accessibility in countries like Niger, where land is unsuitable for crop production, and where 29% of thepopulation relies on animal breeding activities. Although some works have looked at the issue of human access to drinking water, less attention has been paid to the issue of water accessibility for animals. There is a need to explore the latter as water requirements for human being are not the same than for livestock by far, especially in terms of quantity and water supply provision. Better access to water for animals is likely to improve the welfare of population especially in rural area because improving animal performance in farming and milk production. This paper provides an assessment tool of the water accessibility for livestock in Niger and investigates the relationship between livestock accessibility to water and agricultural productivity, poverty, and ultimately food security. Our multidimensional index includes manywater related dimensions and is a mean to evaluate livestock and crop security which in turn might have an impact on agricultural households.

We used available agricultural survey data in Niger and define a multidimensional index integrating all the relevant dimension through an objective weighting scheme by applying a general covariance structure model which includes a Confirmatory Factor Analysis, and therefore deals with measurement issues.

The results show heterogeneity in livestock accessibility to water across the country and indicate significant and positive relationships between this accessibility index and household welfare indicators.

Keywords: Water, Multidimensional index, Livestock, Natural resource, Welfare, Niger

PAPER

1. Introduction

In a country where a large share of the population, especially the poor, depends on livestock, it makes sense to link livestock conditions to household livelihood conditions. In the context of aridity and climate change, water needs of domestic animals become harder to satisfy. This will not be without consequences for households.This paper aims to investigate the linkages between animal water access and household welfare, proxied through inverse poverty perception measure. We will develop a suitable framework for the assessment of livestock water accessibility and household welfare nexus. Due to the multidimensionality of the concept of water accessibility, we use appropriate approach to include all the relevant dimensions and take into account measurement dimensions. As for the human water accessibility index, water accessibility for animal is difficult to measure because of the huge number of aspects that might enter into account. From the study we can learn how water access can be linked to household welfare. The water index is a composite index that integrates many dimensions related to the difficulty of cattle to find water.Similarly, we adopt the same multidimensionality concept to define the measure of welfare and food insecurity.

A predicted increase in demand for livestock products in developing countries might generate new market opportunities and boost income for poor households(Delgado et al. 1999). In parallel to this projected demand side effect, improving animal water availability can contribute to raise animal productivity, livestock production, and ultimately household welfare.

Animal water accessibility need be analyzed due to this water requirement resulting from the future demand and from the high contribution of livestock in the livelihood of individuals, especially the poor and those living in rural areas.

2. Method and data

The study is based on the 2011 National survey on household life conditions and agriculture in Niger. This survey covers around 4000 households. The data collection was done in two steps with a first round during the cultivation and the preparation of cultivation areas from mid-July to mid-September 2011, and the second round during the harvesting period in November and December 2011. The survey was based on three questionnaires: the household questionnaire that collected information on socioeconomic characteristics of households, the agricultural questionnaire to get data on farming activities, and the community questionnaire that provided information on the available infrastructures at district level.

Our methodology is described below.

$$WA_S = \gamma\, WA + \varepsilon$$

$$F_S = \delta\, F + \upsilon$$

$$W_S = \rho\, W + \omega$$

$$W = \varphi\,(WA, F, X) + \mu$$

$$F = \psi(H) + \varsigma$$

Where *WA* represents the multidimensional and latent Livestock Water Accessibility index, WA_S the observed water accessibility indicators. Wis the household welfare variable, measured as a latent variable derived by using household own perception of poverty W_S. *F* is latent variable measuring the food insecurity prevailing at the household level.X and F represent household socioeconomic and environmental characteristics. Household welfare depends on their food security level, their health stock as well as on their livestock water accessibility status. The parameters y,*∂* and *p* are the loading factors that link the latent variable to the observed variables.

3. Results and discussions

The results are presented in the table below.A complete description of the variables is provided in the appendix. The lower part presents the estimates of the measurement model for all the latent variables. All the manifest variables are positively correlated with the associated latent variables. The upper partpresents the structural model. It shows the determinants of householdwelfare and includes the specific relationship between the animal water accessibility index and the welfare variable. The results show that animal water accessibilityimpacts positively and significantly household welfare.Animal water accessibility is essential for livestock production and might impact household welfare through improving livestock productivity, provision of goods and service, and income diversification.
We found that household welfare perception household is positively correlated to food insecurity. The latter is not affected by animal water accessibility at the household level. Household headed by women tend to have the worst appreciation of their welfare and tend to be more food insecure. Household with more elders have a lower welfare level.
Promoting development programs that increase directly or indirectly animal water accessibility can be make important contribution to poverty reduction given the enormous potential of livestock to contribute to livestock.

4 Conclusion

Using household level data from Niger, the analysis show a positive effect of livestock water accessibility on household welfare but not food security. In fact, animals are not self-consumed in general, even in case of severe threat of food insecurity. Animal water accessibility might improve animal health and therefore their labor productivity or increase available animal products. These often sold at the local market place to ensure substantial revenue for household.

Measuring Water-use in Response to Climate Change: An Analysis of the Efficiency of Italian Crop Production System

S. Auci | Università degli Studi di Palermo | Palermo | Italy

DOI: 10.1481/icasVII.2016.d24b

ABSTRACT

Official meteo-climatic statistics show the variability of weather conditions. Their effects on socio-economic and natural environments should be analyzed in multi-dimensional studies. Among sectors, agriculture is expected to be the most sensitive as well as water resources availability. The aim of our analysis is to measure the performance of Italian regions in crop production by estimating both production technology - including a measure of irrigation water used as input - output elasticities and returns to scale and productive efficiency or technical efficiency where rainfalls and temperatures are proxies of CC conditions in the period 2000-2010 at Italian regional level, using the stochastic frontier approach (SFA). The scarce official statistics on irrigation water in agriculture make our analysis challenging. Our results point out the need i) to strengthen official statistics on irrigation water to improve the analysis on inputs of farmer's crop production in Italy; ii) to update meteo-climatic and hydrological measures according to the official international guidelines.

Keywords: Climate Change, Crop Harvested, Irrigation Water, Stochastic Frontier Efficiency.

PAPER

1. Introduction

As climate is an essential component of the natural ecosystem, the exasperation of weather conditions can have some effects on socio-economic and natural environments. Several sectors can be affected by climate change (CC) and climate variability but water resources and agriculture are expected to be the most sensitive. Both the IPCC (2014) and the OECD (2014) confirm that the increase of greenhouse gases (GHGs) will cause positive changes modifying the speed of crop growth and negative changes in temperatures and rainfalls. Hence, CC will alter the water cycle, changing temporal and spatial redistribution of water resources, such as the frequency of occurrence of droughts and floods, which are expected increasing in many areas. These changes in rainfall and temperature patterns may affect crop water requirements and more generally crop production system since water is the most critical input for sustainable agricultural development – as irrigated areas will increase in forthcoming years. CC can affect the amount of water available (supply-side) and of crop water requirements (demand-side) due to changes in rainfall patterns. Whether understanding of how CC can influence local water availability is widely analyzed, CC effects on crop production function considering water resources used for irrigation as an input are not well deepened. The majority of studies has focused on climate projections investigating the impacts of CC on global agricultural water requirements (Döll, 2002; Zhang and Cai, 2013); on water resources and water availability for Africa (Kusangaya et al. 2014) for China (Tao et al., 2003); on groundwater recharge rates (Döll et al., 2002; Taylor et al., 2012). A brief review of studies mainly based on the Ricardian method to evaluate the impact of CC on rural areas is described in Dasgupta et al. (2014). Other studies have investigated the economic effects of CC on agricultural sector (Giupponi and Shechter, 2003) based on long-term analyses at the aggregate level, i.e. continental or national scales (Xiong et al., 2010). In contrast, few studies have performed short-term analyses at a sub-regional level. In the case of agriculture, models based on discrete stochastic programming model have been used to forecast the effects of changes in water availability on agriculture due to CC (Dono and Mazzapicchio, 2010). A three-stage discrete stochastic programming model has been used to represent the choice process of the farmer based on the expectation of possible scenarios of rainfalls and higher minimum temperatures for a specific irrigated area of Italy in the next future.

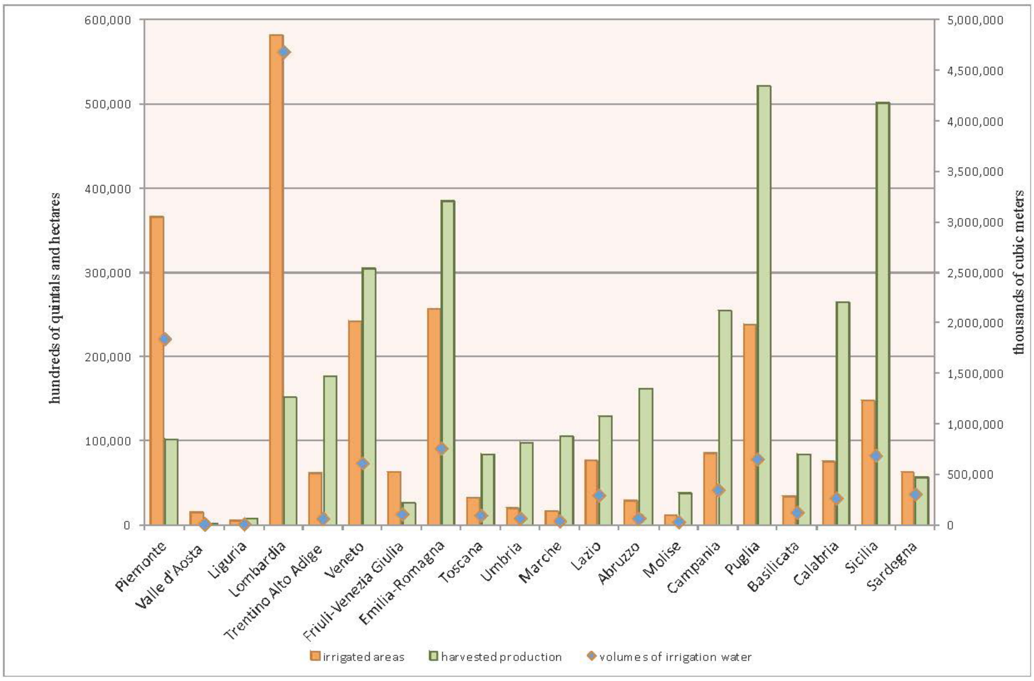
These variables affect the availability of water for agriculture and the water requirements of irrigated crops (Dono et al., 2011). Our study is a critical contribution within the literature on the impacts of CC on agriculture. The chosen model considers a crop production function for Italy where water resources are considered as inputs. By using an empirical analysis such as the Stochastic Frontier Approach (SFA), the technical efficiency of crop production and the inputs' efficiency have been estimated at local scale while meteo-climatic statistics show that CC has been taking place in these last decades. The inadequate official statistics on water resources for irrigation in agriculture make our analysis challenging. Comparability issues and data-lacking both at spatial and temporal scale forces us: i) to consider only the period 2000 2010; ii) to construct an ad hoc variable to measure the volume of irrigation water to complete our panel data and iii) to provide estimates at regional level instead of at farmer's level. By applying the SFA methodology, we can as well estimate efficiency at regional scale in the Italian crop production system. Empirical estimate results can be useful tools for policy makers in defining the optimal climate mitigation and adaptation policy actions in agriculture. In addition, our results recommend the urgency of increasing collection of data and official statistics production at local level on irrigation water volume and on meteo-climatic and hydrological measures, issued by Istat. Therefore, multidimension phenomenon datasets fitting for the purpose of CC effects could be improved by either integrating already existing datasets from different sources (such as administrative archives, official statistical surveys, trade associations, land reclamation authority) or developing ad hoc sections within existing surveys more respondent to the economic needs of measuring the efficiency of 3 farmers and their capability to adapt to CC. The paper is organized as follows. In Section 2 we briefly analyze data used for the crop production function in the SFA model. In section 3, we present our empirical model and the main results. Finally, we summarize the findings of our research.

2. Italian crop production and CC related data

Agricultural sector is one of the most susceptible as changes in meteorological conditions heavily affects crop production trends, yield variability and reduction of areas suitable to be cultivated, specifically in the Mediterranean countries. Many studies have evaluated the effects of CC on agriculture in Europe taking into account important regional differences (Reidsma, et al., 2007, Olesen and Bindi, 2002; Iglesias et al., 2009). CC is expected to intensify problems of water scarcity and irrigation requirements in all the Mediterranean regions and thus in Italy (IPCC, 2014; Goubanova and Li, 2006; and Rodriguez Diaz et al., 2007). The geographical position of Italy at the centre of the Mediterranean basin and its historical high agricultural vocation make Italy vulnerable to the negative consequences of CC. Italy is the second largest producer of "*fruit and vegetable*" in Europe after Spain offering a wide range of high quality and typical Mediterranean products, officially recognized as IGP and DOP. Weather conditions could lead to inefficiency in the agricultural sector, even because it includes many small firms with a lower capability to adapt to a new climatic situation. In the last twenty years, changes in weather conditions occurred in Italy and a rise of water used for irrigation especially in the South, traditionally suited to agriculture activities, have contributed to threaten crops and reduce areas suitable for cultivation.

To evaluate climate-related impacts on the agricultural sector across Italian regions, long run time series of data should be necessary. Forced by data availability, the focus of our analysis is mainly on the Italian regions' efficiency in the period 2000 to 2010, analyzing the short-term effects of CC on Italian agriculture. To estimate CC effects on the efficiency of agricultural yields at Italian regional level (NUTS2), a dataset of CC and agriculture sector at regional level has been collected by using official statistics, mainly produced by Istat. All variables are measured in physical units.

Figure 1. - Volumes of irrigation water, irrigated areas, harvested production Italian Regions, Year 2010 (thousands of m3, hectares, hundreds of quintals)



These statistics regard both inputs and output of the production function and inefficiency determinants as proxies of CC. A panel dataset has been collected on the following variables: i) agricultural harvested crops production and production areas (source Istat survey of Estimate of Crop, Flower and Plot Plant Production and Area); ii) irrigated areas, seeds and fertilizer used, days of work of farm employees (source Istat Survey on Agricultural Holding Structure and Output, V and VI Agricultural Census, Survey on seeds and Survey on fertilizer); finally iii) temperatures and rainfall (source Meteo-Climatic and Hydrological Istat Survey). To develop our analysis, two aspects have to be considered. Firstly, although meteo-climatic and hydrological official statistics have been produced until 2014, meteo-climatic time series have been updated only for Italian regional capitals. This reason forces us to base our analysis on 2000-2010 time series containing statistics suitably spatialized. Secondly, because of the lack of data on volumes of irrigation water used in agricultural crops, we constructed a proxy. In the SFA model, we should have included the variable "*volumes of irrigation water*" jointly with "*irrigated areas*" but official statistics on volumes of irrigation water used by crop in Italian agriculture was provided, once in 2010, in occasion of Istat VI Agricultural Census. Figure 1 compares *irrigated areas* and *total harvested production with volumes of irrigation water* and underlines the multifaceted situation for each Italian region. What is the most amazing consideration is that Lombardy uses about 42.26% of the total of irrigation water to obtain only 4.39% of the harvested production with respect to the total 4 production. While, in the opposite case, we find Emilia-Romagna and Puglia, where respectively they use only 6.84% and 5.90% of total volume of irrigation water to obtain a harvested production of 11.17% and 15.13% with respect to the total harvested crops. Quite certainly, this situation could be the consequence of meteo-climatic variability, different typologies of crops cultivated, irrigation technology used, and environmental conditions in each region.

Starting from the Census, we constructed *ad hoc coefficients* for 2010 by dividing volumes of irrigation water with respect to irrigated areas (K_{ij}=*irrig_waterij/irrig_areaij*) by each crop (i) and Italian region (j). To fill our dataset, we reconstructed the variable "*volumes of irrigation water*" for each year considered in our analysis, by multiplying the 2010 Kij coefficients for irrigated areas by crop and region.

3. Empirical model and main results

By applying the SFA proposed by Battese and Coelli (1995) to our sample, the performance of Italian regions in crop yields is evaluated by estimating production technology and productive efficiency. The production technology allows the study of production inputs (labour and physical capitals), output elasticities and returns to scale, while the productive efficiency, or technical efficiency, allows the analysis of getting the maximal output from available resources, given the level of inputs. This efficiency can be directly affected by observable exogenous variables such as CC conditions (rainfalls and temperatures), which reflect the heterogeneity of Italian regions in the agricultural sector. Two are the advantages of using the SFA methodology. Firstly, production inputs and efficiency factors are estimated simultaneously using two distinct functions. Secondly, distances from the efficient frontier between those due to systematic components and those due to noise are disentangled. The main idea is that the maximum output frontier for a given input set is assumed to be stochastic in order to capture exogenous shocks beyond the control of individuals.

The parametric estimation of the SFA is based on the standard Cobb-Douglas (CD) production function, whose practical advantage - with respect to more flexible forms such as the translog function - is the limited number of variables required. Expressing output and inputs in natural log values, the CD function can be written as:

$$(1)\qquad \begin{aligned} ln(Y)_{it} &= \beta_0 + \beta_1 ln(Kseed)_{it} + \beta_2 ln(Kfert)_{it} + \beta_3 ln(Kvol\_irr)_{it} + \beta_4 ln(Kirrig\_area)_{it} \\ &+ \beta_5 ln(Citrus\_area) + \beta_6 ln(Fruit\_area) + \beta_7 ln(Vegetable\_area) + \beta_8 ln(L)_i + v_{it} - u_{it} \end{aligned}$$

where Y is the agricultural yield measured by the ratio between harvested production (in kilos) and cultivated areas (in hectare), physical capitals are measured by Kseed which represents the amount of seeds used for the cultivations, *Kfert* which stands for the tons of fertilizers used in agriculture, Kvol_irr which is the irrigation water volumes, Kirrig_area which means the hectares of irrigated areas, Citrus_area which represents citrus plant cultivated areas (in hectare), Fruit_area which is fresh fruits cultivated areas (in hectare), Vegetable_area which means vegetables cultivated areas (in hectare), and L is labour force measured by the days of work in farms. While the technical inefficiency model is characterized by several observable explanatory variables as follows:

$$(2)\qquad \begin{aligned} u_{it} &= \gamma_0 + \gamma_1 Rainfall_{it} + \gamma_2 Temp\_min_{it} + \gamma_3 d\_North-west_{it} + \gamma_4 d\_North-east_{it} + \\ &+ \gamma_5 d\_Centre_{it} + \gamma_6 d\_South_{it} + \varepsilon_{it} \end{aligned}$$

where Rainfall is measured by the deviation of annual total rainfall average from the CLINO 1971-2000 rainfall average value and Temp_min is defined as the deviation of annual minimum temperature average from the CLINO 1971-2000 minimum temperature average value. The dummy macro-areas are as usual: North-west, North-east, Centre, South while Islands is missing due to collinearity.

The stochastic frontier estimation allows us to measure the value of productive efficiency of harvested production in each Italian region. The technical inefficiency of the i-th region in the t-th period is given by:

$$(3) \qquad TE_{it} = e^{(-u_{it})} = e^{(-z_{ti}\delta - \varepsilon_{ti})}$$

The technical inefficiency values will oscillate between 0 and 1, being the latter the most favourable case. If TEit<-1 then the observable output is less than the maximum feasible output, meaning that the statistical unit is not efficient.

In Table 1, we present both the CD stochastic production function estimated coefficients and the technical inefficiency equation estimated coefficients. The coefficients of the CD function can be interpreted as the partial output elasticities, which show the percentage change of output in response to one percent change in an input. Not all the estimated output elasticities are positive.

Physical capitals measured by fertilizers used (Kfert), seeds used (*Kseed*), and areas cultivated with citrus plant (*Citrus_area*) and with fresh fruit (*Fruit_area*) show positive and significant elasticities, indicating that these specific capital inputs are productive inputs for increasing agricultural annual yields (Tasnim et al., 2015). The estimated values of the coefficients of irrigated areas (*Kirrig_area*) and vegetable cultivated areas (*vegetable_area*) are negative and significant. There is no scope of increasing production by further increase of those inputs. The input labour force (L) shows a positive coefficient and significant in the annual Italian regional agricultural yields differently from Tasnim et al. (2015). The elasticity of irrigation water volume (*Kvol_irr*) is positive and significant showing that an increase in the demand of water for irrigation has positive effects on agricultural yields. Moreover, since output elasticities for irrigation water volumes and for irrigated areas show the greatest values, the empirical findings confirm that water for irrigation remain the most important factor in the crop production function. The returns to scale (RTS), calculated as the sum of the output elasticities, measure the percentage change of output due to a one percent increase in all inputs. The RTS coefficient is smaller than unity, meaning that the Italian regional crop production presents decreasing returns to scale. Considering the inefficiency model, rainfall variable shows a negative and significance sign, while minimum temperature variable coefficient is positive but not significant.

note: *** p<0.01, ** p<0.05, * p<0.1.

The more is the deviation of the annual total rainfall average from the 1971-2000 rainfall average value the more efficient is the crop yields for Italian regions. Therefore, Italian regions in term of agricultural yields become more inefficient when the annual rainfall value diminishes with respect to the 1971-2000 rainfall average value. This is in line with the IPCC (2014) analysis where in the Mediterranean area the annual rainfall average will tend to decrease in the next future.

Instead, the more is the deviation of the annual minimum temperature average from the 1971-2000 minimum temperature average value the more is the inefficiency of Italian regions in crop yields, even if this effect is not statistically relevant. Italian regions' agricultural crop yields decrease due to more inefficiency caused by an increase of annual minimum temperature. This negative effect, foreseen and analysed even by the IPCC (2014), implies that an increase in temperature will influence negatively crop yields in the Mediterranean basin. The negative signs of the estimated coefficients of geographical dummies indicate a positive effect on efficiency, meaning that regions belonging to one of those macro-areas – South, Centre, North-east and North-west of Italy – with respect to Islands are more efficient. The summary statistics of estimated technical efficiency (TE) scores are even reported in Table 1. The TE scores show a low mean value meaning that Italian regions in mean are quite distant from the efficient frontier.

In Table 2, by splitting our sample on Italian macro-areas, the analysis of variance (ANOVA) is proposed in order to test for differences in the means of technical inefficiency. Results confirm that differences in the Italian macro-area means of technical inefficiency are significant. Thus, regions belonging to North-east like Trentino-Alto Adige, Friuli-Venezia-Giulia and Veneto are the more efficient where the mean is 0.98. On the opposite case, Sardinia and Sicily, belonging to Islands macro-area, are the worst efficiency regions in terms of agricultural yields and they are the weaker regions in case of changing weather conditions.

Table 2. – Anova of TE by Italian macro-areas

Region Code	mean
North-east	0.98
South	0.42
Centre	0.37
North west	0.34
Islands	0.07
F	488.51
Prob > F	0.00

4. Conclusions

In the 2001-2014 period, Italy recorded a special "warming" because the annual mean temperature (equal to 15.1°C) has increased of about 1°C with respect to CLINO 1971-2000 temperature. In the same period, Italy recorded a change in rainfall pattern, because the total annual mean precipitation has been equal to 740.8mm, a reduction of about 1.1% with respect to the same CLINO period. Such weather changes has had a negative influence on agriculture production that is the most susceptible sector to changing weather conditions and have contributed to rise volumes of water used for irrigation, especially in the South. In our empirical and short-term effects of CC analysis, economic impacts of CC on Italian regional agricultural production and technical efficiency have been analyzed for the period 2000-2010. Among inputs, irrigation water volume, the most important factor in the crop production function, shows a positive and significant elasticity. Therefore, an increase in the demand of water for irrigation has certainly positive effects on agricultural crop yields. Moreover, the inefficiency model shows that when rainfall declines and annual minimum temperature increases, Italian regions become more inefficient. Results confirm that differences in the Italian macro-area means of technical inefficiency are significant. Regions belonging to North-east are the more efficient while Sardinia and Sicily, belonging to Islands macro-area, are the worst efficient regions in terms of agricultural yields. They could be the weaker and more vulnerable regions in facing changes in meteo-climatic and hydrological conditions. As CC affects many dimensions, official statistics on different thematic issues need to be integrated and harmonized to provide a solid basis for empirical analyses on CC impacts on agriculture. Strengthening the production of official statistics at adequate temporal and spatial scale on irrigation water to ameliorate the analysis on water resources required by farmers is needed.

Updating meteo-climatic and hydrological variables according to the latest official international guidelines to develop long-run CC analyses. Aiming the target to develop CC Related Statistics (CCRS) and new indicators following the 2014 UN Conference of European Statisticians Recommendations[1] is a necessity coming from international institutions. Therefore, multidimension phenomenon datasets fitting for the purpose of CC effects could be improved by either integrating already existing datasets from different sources, such as administrative archives, official statistical surveys, trade associations, land reclamation authority, or developing ad hoc sections within existing survey questionnaires more respondent to the economic needs of measuring the efficiency of farmers and their capability to adapt to CC. In a context characterized by uncertainty inherent in climate variability, the role of policy is crucial in managing water resources across space and time to prevent agricultural yield fluctuations causing welfare loss.

Outliers identification and handling: an advanced econometric approach for practical data applications

G. Palmegiani | LUISS University of Rome | Rome | Italy

DOI: 10.1481/icasVII.2016.d24c

ABSTRACT

Before implementing any statistical analysis it is crucial to check whether outliers are present in the dataset because their existence imply a distorted analysis that leads to unreliable results and incorrect policy decisions. To overcome that, this paper proposes and advanced econometric approach based on a linear regression framework that is capable of identifying and handling vertical outliers under three alternative scenarios. This methodology, that can be generalized to any other dataset, is applied to a real irrigation dataset on 15 countries sorted out in two groups in order to compute reliable summary statistics on unit irrigation costs that help governments, international organizations and water management in implementing cost efficient water investment decisions as well as knowing how much to pay on average, at maximum, and at minimum, for a given irrigation investment project type located in a given country. Once vertical outliers are handled, two main conclusions are found. First, unit irrigation costs tend on average to be lower for Middle-East countries rather than Afro-Arab countries. Second, is not shown that large scale irrigation investment projects are on average more expansive than small scale irrigation investment projects since it depends on both the country and scenario chosen. Although, the first result is in line with the reality that gives to Afro-Arab countries higher average unit irrigation costs, the second result confirmed at pooled and country level has not been sufficiently addressed by the literature and opens to new different water policy recommendations.

Keywords: Outliers, Unit Irrigation Costs, Method of Moments (MM) Estimator

PAPER

1. Introduction

Outliers are atypical observations, present in virtually every dataset, that can strongly distort any statistical analysis producing unreliable results that lead to incorrect policy decisions. This is especially true, as the pioneer Edgeworth (1887) work has shown, when Ordinary Least Squares (OLS) estimator is used as a tool for outliers identification. This happens for two main reasons. First, being this estimator an equal weighted sum of dependent variable observations, it treats with an equal weight observations that are potential outliers from observations that are not potential outliers while discrimination should be needed instead. Second, being also the OLS estimator based on a minimization of squared residuals that means practically minimizing their variance, when outliers are present the variance of the residuals increases considerably and the OLS estimator is largely influenced as well. It implies distorted estimates as well, unreliable results and incorrect policy decisions. These reasons imply that the OLS estimator does not represent a good tool, in reality is the worst, to identify outliers unless a prior different estimator or analysis concludes that these atypical observations are not present. In fact, something which is not typical cannot be identified using an estimation tool that is typical and constructed under a series of regularity conditions. Then, as pointed out by Huber (1964), Rousseeuw and Yohai (1987), Yohai (1987), Maronna (2006) an other outlier identifying tool is needed.

Furthermore, outliers are mainly of four types according their influence on the OLS estimator. Vertical outliers are those observations that are outlying respect to the space spanned by the dependent variable but not outlying in the space spanned by the regressors. Horizontal outliers are those observations that are outlying respect to the space spanned by the regressors but not outlying in the space spanned by the dependent variable. Good leverage points are observations that are outlying in the space spanned by the regressors but that are located close to the regression line. Bad leverage points are observations that are both outlying in the space of explanatory variables and located far from the true regression line. As mentioned, these types of outliers influence OLS estimates in different ways. Vertical outliers affects OLS estimates and in particular they affects the estimated regression intercept. Horizontal outliers affects OLS estimates and especially they affects the slope coefficients of the regression. Good leverage points does not affect the OLS estimates because they are points located closely to the regression line but it affects statistical inference since they do inflate the estimated standard errors. Bad leverage points affects significantly the OLS estimates of both the intercept and slopes coefficients.

In addition, outliers do not come alone especially in survey data but are almost always accompanied by missing values, large number of variables, sampling weights and measurement errors. Handling each of these data features requires further analysis and study.

This paper outperforms all these challenges proposing an advanced econometric approach for outliers identification based on regression framework estimated using Method of Moments (MM) rather than OLS in a three scenarios context. This methodology, that can be generalized to any other dataset, is applied to a real irrigation dataset in order to compute reliable unit irrigation costs that can help governments and international organization in formulating specific territorial policy recommendation and advices, to enhance the water population conditions as well as suggesting the right price per hectare that an international investor should efficiently pay for an given irrigation investment project in a given region or country.

The rest of the paper is organized as follows. The next section presents the dataset used as well as some basic variables' assumptions, Section (3) describes the methodology used to identify and handling outliers, Section (4) applies the methodology described before computing reliable summary statistics on unit irrigation costs at pooled, region and country level as well as by irrigation type level in a three scenarios context, Section (5) concludes summing up the main paper findings and finally Section (6) gives possible further extensions.

2. The dataset

The dataset is collected by aggregating specific country irrigation portfolios spreadsheets. The aggregated dataset consists of two main variables:

• Total = is the total irrigation investment cost (expressed in unit of United States Dollars (USD));

• Hectares = is the surface (expressed in hectares) covered by each irrigation investment project.

Regarding the total cost variable, since each investment project can be devoted to more than one types of irrigation project, indeed, large scale (LS) projects, small scale (SS) projects and rehabilitation and modernization (RM) projects, it has been calculated exactly the proportion of the total cost devoted to each type or irrigation project. It has been assumed the total cost variable is free from measurement errors. Regarding the hectare variable, it is known just the entire irrigation investment surface while the surface devoted to specific type of irrigation projects remains unknown. Further, it has been assumed both that the hectare variable is properly measured and free from outliers. It implies that, just vertical outliers are present in the real dataset and just statistics to identify vertical outliers are needed. Finally, the total number of countries involved are 15 sorted out in Middle-East countries and Afro-Arab countries while the total number of irrigation investment projects here considered are 225.

Given these assumptions about variables, the main question of interest is how calculate reliable summary statistics on unit irrigation costs at pooled, region and country level and by type of irrigation project. Because having reliable unit irrigation costs it is crucial to implement correct water and agriculture policies at these territorial levels and for these investments types.

3. The cost analysis: the methodology used

Given the variables' assumptions, the summary statistics on unit irrigation costs have been worked out after identifying outliers respect to the cost variable. Once vertical outliers has been identified, the mean, the standard deviation, the maximum value and the minimum value of unit irrigation costs are computed at pooled, region and country level and by type or irrigation project in a three scenarios context.

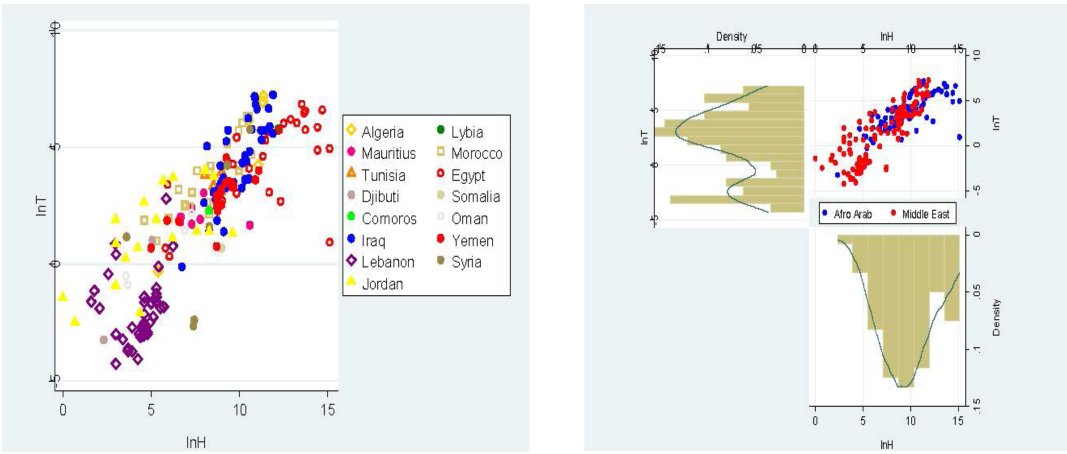
As mentioned, the outliers identification has been carried out using a linear regression of the log of total cost on the log of hectares covered and on the log of squared hectares estimated by MM rather than OLS. Then, the functional regression form used to identify outliers is:

$$ln\left(TC_{i,h,k}\right) = b_0 + b_1\ ln\left(H_{i,h,k}\right) + b_2\left[ln\left(H_{i,h,k}\right)\right]^2 + \varepsilon_{i,h,k} \quad forall \quad i = \{1,2,3,\ldots,225\}, \quad h = \{LS,SS,RM,ALL\}, \quad k = \{pooled, region, country\} \qquad (1)$$

where, $\ln(TC_{i,h,k})$ denotes the log of total irrigation investment cost for observation *i*, irrigation type *h* and territorial aggregation *k*, $\ln(H_{i,h,k})$ denotes the log of hectares covered by the irrigation investment project for observation *i*, irrigation investment type *h* and territorial aggregation *k*, $[\ln(H_{i,h,k})]^2$ denotes the squared of logs along the hectares covered by the irrigation investment for observation i, irrigation investment type h and territorial aggregation k, $E_{i,h,k}$ denotes the regression error term for observation *i*, irrigation investment type *h* and territorial aggregation *k* and finally b_0 is a constant term while b_1 and b_2 are the elasticities.

This is a log-log functional regression form with a quadratic regressor term. This functional form has been tested severally and confirmed to be optimal for the starting dataset at left of Figure (1) at different territorial levels for the following reasons. Regarding the log-log form, first, when logs of both dependent and independent variable are taken the distributions of variables are more near to a normal distribution as shown at right of Figure (1) and it is coherent with classic regression assumptions. Second, when logs are taken the R-adjusted increases considerably and it is usually desirable when a statistician have to choose between levels and logs. Third, the Box-Cox test rejects both the functional form in levels and the function form log-lin, then it is confirmed further on that both levels and log-lin forms are not appropriated. While regarding the inclusion of the quadratic term, this choice has been motivated by the necessity to capture no-constant elasticity between total costs and the hectares covered that allows increasing or decreasing marginal costs effects. Further, this term has been included only when, inside the regression estimated MM, it is significant according to the t-test. Furthermore, when it is t-significant this term is also capable of improving R-adjusted considerably.

Figure 1: *The starting log-transformed dataset [at left] and log-variables distributions [at right] for all countries (this figure, at left, points out the starting dataset variables by scattering the log of total irrigation cost versus the log of hectares covered by country, while at right, it shows the related depended and independent variables distributions with the same scatter now sorted out by region)*



As remarked, the regression shown in Equation (1) has been estimated MM rather than OLS to discriminate between potential outliers observation and no potential outliers observations. Then, once estimated, it has been drawn out a measure of vertical outlyingness given by the robust standardized residuals (denoted by $S_{stdresi,h,k}$) and flagged outliers as those observations that have a robust standardized residual larger than 2.25 in absolute value.

Once flagged the outliers, unit irrigation costs has been computed in the following three scenarios context. In scenario A, no vertical outliers are assumed then independently from the outlyingness statistics drawn, all observation are kept and the unit irrigation cost are computed as the ratio of total cost on the hectares covered, indeed:

$$UC^A_{i,h,k} = \frac{TC_{i,h,k}}{H_{i,h,k}} \quad | \quad abs\left(S_{stdres_{i,h,k}}\right) \leq 2.5 \quad or \quad abs\left(S_{stdres_{i,h,k}}\right) > 2.5 \qquad (2)$$

where $UC^A_{i,h,k}$ denotes the unit irrigation cost computed under scenario A for observation i, irrigation investment project type h and territorial aggregation k while $abs\left(S_{stdres_{i,h,k}}\right)$denotes the absolute value of our vertical outlyingness statistics measure.

Differently, in scenario B vertical outliers are cancelled out while no-vertical outliers observations are kept and the unit costs are computed as the previous scenario, indeed:

$$UC^B_{i,h,k} = \begin{cases} \frac{TC_{i,h,k}}{H_{i,h,k}} & | \quad abs\left(S_{stdres_{i,h,k}}\right) \leq 2.5 \\ the\ i_{th}\ observation\ is\ cancelled\ out & | \quad abs\left(S_{stdres_{i,h,k}}\right) > 2.5 \end{cases} \qquad (3)$$

Finally, in scenario C all observations are kept but vertical outliers are mean demanded once divided by their absolute value of the robust standardized residuals. Differently, for no-vertical outliers observations unit costs are computed as usual, indeed:

$$UC^{C}_{i,h,k} = \begin{cases} \dfrac{TC_{i,h,k}}{H_{i,h,k}} & | \quad abs\left(S_{stdres_{i,h,k}}\right) \leq 2.5 \\ \dfrac{abs\left(\frac{TC_{i,h,k}}{H_{i,h,k}} - E_{h,k}\left[\frac{TC_{i,h,k}}{H_{i,h,k}}\right]\right)}{abs\left(S_{stdres_{i,h,k}}\right)} & | \quad abs\left(S_{stdres_{i,h,k}}\right) > 2.5 \end{cases} \tag{4}$$

where, $E_{h,k}\,[.]$ denotes the averaging function that apply the mean operator to unit irrigation costs over observations i given irrigation type h and territorial aggregation k.

This outliers weighting scheme it is in line with the form of MM-estimators and it has been shown to produce very reliable summary statistics on unit irrigation costs as pointed out by the practical following application provided in the next section.

4. The cost analysis: the results and policy decisions

This section applies the methodology explained before proving reliable summary statistics on unit irrigation costs, such as, the mean of unit costs, their standard deviation, the maximum value and the minimum value at different territorial levels, namely, at pooled (Table (1)), regional (Table (2)) and country level (Table (3)) and by type of irrigation project, namely, small scale (SS), large scale (LS) and rehabilitation and modernization (RM).

Looking at pooled level, Table (1) shows the first and the most important result of this paper, it is not shown that LS irrigation investment projects are on average more expensive than SS irrigation investment projects but it depends on the scenario chosen. In fact, the mean of unit irrigation costs for LS irrigation investment projects is higher than the mean of unit irrigation costs for SS irrigation investment projects only in scenario B where vertical outliers are deleted.

Middle-East region						
UC	150	14293.83 (39838.63) [42.21 ; 339750]	121	3072.88 (4191.35) [242.85 ; 25222.91]	150	4638.69 (6134.29) [242.85 ; 39647.78]
UCss	49	33677.33 (64207.84) [42.21 ; 339750]	26	2895.61 (3833.23) [470 ; 18077.14]	49	6937.83 (7689.96) [470 ; 38600.26]
UCls	45	5219.41 (6409.05) [251.2 ; 28040.57]	42	4501.95 (5154.73) [355 ; 25222.91]	45	4423.91 (5013.56) [355 ; 25222.91]
UCrm	67	3865.83 (10346.86) [242.85 ; 78846.16]	61	1761.49 (2254.66) [242.85 ; 14089.38]	67	2021.69 (2583.51) [242.85 ; 14089.38]

Differently, when all observations are held or outliers weighting scheme is carried out the mean of unit costs referred to LS irrigation investment projects is lower than the mean of unit costs referred to SS projects[1]. This result imply that, larger is the scale of a given irrigation investment project and smaller could be on average the unit cost paid per hectare. It means that the investor, whether he has the option to choose the type of investment, could save on average money implementing a more efficient water policy by investing in LS projects rather than SS projects if he believes that his information has not atypical values or these values are present but he retains weighable.

Looking at the region level, Table (2) shows the second most important result of this paper. Once vertical outliers are handled, on average unit irrigation costs tend to be lower for Middle East countries rather than Afro-Arab countries[2].

[1] In fact, in scenario C the mean of unit irrigation costs for LS projects is around 1900 USD per hectare cheaper than the average of unit costs for SS projects (6905,14 USD paid on average per hectare versus 5014,48 USD paid on average per hectare). Further, this LS project mean convenience increases amply in scenario A (26787,76 USD versus 5139,91 USD per hectare). Differently, in scenario B the mean of LS projects becomes higher than the mean of SS projects (5095.75 USD versus 3810,71 USD per hectare).

2 In fact, in both scenario B and C the means of unit irrigation cots are lower for Middle-East country rather than in Afro-Arab countries. For example, in scenario B, the mean vary between 1761,49 USD per hectare and 4501,95

Looking at country level, Table (3) confirms, at this territorial level, that once vertical outliers are handled LS irrigation investment projects are not on average more expensive than SS irrigation investment projects but it depends on the chosen country. For example, LS projects are cheaper on average than SS projects in Lebanon, Egypt and Oman in both scenario B and C. This implies that higher is the scale of the irrigation project and lower is on average the cost paid per hectare. It follows that for an international investor are on average more convenient in these countries LS projects rather than SS projects because the cost per hectare for LS projects is smaller.

Table 3: *Unit irrigation costs at country level: main summary statistics (this table, shows the number of observations, the mean, the standard deviation, the minimum and the maximum value of unit irrigation costs (UC) computed as in scenarios explained in Section(3) by irrigation investment type*

Differently, in Iraq. Morocco and Algeria LS projects remain on average more expensive than SS projects in both scenario B and C. This implies that higher is the scale of the irrigation project and higher is on

USD per hectare for Middle East countries while Afro-Arab countries have produced a mean between 4964,75 USD and 6698,65 USD per hectare. Then, means in Middle-East country are lower than means in Afro-Arab country for any type of irrigation investment. Further, in scenario C, the mean of SS irrigation investment project is 6937,83 USD per hectare for Middle-East countries while the mean for Afro-Arab countries is 7155,54 USD per hectare. Furthermore, the mean of RM irrigation investment project is 2021,69 USD per hectare for Middle-East countries while the mean for Afro-Arab countries is 4840,63 USD per hectare. Finally, also considering irrigation projects as whole, is has been confirmed that on average unit costs are lower for Middle East countries rather than Afro-Arab countries (4638,69 USD versus 6939,34 USD per hectare in scenario C and 3072 USD versus 6972,65 USD per hectare in scenario B).

average the cost paid per hectare. It follows that for an international investor are on average more convenient in these countries SS projects rather than LS projects because the cost per hectare for SS projects is smaller.

Finally, for other countries, such us, Mauritania, Tunisia and Syria since some type of irrigation investment projects are missing at total a comparison between SS projects and LS projects in not possible unless new observations or an enlarged dataset is created or provided. Then, for these countries is not possible to formulate investor policy recommendations.

5. Conclusions

The negative influences of outliers on datasets applications is known for a long time. This paper has proposed an advanced econometric method, applied to a real irrigation investment dataset, to handle this issue in a three scenarios context.

This methodology, that can be generalized to any other dataset, has produced reliable summary statistics on unit irrigation costs at different territorial levels and by type of irrigation investment that will help surely governments, international organizations and water management in implementing more efficient water investment decisions and water policies as well as knowing how much to pay on average or at maximum or at minimum for a given irrigation investment project type located in a given country.

Nowadays, the use of these robust statistical methods is becoming more and more important in many fields and applied sciences because outliers are virtually present in any dataset and they must be handled robustly in order to produce correct policy decisions and recommendations.

6. Further developments

These results raise several issues for future applied research. Four are mentioned here. First, it has been assumed that regressors have not outliers and they are properly measured. These two assumptions have implied first that, given the goodness of the estimated regression line, may be present as only vertical outliers and second that the hectare variable is well reported and measured without a measurement error. Then, vertical outliers has been identified under a linear log-log regression with or without a squared regression term, indeed the most suitable functional form case per case, as those observations that have a robust standardized residual larger than 2.25 in absolute value. Although this methodology has produced reliable, realistic and no distorted summary statistics on unit irrigation costs both regressors and the dependent variable might be poorly reported that means a measurement error in the regressors and or in the dependent. Further, measurement error might be correlated that means an additional challenge to handle. Under horizontal outliers and measurement errors the methodology here explained must be tuned and it represents the first future possible development. Second, outliers have been identified assuming no other variables affect the relationship between the total cost and the hectares. This assumption needed to be confirmed in order to avoid the omitted variable bias that can distort any regression consistently. Third, a Bayesian approach rather than traditional regression to identify potential outliers might be carried out taking advantage from the near normality of the log-data transformation. Further, once outliers have been Bayesian identified also a model based directly on the distributions is possible. Fourth, our results are based on 225 initial irrigation projects in two regions. Would there be additional improvements if we were to use more irrigation projects? Therefore, would there be additional improvements if we were use global data rather than two region country data instead? In other words, the issue of systematically selecting data observations from very many other data observations is a difficult challenge that requires further research. In general, having more information is a plus then it follows that enlarging the starting dataset, thought merging or appending also from different data sources should be needed and it represents the most important further development to carry out.

Water use in agriculture and in food products industry. A case study for Italy to evaluate pressure on water resources

D. Vignani | Istat | Rome | Italy
G. Tagliacozzo | Istat | Rome | Italy
S. Tersigni | Istat | Rome | Italy

DOI: 10.1481/icasVII.2016.d24d

ABSTRACT

The increasing demand of water resources (wr) due to population growth, production and consumption activities of socio-economic systems, combined with Climate Change (CC) effects on hydrology and water use, are exerting a strong pressure on this natural resource. To face the risk of water scarcity, the challenge is to reduce the wr use intensity in agriculture, industry, energy production and civil use. A consistent and detailed knowledge on the amount of water used by each sector is essential to improve wr management, addressing appropriate policies to protect water availability and quality. In Italy the construction of a comprehensive and consolidate system of data collection on wr used by economic sectors is in place, to reach a higher degree of robustness and comparability of the estimations. To this aim, the role of official statistics need to be strengthened to fill data gaps and to enable more reliable analysis. Collecting data on water volumes used by sectors through statistical surveys and administrative archives can allow to highlight differences on wr requirements linked to various types of products, production processes, technologies used and specific features of the Italian productive structure. The aim of this paper is to present methodology and results of a study developed for Italy by Italian National Institute of Statistics (Istat) to estimate for the first time the volumes of wr used in the production of agricultural crops and vegetable food processed products. An estimation procedure based on the integration of data collected from various sources with official statistics provided by current surveys is implemented. The amount of irrigation water for agricultural crops and water used as input by industry to process vegetable food products is estimated. Results, carried out at the national level, provide an estimation of volumes of water used by the vegetable food chain segment to meet its own activities (reference year 2012). From these results, measures of pressure on wr by domestic production activities are provided.

Keywords: Water Resources, Agricultural Crops, Food Products Industry, Pressure Indicators

PAPER

1. Introduction

Interactions between Climate Change (CC), wr and socio-economic systems are complex and region-specific. CC can affects hydrology and wr through several dimensions: changes in the patterns of climatic variables (precipitation, temperatures, heat waves, extreme events), wr availability, impacts on water quality, changes in runoff, river flows, floods and droughts. Changes in the water cycle can deeply affect countries of many areas of the world, due to their negative impacts not only on agricultural production and food security but also on non-agricultural water uses such as industrial and urban uses. In this context, increasing competition for freshwater use in the sectors mentioned (including through population growth) has resulted in unprecedented pressures on wr, with many countries experiencing conditions of water scarcity as well as in ensuring the integrity of ecosystems. Moreover, water quality continues to worsen, further limiting the availability of fresh wr (IPCC 2014, OECD 2014). According to environmental sustainability and from a policy perspective, CC impacts on water cycle and consequences for agricultural, industrial and urban water uses, highlight prioritizing wr conservation and management in a sustainable way. To face the risk of water scarcity, the challenge is to reduce the water use intensity in agricultural and industrial sectors, in energy production processes and civil use. A consistent and detailed knowledge on the amount of water used in each sector is essential to improve wr management and to address an appropriate mix of policies to protect water availability and quality and to achieve a sustainable growth. Lack of integrated wr data is a systematic impediment to informed decision making about the sustainable use of such natural resource. Concerning Italy, data availability on the amount of wr abstracted, supplied, used, discharged and treated for different uses doesn't completely meet the information needs. Water statistics are produced by various agencies and institutions - often with administrative purposes - preventing data homogeneity, standardization and comparability at temporal and local scale. Istat has been working for several years to improve national knowledge on wr statistics, following EU guidelines relating to the Water Framework Directive 2000/60/EC and Eurostat initiatives on Water Statistics and Water Accounts (UNITED NATIONS 2012 - 2013). In this framework, the construction of a comprehensive

[1] Contribution to the ICAS VII: Rough draft on gender and rural women's empowerment in relation to DW/rural employment.

and consolidate system of data collection on wr used by different sectors is in place. Objective is to reach a higher degree of robustness and comparability of these environmental statistics to provide measures (in physical and monetary terms) of the phenomena taking place, also consistent with the system of monetary national accounting, to support policy decision making. Due to the aim complexity, the role of official statistics need to be strengthened to fill existing data gaps and to enable more reliable multidimensional analysis. To reach this objective collecting data on water volumes used by industry through an integration of sources is needed. By integrating current statistical surveys with administrative archives of public institutions and industry associations can allow to underline differences on water requirements linked to various types of products, production processes, technologies used and features of the Italian productive structure.

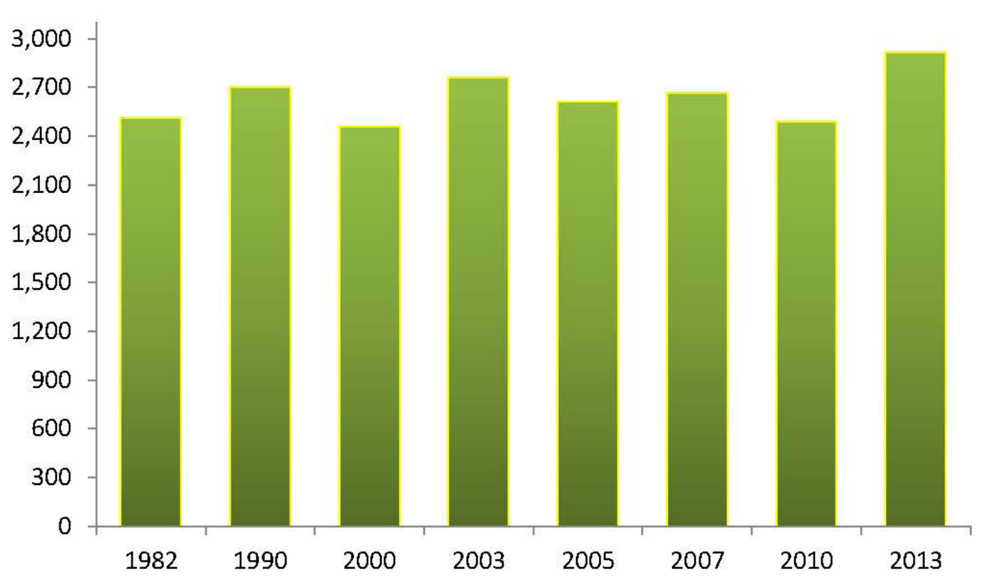
The aim of this work is to present methodology and results of a study developed for Italy to estimate for the first time overall volumes of wr used in agricultural crops production and in food products production whose origins are vegetable. Moreover measures of pressure on wr due to domestic production activities have been calculated. Istat have implemented an estimation procedure based on the integration of data collected from various sources: i) official statistics provided by current Istat surveys as Farm Structure Survey, Industrial Production PRODCOM Survey 2012, VI Italian General Agricultural Census 2010; ii) administrative archives of Italian public institutions; iii) a selection of representative Italian firms; iv) Industry Associations; v) EPD Environmental Product Declaration of firms ISO 14025; vi) international literature (Hosang and Bischof 1998, WS Atkins Ltd & Cranfield University 2002); vii) methodological guidelines for the OECD/Eurostat Joint Questionnaire on Inland Water (Eurostat 2012). The amount of irrigation water by type of crop and of water used as input by manufacturing industry for processing vegetable food products by groups of products have been estimated (Nace Rev. 2 and Ateco 2008 classifications). Produced at the national level, results of our study provide official estimates of the amount of water required by the food chain segment related to the production of fresh and processed vegetable products to meet its own activities. Results also highlight the more waterdemanding crops and the more water-intensive industrial food products. From these estimates, measures of pressure on wr exerted by domestic production activities due to the production of agricultural crops and vegetable food processed products (intended to satisfy final domestic and foreign demand) are provided. The paper is organized as follows. In section 2, data on irrigation water used by agricultural crops are analysed. In section 3, we present main results of the Istat study developed for year 2012 aiming to improve water statistics on industrial activities by producing, for the first time, official estimates on the volume of water used by manufacturing industry by sector.The findings of our research are summarized in the last section, providing measures of pressure on wr exerted by domestic production activities.

2. Water use for irrigation

Irrigation represents in Italy one of the most relevant pressures on natural environment in terms of wr use as in other Mediterranean countries, where increasing hot and dry seasons create conditions for additional water requirements to ensure the optimal growth for several crops (Istat 2016). Irrigable and irrigated areas represent two basic indicators to assess irrigation needs trend and their share in the total utilized agricultural area (UAA).

Irrigable and irrigated areas greatly vary among countries mainly because of regional climate and type of crop production. Based on official statistics provided by Istat Farm Structure Survey of agrarian year 2012-2013 (Istat 2015) the irrigable areas of Italian farms were equal to 4,074,750 hectares by 783,647 farms (Figure 1).

Figure 1 – Irrigated areas. Italy, agrarian years 1982-2013, thousands of hectares

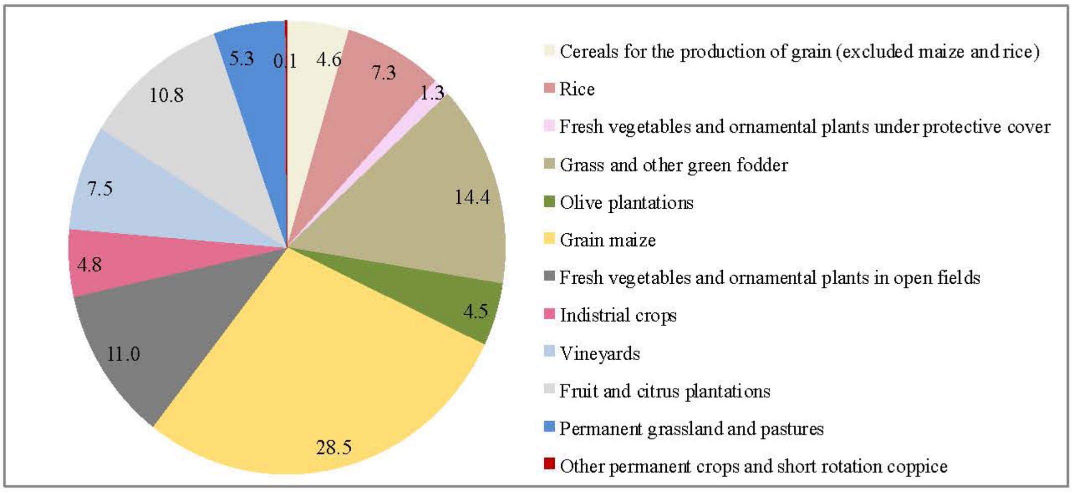


Source: Istat - Farm Structure Survey and General Agricultural Census

Compared to the agrarian year 1981-1982, irrigable areas have increased by about 3%. In agrarian year 2012-2013 irrigation was carried out by 720,335 farms (49% of farms) on 2,917,649 hectares of irrigated area + 16.2% with respect to 1982.

While for some types of crops full irrigation of the entire cultivated area is a distinctive feature, for other crops irrigation is supplementary and generally used to improve production especially in dry periods. Considering the overall irrigated areas by crops, 28.5% of the irrigated areas are planted with grain maize followed by grasslands and other green fodder reaching 14.4% (Figure 2). Fresh vegetables and ornamental plants in open fields represent 11.0% and fruit and citrus plantations almost 10.8%.

Figure 2 – Irrigated areas by crops typology. Italy, agrarian year 2012-2013, percentage values (%)



Source: Istat - Istat – Farm Structure Survey

Two indicators can be calculated to synthetize data on the irrigation needs. The first indicator is Propensity to Irrigation (PI), estimated by total irrigated areas on cultivated areas. The second is Tendency to the Use of Irrigation Potentiality (TUIP) measured by the percentage ratio between irrigated areas and irrigable areas. From official statistics on the agrarian year 2012-2013, PI is equal to 23.5% and TUIP to 71.6%.

Italian crop production system faces and will cope deep changes of weather conditions and wr availability, intensifying problems of water scarcity and irrigation requirements especially in the South, increasing drought risk and heat stress (Gismondi et al. 2016).

Data on irrigable and irrigated areas alone doesn't give a complete indication of water use intensity, which also depends on the type of equipment used (surface irrigation, sprinkler irrigation, drop irrigation). The type of irrigation system and the size of the agricultural holding may often be linked (Dono et al. 2011).

Being water the most critical resource for sustainable agricultural development, measures in physical units are needed. Volume of water used seems a meaningful indicator to evaluate the pressure on wr exerted by agricultural crops, taking into account several factors (such as CC, current weather conditions, crop type, harvested production, yields, soil characteristics, cultivation practices and irrigation techniques). Volume of water used for irrigation was provided for Italy once in 2010, in occasion of Istat VI General Agricultural Census and it's estimated about 11.6 billion of m3 of irrigation water 2,489,915 hectares of crops by 708,449 farms in agrarian year 2009-2010 (Istat 2014). The average volume of water used to irrigate one hectare of land was equal to 4.7 thousands of m3, with a certain degree of variability based on the type of crop (Figure 3). Rice, representing 10% of the irrigated area, required the highest water volume, almost equal to 18,000 m3 of water per one hectare of irrigated area. Greenhouse and households gardens - despite the low incidence of this crops on irrigated area (2.9%) - required 7,300 m3 per hectare. The less water-demanding crops are rape and turnip rape (beneath 1,000 m3 per hectare) and potatoes (1,300 m3 per hectare), overall represeningt only the 1% of the total irrigated areas.

To measure pressures on wr, the indicator volume of water used for irrigation calculated by area and typology of crop can give more detailed information suitable for analysis on the sensitivity of water demand by crops to CC phenomena and on efficiency in wr use if placed in relation to harvested production, irrigation systems as well as meteo-climatic conditions and soil characteristic.

Strengthening the production of official statistics on volumes of water used in agriculture on regularly basis is needed by integrating different data sources. Expanding temporal and spatial scale and disaggregation level at which data are provided allows to carry out medium and long-term reliable analyses.

Source: Istat – VI General Agriculture Census

3. Water used by food products industry

In Italy there is a lack of uniform estimates on the amount of water abstracted, supplied, used, discharged and treated for industrial uses. Available data are often difficult to be collected, as information is produced by various agencies and institutions with administrative and economic purposes, according to different levels of efficiency in archiving procedures.

For this reason, wr statistics on Italian industrial activities suffer from a large fragmentation of information, data heterogeneity and lack of standardization. Concerning statistics on water used by industry, an official survey useful to improve the knowledge on the matter doesn't exist in Italy (Tagliacozzo, Vignani et al. 2015).

Thus an Istat-Eurostat study was developed since 2013 to improve water statistics and accounts on industrial activities by producing for the first time official estimates at national level on the volume of wr used by manufacturing industry and mining and quarrying industry Nace Rev. 2, sectors 07-08 and 10-33 (Vignani, Tagliacozzo et al. 2016). As industrial water needs are strictly connected with the type of industry and product and largely dependent on technological features of the single plant, different types of industrial processes and technologies used have been taken into account.

An indirect estimation method has been developed and applied. The innovative element of the methodology is represented by:

i) using official statistics coming from the current Istat Survey on industrial production PRODCOM 2012, based on data by units of product of different typology and by value of output (instead of data by number of employees as applied in other studies);

ii) applying specific technical processing coefficients - calculated for unit of product in physical terms - to the amount of units of product, grouped by typology within each manufacturing sector.

The method allows to obtain estimates on overall volumes of water used as input in the production of manufacturing industry by unit of product and by sector. Additionally, an estimation of the water self-abstracted by industries have been developed, under the assumption that small firms (industries with 5 or less employees) are supplied by public water supply network. Published technical studies suggest methods to estimate wr use that are not directly suitable for analysis at a large scale, because they need to be calibrated to fit features of the country-specific industrial structure/ production.

Results show the total amount of water used as input in the production of manufacturing industry is equal to 5,509,128 thousands of m3 in 2012, while the volume of water self-abstracted by industries is 5,314,866 thousands of m3 (Table 1). The difference of 194,262 thousands of m3 represents the volume of water provided to small industries by public water network. This information is important to calculate a water balance of wr uses by all domains (civil, agricultural, energy production, industrial).

A sectorial breakdown allow to identify the volume of wr used by each sector and the share of wr used by the food products sector. Results represent the use of water as a whole in each sector, calculated from the volume of water used by unit and type of product.

The sectors with the higher demand of wr, together using one third of the total amount of water, are: "Chemicals and chemical products" (12.4%), "Rubber and plastic products" (11.7%), "Basic metals" (10.0%). Food products sector is placed in a group of sectors with a medium level of water required as input (6%) equal to 333,182 thousands of m^3.

The analysis have been deepened on the categories of vegetable food processed products to provide an overall estimation of volumes of water used by the food chain segment of vegetable products to meet its own activities. As Nace 10 classification food products includes also products whose origin isn't vegetable (i.e. production and manufacturing of meat, fish, dairy products, milk) a selection of food processed products (VFP) has been made. Wr required as input for their production represent almost 60.7% of the whole water used by food products sector and correspond almost to 184,564,828 thousands of m^3.

Table 1: *Water used by sector. Year 2012, thousands of m^3 and percentage values* (%)

Nace Division	Water use		Water use (>5 employees)	
	m^3	%	m^3	%
7-8 Mining and quarrying minerals	260,685	4.7	231,528	4.4

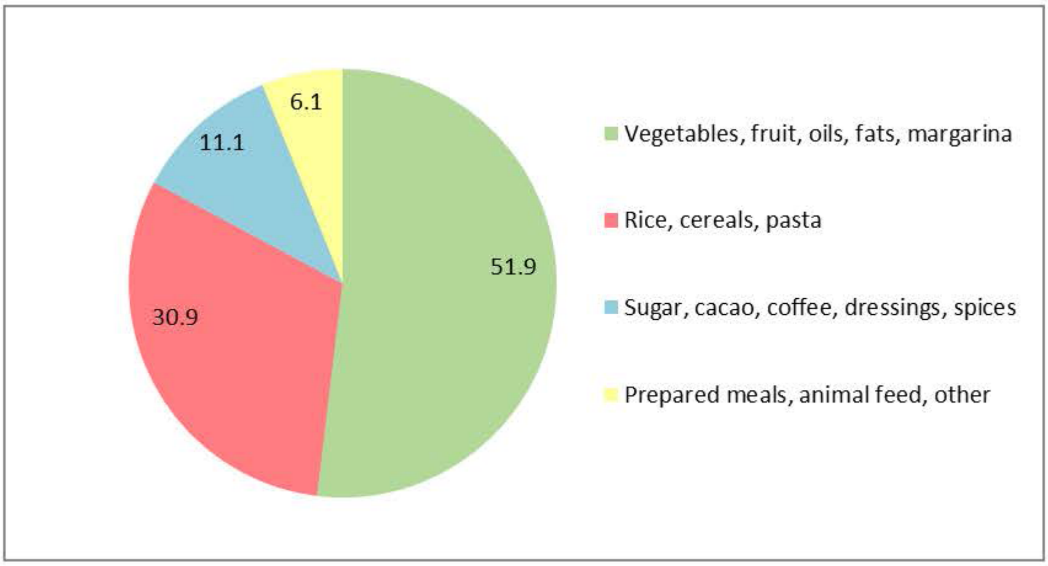
VFP products has been classified in four category of homogeneous products (Figure 4). The category including Vegetables, fruit, oils, fats, margarina uses 51.9%of the overall water used in the production of VFP, followed by Rice, cereals, pasta, that use about 30.9% of the total. The third group is represented by Sugar, cacao, coffee, dressings, spices (11.1 %) and the last one by Prepared meals, animal feed, other (6.1%).

To measure the pressure of water demand by products at net of production levels a Water Use Intensity

Figure 4 – Volumes of water used by categories of vegetable food products. Year 2012, percentage values (%)



(WUI) indicator have been calculated by the ratio between volumes of water used an sold production, by sector. Considering, in fact, unit of production vary within and between sectors among several type of measurement (weights, volumes, m2, number of pieces, monetary units), a normalization method into monetary terms allows to compare the demand of water, net to the sector's production levels and type.

The WUI indicator represents the volume of wr necessary to produce one euro of production sold. Calculated as average value among all sectors, it is equal almost to 8.8 litre/euro. The food products sector records a WUI equal to 3.9 litre/euro.

Our work represents a first attempt to estimate volume of wr used by industrial activities through and indirect methodology applying technical coefficients to unit of products. Although the method can be replicated for each year considered, the estimations - mainly due to PRODCOM sample features- have statistical significance at national level. Regional as well as sectorial breakdown decreases the estimation robustness. Goal to achieve is to strengthen the production on regularly basis of official statistics on volumes of water used by national manufacturing industry through collected data with the aim to expand temporal and spatial scale and disaggregation level at which data are provided.

4. Conclusions

In the context of CC, increasing competition for freshwater use in different sectors has resulted in high pressures on wr, with many countries facing the risk of water scarcity. To improve wr management and to address appropriate policies to protect water availability and quality, a consistent and detailed knowledge on the amount of water used by each sector is essential. In this context, the role of official statistics need to be strengthened to fill data gaps and to enable more reliable analysis on the pressure on wr. In Italy, Istat have been worked for the construction of a comprehensive and consolidate system of data collection on wr used by economic sectors and by population. Being water the most critical resource for a sustainable agricultural development, measures in physical units are needed. Volume of water used seems a meaningful indicator to evaluate wr pressure exerted by agricultural crops and food industry. This paper presents methodology and results of a study recently developed by Istat. For the first time volumes of wr used in national agricultural crops production and in vegetable food processed products production have been estimated. The amount of irrigation water by type of crop and of water used as input by manufacturing industry for processing vegetable food products by groups of products have been provided for one year, limited by data availability. The statistical procedure is based on the integration of data collected from various sources with official statistics provided by current surveys. Concerning national agricultural crops, water used for irrigation was estimated about 11.6 billion m3 in 2010, as provided once by VI Italian General Agricultural Census. Concerning vegetable food products industrial sector, the volume of water used as input corresponds almost to 184.564.828 thousands of m3 in 2012, as provided by the Istat study. The innovative element of the methodology applied is represented by: i) using official statistics coming from the current Istat Survey on industrial production PRODCOM, data by units of product of different typology and by value of output; ii) applying specific technical processing coefficients,- calculated for unit of product in physical terms, to the amount of units of product grouped by typology within each manufacturing sector. The indicator volume of water used calculated in physical units can give more detailed information suitable for conducting analysis on pressures on wr , sensitivity of water demand by crops/products to several factors (CC effects, irrigation systems, technology used) and efficiency in wr use. This work permits to fill some gaps on water pressure analysis so as to encourage strengthening the production of statistical information necessary for a comprehensive and multidimensional analysis. As underlined, several data sources can satisfy partially information demand on wr use and macro-aggregates at national scale only can be calculated in many cases. At date, in the Italian statistical system data on wr are collected with different purposes and integration is limited.

MEASURING THE VALUE OF ECOSYSTEMS SERVICES, LAND DEGRADATION AND BIODIVERSITY LOSSES

Session Organizer
S. Lucci | ISPRA - Institute for Environmental Protection and Research | Rome | Italy

ABSTRACT

The global effort to end poverty and improve food security faces a special challenge of doing so while ensuring that farms, forests and landscapes continue to produce food for generations to come. Integration of environmental goals in development programs, analytic tools, and in analyses to inform investments can contribute toward resiliency of production systems. Accordingly, the Sustainable Development Goals (SDGs) have committed to a number of targets which contribute to improved ecosystem services (ESS), land restoration and increased biodiversity. Similarly, the CGIAR strategy includes 'improved natural resources systems and ecosystem services' as one of its three System Level Objectives. The challenges facing efforts to sustainably increase agricultural productivity are many, including soil degradation, overdrawn and polluted waters, reduced pollination health, and diminishing genetic resources. Uncertainties associated with climate change pose further risks. Safeguarding agricultural biodiversity can provide sustainable solutions in tackling these challenges. Existing research indicates that agricultural biodiversity leads to production systems that are more resilient to biotic and abiotic stress, it improves ESS such as pollination health, water quality and use efficiency, and improves soil health. The commitment of the global community to integrate ESS and natural resources systems in its development goals provides an opportunity to create a framework for establishing baseline indicators and monitoring progress toward enhancing these goals. A challenge toward measuring the value of ESS and natural resources system lies in the fact that the services and systems studied are very site specific and development goals are measured at larger scales such as at national levels. Finally, most agricultural models to date have tended to analyse how yields or profits can be maximized or incomes increased. But these models have generally not examined what these scenarios mean for the natural environment and its ability to sustain future food productive capacity. Nor have the models explicitly linked agricultural biodiversity to ESS and in turn to sustainable productivity gains.

This session will include 4 papers devoted to the following areas,

1. A standard and practical approach to measure and monitor agricultural biodiversity across scales from the field to the national level. This discussion should focus on a few recommended indicators which can be used across different scales and are suitable for use in research across different disciplines, including in bioeconomic modelling.

2. A standard and practical approach to measure and monitor the outcomes of efforts to restore degraded land and forests. This discussion should focus on a few recommended indicators which can be used across different scales and are suitable for use in research across different disciplines, including in bioeconomic modelling.

3. A standard and practical approach to measure and monitor one or more of the ESS such as soil health or pollination health. This discussion should focus on a few recommended indicators which can be used across different scales and are suitable for use in research across different disciplines, including in bioeconomic modelling.

4. Approaches for analysing trade-offs between productivity, nutrition outcomes and environmental outcomes at multiple scales, such as households, agricultural sector and economy-wide.

ABSTRACT

For regular analysis and tracking of changes in the valuation of ecosystem services in irrigated agriculture, indicators and data sources included in a unified system of statistical services in rural areas are needed. In general, the development and introduction of such indicators and data will help to guide monitoring ecosystem services in areas such as cotton and grain farming, the main agricultural crops in irrigated agriculture of Uzbekistan.

Currently, almost all information is obtained through interviews, which is very labor intensive and covers a rather small radius of the population and areas involved in agricultural activities. Therefore, the development of new indicators for statistical reporting systems will improve the ability of ecosystem services' value estimates at the level of decision-making.

Keywords: Economic Assessment of Ecosystem Services, Bio-agriculture, Irrigated Agriculture, Agricultural Economics

PAPER

1. Introduction

Agriculture is one of the priority areas of national economy. Uzbekistan has favourable climatic conditions for production of various agricultural, including industrial crops. A significant portion of sown areas and almost all land under technical crops are irrigated lands served by a large public irrigation system.

Diminishing soil fertility in agriculture is one of the issues that need to be tackled. The content of humus in the soil decreases. Thus, in the study area, about 76 % of arable areas have content below 1 %, 22 % contain from 1 to 2% organic matter, and the remaining about 1% of irrigated arable land contains from 2 to 3% organic matter.

Improvement of soil structure can be achieved by rational combination (rotation) of crops. It is necessary to expand the area under crops and trees allowing the accumulation of nutrients in the soil. A rational choice of crops can reduce the amount of mineral fertilizers and various other chemicals, contaminating land and water.

Some international studies show, that average GHG emissions from traditional cotton cultivation can be 3,236kg CO e/ha and 1.5 kg CO e/kg of seed cotton produced. For a detailed analysis of carbon emissions from cotton cultivation, a further study is needed, because farmers and local authorities do not collect such data[1].

In accordance to some literature[2], the soil organic carbon stock (SOC) under irrigated cotton varied from 15 to 43 Mg C ha^{-1}. Perennial crops generally have the widest range of SOC stock as from 11 to 241 Mg C ha^{-1}, similar to a land use as pasture type. Currently the area under orchards and vineyards in the surveyed farms is only around 1.5 %. Absorption of carbon dioxide by tree planting in the surveyed farms approximately amounted to only 35 m3 per year. In the economic program of socio-economic development of the country in 2016, the President of Uzbekistan stressed the need to reduce by 2020 the volume of procurement of cotton to 350 thousand tons. The result, on released cotton plantations will be grown vegetables, potato, fodder, oilseeds and other crops, gardens and vineyards[3].

The traditional varieties of crops (cotton and wheat), subsequent reduction of productivity of

irrigated areas, and the orientation of farmers to maximize harvest rather than economic benefits of the production function (not examined) require constant and increasing amounts of mineral fertilizers. This process leads to the subsidence of many harmful substances in soil and water, which directly affects the living organisms in the soil. Useful insects (entomophages, etc.) are spreading as a consequence of biological plant protection on irrigated fields. Despite this, use of the land under cotton has consequences such as the extinction of previous organisms and their habitat, staying birds, and various small animals.

Some traditional methods often harm land resources, at the same time causing damage to the environment. So, the burning of straw per hectare leads to emissions of 500 g of nitrogen oxide and 380 g of hydrocarbon, 3 kg of ash, 20 kg exhaust and carbon gases, which leads to the spread of various diseases. This process disrupts the structure of the soil, which leads to increased soil erosion and declining yields. In addition, entomophages and useful creeping animals die, local plants around the cereal fields are damaged and disappearing.

There are only few statistical materials indicating an influence of agricultural production systems on the environment. Statistical data almost correspond to the set of indicators that are applicable to centrally planned management of agriculture. There are indicators of production volumes, production costs of agricultural products. They tend to give information about the implementation of plans, but do not express the analytic capacity to maintain the conditions for sustainable economic and environmental sustainability of land and water use.

Maintaining the humus balance, the volume relations of plants with nutrient properties of the soil or organic matter, uptake and release of carbon, the prevention of various types of land degradation and others need to be considered as indicators of statistical information at the district level. The basis for the economic calculations is the fact that any economic effect from the use of land in agriculture must maintain the natural fertility of the soil. For this we use and propose indicators of crop rotations in the study area. Cotton cultivation is one of main form of agricultural production in the study area, as well as in Uzbekistan. The main question is how the farmers can conduct the proposed agricultural production in an economically advantageous way, will they change the structure of production taking into account conservation of natural resources?

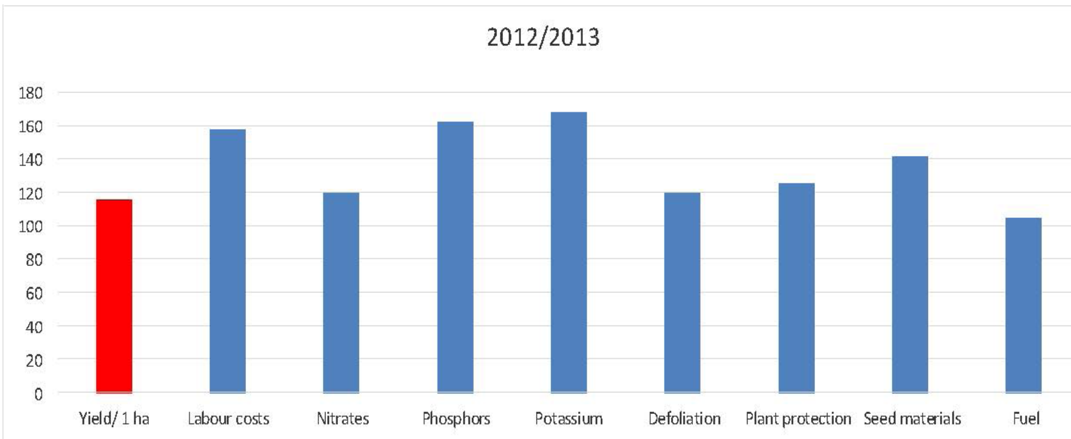
2. Cotton cultivation as a traditional form of land use

In the study of irrigated agriculture, the main products obtained from the interaction with ecosystem services include food, fuel and fibre, the nutrients for their growing. In addition, thematic area focuses on supporting ecosystem services - formation and soil conservation, supporting habitat, air purification, carbon sequestration, allocation of water resources, and cultural – i.e. creating areas for recreation and aesthetic values.

The analysis of the researched farms shows that yields tend to decrease. The yield increase is achieved due to the disproportionate increase of the costs of various production factors. So, when considering years with increasing yields (2013, Figure 1), it is clear that in comparison with 2012 the increase in yield of raw cotton per hectare was accompanied by a high increase in almost all factors of production except fuel.

This aspect clearly indicates a decline in the value of land, as part of the ecosystem, which is the

Figure 1 – Increase of production factors volume comparing to the cotton yield growth



Source: calculated by author based on survey data.

main economic factor in the context of irrigated agriculture. Considering ecosystem services, it directly reflects the provision of nutrients for the production of products from cotton cultivation tends to decrease. Therefore, the main objective of changing the situation, in our opinion, is the change or improvement of the crop rotation system adopted in local conditions.

It should be noted that the demand for by-products from cotton production increases. For example, cotton stalks can be used as raw material for production of furniture and other composite materials. On the other hand, the eventual liberalization of the domestic cotton market may increase the prices of raw cotton. Given the fact that changes also occur in the prices of production factors, it can be assumed that the optimization of production will lead to attractiveness of this type of irrigated agriculture. For a long period, this process will increase the load on land resources, requiring revision of land use from the point of view of crop rotation and reproduction of natural soil fertility.

Source: by author based on survey data

Since cotton is the raw material base for other industrial forms of production, it is necessary to consider what may occur by outflow of resources from these industries in cotton growing. For example, from raw cotton we can receive about 33 % of the weight in the form of fiber, about 54 % as oil and fodder, and the rest as lint. Changes in the demand for such related products directly affect the degree of attractiveness of cotton production. In addition, it is necessary to take into account the price of cotton fibre on international markets. Changes in these areas consequently can cause an increase of investments in the sector of crop production. Thus, it may lead to further overuse of soil, due to the application of a larger amount of mineral fertilizers, more intensive use of agricultural machinery, etc. As a result, the natural fertility in the long term will continue to decline. For a more detailed analysis, alternative uses in other forms of irrigated agriculture are necessary to be considered.

3. Economic and environmental sustainability of traditional cotton production

Although in the study area stubbing of cotton stalks is not as widespread as in the southern and western regions of Uzbekistan, the tendency of stalks cutting for fuel increases. This factor currently is constrained due to the sufficient gas supply. In many other areas remote from the capital, the gas supply is less. Consequently, all of the cotton stalks are removed. This contributes to a significant decrease in the proportion of organic matter, which naturally would be returned to the soil.

The value of cotton stalks can be also estimated in accordance to possibility of obtaining heat energy. According to some calculations[4], 1 kg dry weight of cotton stalks gives energy in about 15 mega joules. So 1 t dry mass of stalks can be equated to the energy obtained from approximately 0.3 t of diesel fuel. Thus, the value of production of raw cotton may be too attractive to refuse it as a production form leading to intense land degradation. Limiting factor is the increased supply of this raw material, especially in the seasonal section. Taking into account local conditions for the calculations, we choose cost rates that were obtained during surveys in the study area. Using data of fertilizers' cost obtained on the studied farms and comparing required amount of their additional contribution due to a withdrawal of organic mass, we can calculate the cost of losses from the collection of cotton stalks by the field after harvest (table 2).

The cotton production takes up to 3 t of organic mass from one ha under collection of cotton stalks for fuel and other needs. In order to cover the loss of nutrients that are not reproduced due to the withdrawal of this organic mass, farmer needs to apply about 14 t of organic fertilizer (table 2). Application of organic fertilizer restores the contents of nitrogen, phosphorus and potassium in the soil. Under normal conditions, 1 t of organic fertilizer covers 5 kg of nitrogen,

[4] T.A. Gemtosa, Th. Tsiricoglou. Harvesting of cotton residue for energy production.

Table 2 – Indicators of calculating cost of mineral fertilizers for reproduction of nutrients in the soil for the permanent cotton production[5]

Total		160959	176787	218173

Source: by author based on survey data

4 kg of phosphorus and 1.5 kg of potassium. To resume the production of raw cotton, equivalent to the previous year, the farmer must purchase the necessary amount of mineral fertilizers with these nutrients.

Based on the table of profitability of growing cotton on the studied farms, the number of required types of fertilizers is multiplied by the price of their purchase. The result is the amount of money the farmer has to spend for the reproduction of substances that are lost due to the loss of humus in the soil. Comparing these values with the income received by the farmer from the sale (withdrawal) cotton stalks from the field, we can see economic loss from such kind of management (table 3). This example shows the economic feasibility of natural reproduction of the soil organic structure in studied conditions.

Table 3 – lEstimated loss from the sale of the cotton stalks for fuel, UZS/ha

Values	2012	2013	2014

4 Possibility of optimization in crop rotation

An alternative option for irrigation farming with preservation of the humus balance and economic utility of crop cultivation forms is the possibility of changing crop rotations. An expansion of the area under cultivation of alfalfa can be taken as an example to calculate an alternative scenario. Currently about 3 % of agricultural land on the studied farms is planted by alfalfa , and about 8 % in comparison with the area under the raw cotton cultivation. The proposed alternative aims at a combination within the rotation of alfalfa and cotton cultivations. For example, the calculation is based on maintaining a zero balance of humus as two years of alfalfa and three years of cotton cultivation.

For initial assessment of economic benefits from the preservation of humus balance in soil, initially we compared the cultivation of alfalfa and cotton from the point of view of their profitability in combination of crop rotation, which retains humus balance within a certain time. Calculations show that the production of alfalfa while maintaining the humus balance brings significant economic benefit compared with cotton (table 4). Its value for the study area is more than 80 %. The production of one crop - cotton in this situation brings in annual revenues of approximately 315 thousand UZSs per ha. On the other hand, lack of alfalfa in the crop rotation for the farm brings the loss of up to 255 thousand UZSs per ha annually. Thus, the farmer would be interested in the use of crop rotation including cotton and alfalfa.

The calculations were based on the revenue generated from the cultivation of cotton with the removal of residues from the field. If you eliminate this indicator, the results can change in favour of cotton. However, the income from growing alfalfa is more profitable form of agricultural production, because the livestock sector in the Metropolitan area is developing intensively and farmers can directly sell alfalfa to livestock producers. But cotton production traditionally will remain as a main form of irrigated agriculture in Uzbekistan. It seems it can be reduced to a certain scale, if it is justified from the point of view of maintaining sustainable land productivity. On the other hand, the government will go easier on the sown areas under cotton, if the productivity of land will increase (score of bonitet). The vacated land will be used for agricultural crops with great potential to sustain ecosystem services and biodiversity through soil improvement. For this purpose, it is expedient to further and more detailed study from the point of view of biological and ecological analysis.

Source: by author based on survey data

At the moment, we mostly use economic interpretation, trying to assess the further course of the implementation possibilities of crop rotations. We are talking about the feasibility of maintaining the humus balance. The challenge is to determine whether the crop rotation is favourable from the point of view of factors as nutrients. On the one hand, it is important to determine how much alfalfa contributes as a supplier of organic mass. On the other hand, it is important to determine the cost of the withdrawal of nutrients by cotton cultivation. It is important to determine the ratio of economic benefits from the factors nutrients such as NPP (Nitrogen, Phosphorus, and Potassium) excluding the impact of the cost of other factors.

Table 5 – Assessment of the value of crop rotation (pictures 2014)

Organic matter, t/ha	6,7	-4,2

The value of land from crop rotation of alfalfa, UZSs	193 743	

Source: by author based on survey data

Calculations show that a farmer will seek to increase the proportion of alfalfa in rotation with cotton. If we take the ratio of cotton to alfalfa as 6 to 4, we can assume that 12 years is the minimum period in which the whole land area may be used under alfalfa 4 years and under cotton 6 years. Calculations of total revenue from use of land under the cotton crop rotation with alfalfa in contrast to the use only under the cotton show that in the first embodiment, the farm receives economic benefit in almost 59 % higher (table 6). 32 % of this additional income in this case is obtained by changing the cost structure of nutrients in the soil.

5. Extension of tree plantations as an alternative scenario for the provision of ecosystem services

Following the alleged alternative option for creating a favourable environment from the point of view of ecosystem services proposes testing approaches to the development of agro forestry. One of the important directions is the creation or renewal of the forest belts around and on the territory of cotton fields. Surveys have revealed that in the past, this issue has received considerable attention at the state level, various programs were implemented to create windbreaks.

By combining these two forms of agricultural production, cotton yield would increase. This is an additional incentive to use this approach, because land allotment from cotton farming is a difficult process. Besides, it is necessary to take into account the risk of long-term investments, which farmers can accept only for a smaller area. Therefore, we can focus on the forestland approximately 3% of arable land currently used under cotton. The studied farms in 2014 used for cotton cultivation an average of 56 ha per farm. Thus, about 2 ha, the farmer can use under planting of trees. In this case, we focus on poplar (table 7). To calculate the net present value we use a discount factor of 1.18.

Table 7 – Calculation results of poplar growing on the cotton fields (the period of poplar maturity expected as 9 years). UZS

	2105	NPV, 2024
Income from 2 ha of planted poplar	-900000	8335862
Income from yield increase by 15%, 54 ha	22941630	116487635
The income from cotton cultivation, 56 ha	17596600	89347894
Income volume by poplar growing on the cotton fields		124823497
The benefit to the farmer, %		39,7

Source: by author based on survey data

The sequence of calculations from the farmer's point of view is carried out in accordance with the definition of benefit from the value of the timber that he can sell in 9 years (8.3 million UZSs), and the additional revenue from raw cotton production (116.5 million UZSs). This is obtained because of higher yields through the establishment of forest plantations. Thus, the net present value of revenue from this combination of both production forms is obtained in an amount of 124.8 million UZSs. If we take into account the production of only cotton, net present value of revenue over 10 years would have been approximately 89.3 million UZSs. Therefore, this alternative would bring the farmer an income that would exceed the traditional income at nearly 40 %. In addition, the risk is quite low due to minimum consumption of territory, severed from the main form of agricultural production.

6. Conclusions

- by retaining cotton residues on the field, the farmers have an opportunity to generate additional income from cotton cultivation. In practice, farmers are not aware of the usefulness of this approach, which requires research and awareness of farmers cultivating cotton;

- the remains of the cotton in the field also contribute to the living conditions for insects and microorganisms on the agricultural fields, contributing to the habitat of birds and small animals, such as hares and hedgehogs;

- reducing the amount of applied mineral fertilizers, and keeping residues of cotton on the field in the form of organic matter contribute to reducing emission of carbon dioxide into atmosphere;

- introducing indicators of crop rotation to indicate positive changes of the natural nitrogen amount in the soil. It would allow both to define levels of reducing mineral fertilizers to accumulate more carbon in combination with natural nitrogen in soil;

- indicating of using food base that is created due to the increase of areas under perennial grasses, farmers can get high economic returns through increased livestock production. Thereby reducing the burden on agricultural land, and obtaining organic matter by livestock develop conditions favourable for biodiversity conservation;

- indicating grow of poplar has utility from the standpoint of air purification, wind protection, recreation and aesthetic perception of agricultural landscapes;

- the main feature of growing poplar are main trunks as building material. Thus, there is carbon sequestration, since only part of wood is used as fuel.

ABSTRACT

In the last decades, Mediterranean landscapes have been transformed by anthropogenic processes, such as changes in land use and climate. In particular, forest transition in mountain areas, and urban sprawl in lowlands could strongly undermine the ability of ecosystems to provide benefits over time. Under these changing conditions, forest ecosystems have reduced their functionality, resilience and stability. In this way, important forest ecosystem services, such as timber, non-wood products, climate regulation, biodiversity conservation, and cultural and spiritual values, will be eroded if forest resilience is not effectively maintained. Accordingly, forest planning is called to spatially allocate management alternatives and strategies in order to balance the final provision of forest goods and services demanded by local communities with the ecosystem functionality. In this study, we implement the "Multi-scale mapping of Ecosystem Services" (MIMOSE) approach in Sicily region to (i) assess the forest ecosystem services bundle over a 20- year time period; and (ii) evaluate how ecosystem services can be balanced to support sustainable forest management at the regional scale. Through the MIMOSE approach, at first we spatially assessed, in biophysical and monetary terms, timber provision and carbon sequestration, according to three forest management alternatives: business as usual conditions, maximizing economic incomes, and prioritizing conservation purposes.We then calculatedthe trade-offs among these ecosystem services and carried out a cross-case analysis. Finally, sustainable future-oriented strategies for forest landscape planning were identified, in agreement with the best balanced set of ecosystem services. The most important outcomes are the following: (i) timber provision is in general a conflicting service, especially when adaptation strategies are promoted; (ii) the best balanced set of forest ecosystem services is achieved by adopting a more conservative approach; and (iii) the bundle of ecosystem services is generally influenced by ecological and management conditions (e.g., differences among forest landscapes in the two regions), and is sensitive to harvest intensity and frequency, as well as to the length of the period used for the simulation. The MIMOSE approach demonstrated to be a spatially-explicit tool particularly suitable to support landscape planning towards balancing forest ecosystem potentialities with local communities' needs. Moreover, the approach can be considered an easy-to-use and replicable tool to cope with sustainable development goals in the Mediterranean area. In this light, the MIMOSE approach can improve the monitoring and assessment of ecosystem services demand and budget from local to national scale, thus contributing to the statistics and environmental accounting for the forestry sector.

Keywords: MIMOSE, forest ecosystem services, forest management and planning, regional scale.

PAPER

1. Introduction

Forest ecosystems are important sources of goods and services (hereinafter Forest Ecosystem Services;FES) for people worldwide, such as(i) timber and non-timber products provision,(ii) habitats and species conservation, (iii) regulation ofthe biogeochemical regimes, and (iv) enhancement of cultural and recreational aspects of a given landscape (for the Italian context, e.g., Vizzarri et al. 2015a). The FES availability depends upon the forest resilience, health and stability (e.g., Proença et al. 2010). Especially in Mediterranean landscapes, often degraded by human-driven interactions, the forest resilience is undermined, and the associated benefits for local communities reduced. Considering these challenging conditions, forest management and planning are called to balance the FES availability with the ecological and socio-economic aspects at local scale. In particular, the acquisition of more detailed information (e.g., chemicals, soil parameters),and the implementation of both advanced tools (e.g., LiDAR techniques) and innovative approaches (e.g., agent-based models) are increasingly requiredto support forest management inmonitoring the spatial and temporaldevelopments of forest landscapes, and in turn quantifyingtherelated changes in termsof FES provided, both in biophysical and economic terms. Theuse of tools such asthe "Integrated Valuation of Ecosystem Services and Trade-offs" (InVEST) or the "Artificial Intelligence for Ecosystem Services"(ARIES), has proven to beeffective in several cases (Posner et al. 2016; and Villa et al. 2014, respectively). Nevertheless, the lack of input data on forest structure, health and productivity, the weak integration between the current management and the socio-economic conditions, and the absence of economic statistics on ES availability strongly reduce the effectiveness of forest management and planning, especially in theItalian landscapes. Tofacethese situations, the "Multiscale Mapping of Ecosystem Services" (MIMOSE)approachwasdeveloped and implemented forforest ecosystems in the Molise region, Central Italy, to map timber provision and carbon sequestration, and assess the related trade-offs (Bottalico et al. 2016). In thiswork, we applied the MIMOSE approach to the forests ofthe Sicily region(Southern Italy),with the aim of highlightingconstraints and potentialities for large-scale FES assessment, and mappingandcomparing different Mediterranean contexts.

2. Material and methods

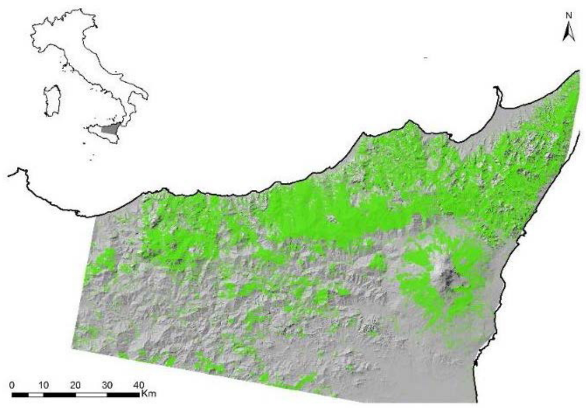
2.1 Study area

The study area is located in Southern Italy, in the north-eastern part of the Sicily region, and covers 962,300 ha (Figure 1). The elevation ranges between the sea level to 3,350 m a.s.l. (Etna volcano). The climate is Mediterranean along the costs, and temperate on the inland reliefs (Rivas- Martinez 2004). Forests and other wooded lands cover approximately 21% of the study area (Figure 1). Downy oak (Quercus pubescens Willd.) (35% of the total forest area), Turkey oak (Q. cerris L.) (13% of the total forest area), and European beech (Fagus sylvatica L.) (9% of the total forest area) are the most widespread Forest Categories (FCs). Plantations cover 17% of the total forest area (Cullotta and Marchetti 2006). The study area is characterized by the presence of protected areas (60% of the total forest area), such as e.g., the Madonie, Nebrodi, and Etna Regional Parks, and several sites belonging to the Natura2000 Network. Part of the forest area (47%) is not actively managed, because mostly covered by neoformation forests, degraded forest lands, often abandoned, and coppice forests exceeding the standard rotation age(mainly left to natural evolution). The remaining area is actively managed, and covered by high andcoppice forests(31% and 20% of the managed forest area, respectively), and forests under "special" management conditions (2% of the managed forest area; i.e. chestnut and cork oak forests).

2.2 The MIMOSE approach

MIMOSE is a spatially-explicit approach to assess, in both biophysical and economic terms, differentFES and related trade-offs in the Mediterranean region, according to alternative management strategies. In the present work, we implemented the MIMOSE approach through the following steps: (i) alternative management strategies (i.e. business-as-usual, BaU; nature conservation, NC; and wood production, WP)

Figure 1. - Map of Italy (left-top) and zoom on the study area. The forest area is reported in green



were applied at the Forest Management Unit (FMU) level in the study area;(ii) the modified InVEST modelwas implementedto quantify and map timber production and carbon sequestration over a 20-year period (from 2015 to 2035);and (iii) a qualitative trade-offs analysis was carried out. Finally, the results from this study were compared with those obtained from Bottalico et al. (2016), in the case of the Molise region. The trade-offs analysis concerns the comparison between the economic benefits derived by FES during the simulation periodby adopting different management strategies (BaU, NC and WP). As main economic benefits, the Total Net Present Value (TNPV; Euro), the Total Social Cost of Carbon (TSCC; Euro), and the Total Ecosystem Services Value (TESV; Euro) were calculated for timber production, carbon sequestration, and their sum, respectively. See Bottalico et al. (2016) for further details about the methodology adopted in this study.

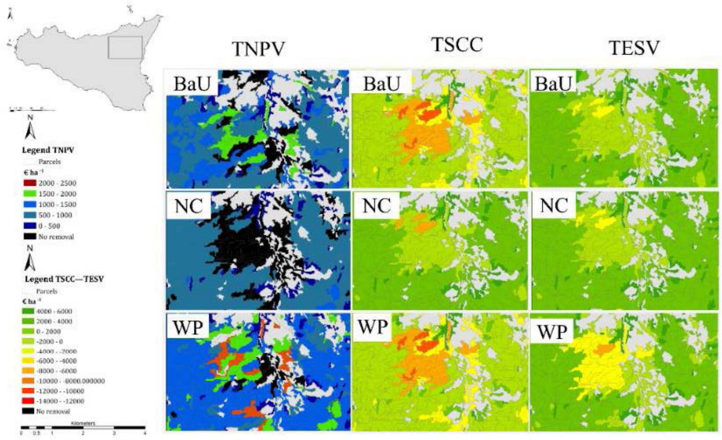
3. Results and discussion

3.1 Forest ecosystem services provision and trade-offs

In the case of timber production, the resultsshowthat the total amount of wood harvested in the area during the 2015-2035 period is 8.8 million m3, 4.7 million m^3, and 12.9 million m^3 for BaU, NC, and WP management strategy, respectively. The corresponding TNPV is 140.6 million Euro, 70.4 million Euro, and 236 million Euro for BaU, NC, and WP management strategy, respectively. In particular, the average amount of timber removals corresponds to 44.2 m^3 ha^{-1}, 23.7 m3 ha^{-1}, and 64.7 m^3 ha^{-1} for BaU, NC, and WP management strategy, respectively. The corresponding average NPV is 707.6 Euro ha-1, 354.4 Euro ha^{-1}, and 1187.3 Euro ha^{-1} for BaU, NC, and WP management strategy, respectively. In the case of carbon sequestration, the resultsshowthat the total amount of carbon stocked in the area during the 2015-2035 period is approximately 1.4 million Mg C, 5 million Mg C, and -2.7 million Mg C for BaU, NC, and WP management strategy, respectively. For carbon sequestration, the negative values correspond to the carbon removed exceeding the current increment during the simulation period. The corresponding TSCC is 83.8 million Euro, 306.1 million Euro, and -167.2 million Euro for BaU, NC, and WP management strategy, respectively. In particular, the average amount of carbon stock increasesof 6.8 Mg C ha^{-1}, 24.9 Mg C ha^{-1}, and decreases of-13.6 Mg C ha^{-1} for BaU, NC, and WP management strategy, respectively. The corresponding average SCC is 421.6 Euro ha^{-1}, 1539.9 Euro ha^{-1}, and -841.4 Euro ha^{-1} for BaU, NC, and WP management strategy, respectively. TESV is 224.4 million Euro, 376.5 million Euro, and 68.8 million Euro for BaU, NC, and WP management strategy, respectively. In particular, the average TESV is 1129.2 Euro ha^{-1}, 1894.3 Euro ha^{-1}, and 345.9 Euro ha^{-1} for BaU, NC, and WP management strategy, respectively.Figure 2 shows some details related to TNPV, TSCC, and TESV in a specific locationof the study area.

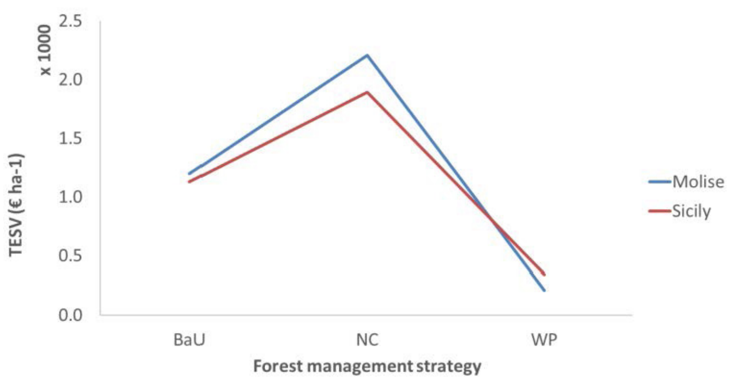
In general, TESV increases of approximately 67.8% when passing from the baseline (BaU) to the more conservative forest management strategy (NC), and decreases of approximately 69.4% towards a more productive strategy (WP). This dichotomous trend is explained by the combination of the forest management strategies (in terms of forest management system applied, harvesting intensity and frequency) and the characteristics of forest stands,such as, e.g., the averagestand age, which is 22 years (in the investigated stands),very close tothe theoretical end of the rotation period in coppice forests, depending on FC (e.g., 15-20 years;Rey et al. 2002). This aspect implies that certain simulated forest practices(e.g., the final cut in coppice with standards forests vs.no forestry intervention in coppice forests) may create a borderline between an increased TESV when adopting a more conservative approach, and a reduced TESV whenimplementing a more productive strategy,ofthe same magnitude. For example, in the case of downy oak forests (covering more than 35% of the total forest area), the reduction of the area subjected to the final cut in coppice forests with standards release (-40.4%) results in an increased TESV (+15.9 million Euro) when passing from BaU to NCmanagement strategy. On the contrary, for the same FC, increasing the area of coppice forestswith standards release (+8.1%) results

Figure 2 - Maps showing the spatial distribution of total Net Present Value (TNPV; Euro ha^{-1}), Total Social Cost of Carbon (TSCC; Euro ha^{-1}), and Total Ecosystem Services Value (TESV; Euro ha^{-1}) for the simulated forest management strategies (BaU=Business as Usual conditions; NC=Nature Conservation; WP=Wood Production) in the Etna volcano surrounding area



in a strong reduction of TESV (-56.2 million Euro),when passing from BaU to WP management strategy. This discrepancy is due to the allocation of a large portion of the downy oak forest areaconverted from coppice to high forest, and left to natural evolution, in the caseof the NC management strategy over the considered period (approximately 40%). In this way, thecarbon accumulation in above-ground biomass in the future is facilitated (cf.Luyssaert et al. 2008). Concerningthe European beech forests (8.5% of the total forest area), thesimulated forestry interventions result in a decreased TESV (-25.7 million uro), when passing from BaU to WP management strategy.This may be due to the fact that e.g., although most of the European coppice with standards forests are actively managed (i.e. harvested), the increasing of TNPV still remains lower in comparison with the decreasing in TSCC, when passing from BaU to WP management strategy. Accordingly, the period chosen for simulations (i.e. 20 years) seems to be short in order to effectively understand the future development of forest stands, and in turn to assess the implications of some forestry interventions on TESV, such as e.g., natural evolution, conversion of coppice forests to high forests. The results show the same trend as synthesized in Bottalico et al. (2016) for Molise region.Figure 3 reports a cross-case comparison of average TESV per hectare between Molise region and Sicily case study.

Figure 3 - Box plot showing the main differences in terms of TESV (ha-1) between both the forest management strategies (BaU=Business as Usual; NC=Nature Conservation; WP=Wood Production), and the two Mediterranean case studies in Italy (i.e. Molise region and Sicily case study)



The average TESV per hectare is higher in the Molise region for the NC management strategy than inthe Sicilian case study,while it is lower for the WP one. This mainly derives from the presence of younger stands, and the implementation of current less intensive forestry interventions in the Sicilycase study, in comparison with the conditions found in the Molise region. In addition, the harvesting rates during the simulation period for the NC management strategy are lower for Sicilian forests, if compared with the Molise ones (55% vs. 62%). On the other hand, the harvesting rates simulated for the WP management strategy are higher for Sicilian forests, if compared with the Molise ones (88% vs. 83%).This is due to the fact that e.g., the European beech forests in the Sicilian case study are mostly located at high elevations, and withinprotected areas. As a consequence, less intensive forestry interventions for these stands were hypothesized when simulating the stand development in the NC management strategy.

The results mainly show that timber provision and carbon sequestration (i.e. climate change mitigation) are in general conflicting services. The biomass removal originateshigh timber revenues (TNPV) and low carbon stock (TSCC), at least in the short run. This indicates that the 20-year simulation period should be extended in order to further understand the development of forest landscapes over time, and find a more balanced TESV. The forestry interventions have to be tailored on the interaction betweenforest management,the biophysical characteristics of the forest stands, and the objectives to be reached (e.g., maximization of timber provision, adaptation strategies). In particular, the combination of the harvesting frequency and intensity with the ecological status of forest stands strongly influences the future FES provision. This is particularly amplified in young stands, whereincreasingharvesting intensity may lead to a strong reduction of biomass, and subsequently of carbon stock in the short period. Especially in Mediterranean forest landscapes, which are often abandoned or degraded (e.g., Scarascia-Mugnozza et al. 2000), forest management and planning must balancetheeconomic incomes with increasedresilience and stability of forest ecosystems (e.g., Vizzarri et al. 2015b). This implies that forest management and planning strategies in these peculiar contexts should be aimed at (i) effectively implementing productive- oriented forest management strategies in healthy and stable forest stands; (ii) reducingharvesting intensity and frequency in less productive forest stands (i.e. conversion to high forests; natural evolution); and (iii) continuously monitoring themanagement outcomes, also with the aid of simulation tools to evaluate future FES provision at different spatial scales.At broader scale, the ecological footprint (China; e.g., Zhao et al. 2009), and the CICES classification (EU; Maes et al. 2016), were proposed as key approaches (i.e. indicators' frameworks) to further understand the human impact on natural capital, and improve the ES flow monitoring.

4. Conclusions

This study demonstrates that MIMOSE is an integrated approach for assessing the influence of alternative management strategies on the FES provision, as well as for understandingthe forest ecosystem dynamics,from the landscape to the regional scale, thus contributing to the statistics and environmental accounting for the forestry sector. In MIMOSE, the integration of spatially-explicit information (biophysical characteristics) with an expert-based approach (management strategies) plays a key role in supporting forest management and planning (Bottalico et al. 2016), at least in the following three ways: (i) current and future-oriented statisticson the development of forest stands are provided; (ii) a spatial distribution (location) of FES is given; and (iii) the effects of forest management alternatives on forest resources is assessed over space and time. Accordingly, the MIMOSE approach can be replicated in other Mediterranean contexts, with relatively low costs, since it is an effective tool for supporting decisionsaimed at implementing more adaptive strategies in changing landscapes, and balancing environmental constraints with socio-economic needs.Finally, the MIMOSE approach is consistent with the need to assess and map ES at multiple scales, in order to detect and monitor the relationships between local communities and natural resources, in terms of e.g., ecosystem structure, processes and final benefits provided (stocks and flows). This is crucial to promote and implement the sustainable development goals, especially in the Mediterranean region (e.g., www.planbleu.org).

ACKNOWLEDGEMENTS

This work was carried out under the research project "Development of innovative models for multiscale monitoring of ecosystem services indicators in Mediterranean forests (MIMOSE)", funded by the FIRB2012 program of the Italian Ministry of Education, Universities and Research (Grant: RBFR121TWX, project coordinator: F. Lombardi).

ABSTRACT

The project aims to identify the quantifiable and permanent variables to assess the overall development of the marine ecosystem of Mostaganem. This identification is based on a methodological approach of dialogue, which is between the social sciences responsible for the identification and characterization of sustainable development in the particular context of Mostaganem marine ecosystem and marine scientists responsible for the representation and quantification of such knowledge. This question is to obtain operational elements for managers in charge of the sector. It therefore underpins the thinking and detailed position on the nature and operation of the system of sustainable management of the marine ecosystem in Mostaganem. The study area is a marine ecosystem known for its biodiversity and its sites of biological and ecological interest. This study provides results on the characterization of Mostaganem coast, diagnosis and analysis of environmentally sites bioecologique, tourism, and socio-economic challenges. This is due to human activities and tourism development alternatives for sustainable development with regard to physical balance and landscape quality of the site. This research used a baseline study and proposes solutions to development problems facing initiatives Mostaganem Marine ecosystem development.

PAPER

1. Introduction

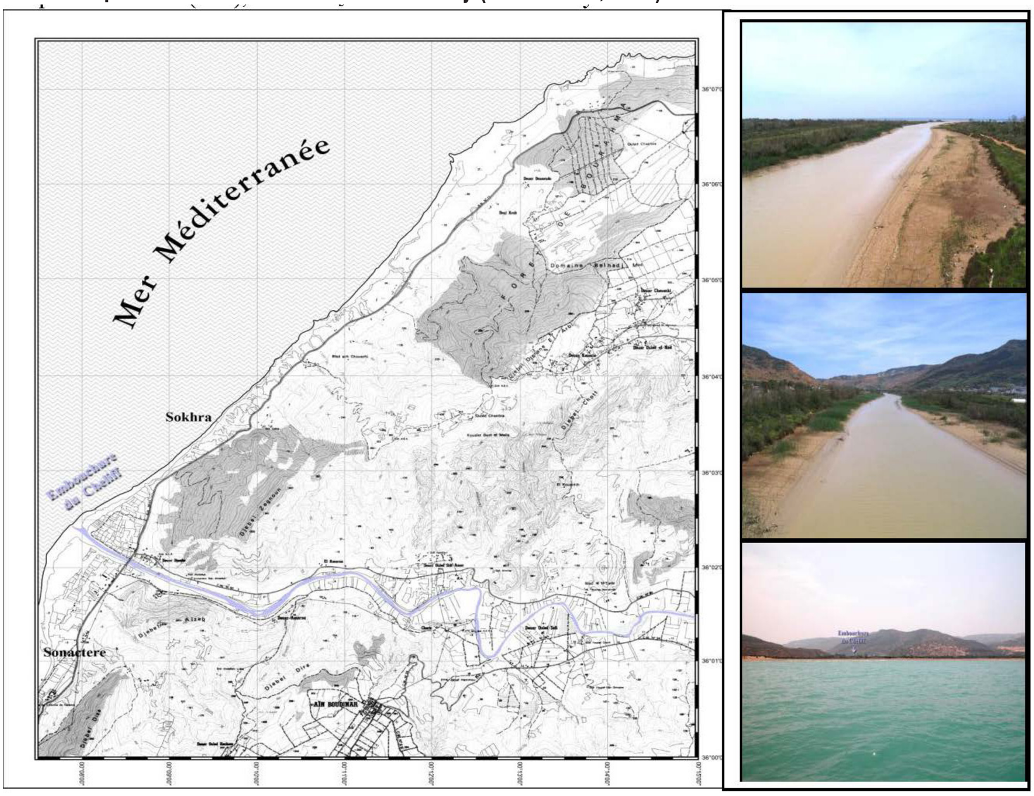
The Cheliff River (Fig. 01) is the largest River in Algeria; it's 700 km long with a flow rate of about 2700 m3/s (Bouzelboudjen & Mania, 1989; Gagneur & Kara, 2001; Al-Asadi et al., 2005, Kies et al., 2012; Kies & Kerfouf, 2014a). It passes through different wilayas like as Mostaganem, Relizan, Ain-Defla and Cheliff. The River of Cheliff is dynamic, extremely variable and plays crucial roles within the structure, the function and also the evolution of the marine coastal of water ecosystems of the bay of Mostaganem (Kies, 2015). Nutrient availability at Cheliff River controls the abundance and structure of phytoplanktonic populations at the bay of Mostaganem. Eutrophication problems are clearly identified in this body of water with micro invasive algae covering its surface at certain times of the year (Kies et al., 2012; Kies & Kerfouf, 2014a; Kies, 2015). Some work on the Cheliff River have indeed established direct links between pollution of the sea state and domestic and industrial wastewater discharges directly discharged into the Cheliff River without any treatment (Bouzelboudjen & Mania, 1989; Kies & Taibi, 2011; Kies et al., 2012; Kies & Kerfouf, 2014a,b; Kies, 2015).

Bay Mostaganem is located in the Algerian west coast. This bay receives urban and industrial discharges via the hydrodynamics of water, swells brewing phenomena and water circulation. Because of the intensification of effluent discharges and many leisure complex construction, the Bay of Mostaganem which was in the past a little disturbed natural environment, is about to turn into a real dump of urban waste. The objective of this study is to assess the physico-chemical quality of surface waters of this bay. Thus, a temporal and spatial study has tracked the seasonal changes in temperature, salinity, pH, dissolved oxygen, ammonium, nitrite, ortho phosphates, Suspended Mater (SM), of BOD5 and COD from January 2014 till December 2015.

2. Materials and methods

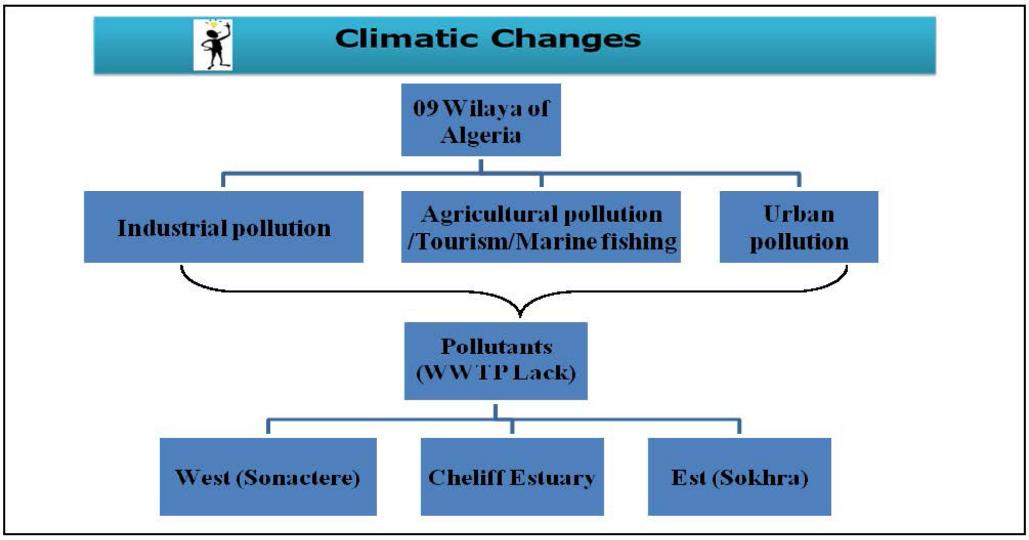
We selected two different stations. The first one "Station 1" located in the River of Cheliff (Sour and Sidi Belattar). The second "Station 2" was fixed on the bay of Mostaganem, which is divided in two regions, the Sokhra bay at the Est of Estuary of Cheliff River and Sonactere bay at the West of the same Estuary (Fig.01 & Fig. 02). Twenty four (24) samples were collected at each station during the studied period (from January 2014 until December 2015).

Figure 1. - Mostaganem map with Cheliff River (colored in blue) and beaches of Sonactere and Sokhra, with the photos of Cheliff River and its estuary (Kies & Taibi, 2011)



We used identification key for species determination (Bougis, 1974) and fomol solution (70%) for fixation of phytoplankton specimens. Algal taxa were identified using an inverted microscope at magnifications of x 400 (Vollenweider, 1971; Rodier, 1996).

Figure 2. - General diagram of the behavior of pollutants in the Cheliff River, the Cheliff estuary and the Mediterranean Sea) (Kies et al. Present research)



3. Results and discussion

3.1. Phytoplankton abundance

A total of 70 phytoplankton species were identified during our survey in the two stations. The dominant cluster is Chlorophyta (along the period of study particularly in summer time) followed by Chrysophyta cluster that proliferates in autumn season 2014. At Station 1 (Tab. 01), the maximum of Cyanophyta (blue-green algae) was recorded in May 2014, and the minimum in January 2015. At Station 2 (Tab. 01), the maximum of blue-green algae was recorded in November 2014, and the minimum in February 2015.

Euglenophyta species were found at Station 1 (River of Cheliff), during the sampling period. A maximum was recorded in August 2014 and the minimum in January 2015. Euglena species were found too during the sampling period at Station 2 (Bay of Mostaganem) with value ranged between a maximum at July 2014 and a minimum at December 2015. The Green algae (Chlorophyta) were dominant at Station 1 than at Station 2 (with 42 and 38 species respectively). In May 2014, the maximum number of green algae was recorded at both stations. The minimum was recorded in January 2015 at Station 1 and in March 2015 at Station 2. The maximum number of diatoms (Bacillariophyta) was recorded in June 2015 at both stations. Low numbers of diatoms were found in November 2014 at Station 1 and in March 2014 at Station 2 during the sampling period. This phylum was found in five of ten occasions at Station 2. The Cheliff River was powerfully dominated by chlorophyll (Gagneur & Kara, 2001; Al-Asadi et al., 2005), whereas the bay of Mostaganem had equal proportions of diatoms (i.e.: *Nitzschia acicularis, Cyclotelle meneghiana*) and chlorophyte (i.e.: *Oocystis, Scenedesmus*).

Table 1. - Seasonal distribution of microalgae in the two stations studied

Phyla	Station 1		Station 2		Genera dominated at 1 & 2	Rare Algae At Sation 1 (Cheliff River)
	Max	Min	Max	Min		
Chrysophyta	06.2015	11.2014	06.2015	03.2014	Nitzschia Navicula Cyclotelle Gyrosigma	Melosira granulata
Chlorophyta	05.2014	01.2015	05.2014	03.2015	Strombomonas Scenedesmus Oocystis Dictyococcus Tetraedron Coelastrum	Pediastrum Tetraedron Staurastrum Cosmarium Monoraphidium Chlamidomonas
Cyanophyta	05.2014	01.2015	06.2015	01.2015	Oscillatoria subsalsa Nostocopsis Microcystis	Oscillatoria tenuis
Euglenophyta	08.2014	01.2015	07.2014	12.2015	Euglena	Trachelomonas

3.2. Connectivity between river and the sea

A follow-up in 2014-2015 of pollution indicators (temperature, pH, dissolved oxygen, ammonium, nitrite, ortho phosphates, BOD5, COD, and SM) in surface waters was carried out in order to estimate the quality physicochemical of the Bay of Mostaganem. The results revealed the existence of a water contamination by domestic and industrial wastewater from the urban area of the nine provinces of the country carried by the Cheliff River marked by significant spatial and temporal variation. By analyzing the graphs of the variables obtained from January 2014 till December 2015 (Fig.03), we have a tendency to notice for this era "of contact" that nutrients [NO2 (nitrites), NO3 (nitrates), NH4 (ammonia), Ptot (total phosphorus), SiO2 (silicates)] area unit terribly dependent parameters with Chlorophyll. a, that support a rise of OM (organic matter) described by the DBO5 (biological demand for oxygen), whereas parameters [OD (dissolved oxygen) and T° (temperature)] area unit associated with the supply of the suspended matter (SM) and to the turbidity (Turb). Since there is a consumption of the varied nutrients (N, P, Si) by the microflora species with nearly identical concentration. Therefore, there is a phytoplanktonic diversity for the period of connectivity between the watercourse and the ocean.

The discharge of wastewater into the environment may cause a rise in temperature. The temperature variations curves of the companies studied have the same evolution, with different amplitudes. The most significant differences are observed in February and April, and the lowest was in rainy season (Bouzelboudjen & Mania, 1989). This relative stability reflects thermal homogeneity of the waters of the bay (Kies et al., 2012; Kies, 2015; Elegbede et al., 2015). Most vital reactions are slowed or even stopped by a significant lowering of the temperature. In contrast, temperature increases can have effects to kill certain species, but also to promote the development of other species resulting ecological imbalance (Kies & Taibi, 2011; Kies et al., 2012; Kies & Kerfouf, 2014b; Bu et al., 2014; Kies, 2015). The pH of the

Table 2 - Variations of Physical and Chemical Parameters

Descriptive Statistics	Obs.	Min	Max	Mean	SD	CV
T	48	8	27	14,13	6,36	2,22

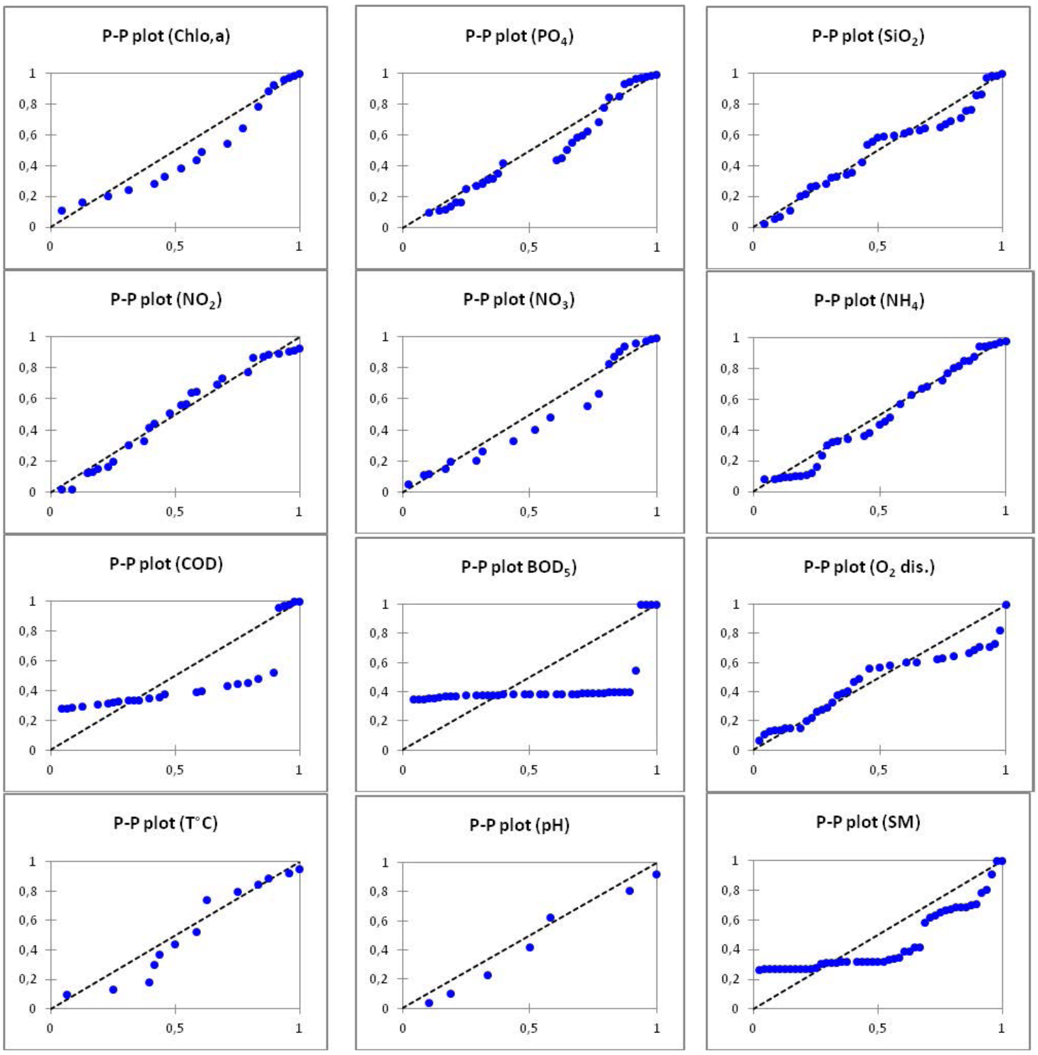
PO_4	48	0.03	2.06	0,88	0,75	1,17

water of Mostaganem bay is relatively alkaline. The seasonal average values are between 7.1 and 8.3 (Fig. 03).

Figure 3 - Monthly changes of the physicochemical parameters during the periods of contact between the River (Chellif) and the sea (Mostaganem shallow water area) during 2013 and 2014



This slight alkalinity shows the influence of sea water generally basic compared to those of continental origin. The highest pH values were observed in April, during the period of strong marine influence and the lowest in June and October, during the rains and floods. For dissolved oxygen, the average values of the dissolved oxygen content of the surface water of the Mostaganem bay fluctuate between 3.9 mg/l and 9.1 mg/l (Fig. 03 & Tab. 02). The lowest levels are obtained in February (Great dry season), related to the consumption of oxygen by the organic matter from wastewater traces. As for ammonium, nitrites and orthophosphates, the high levels of these nutrients observed in the Bay of Mostaganem result of several phenomena whose discharges of domestic and industrial wastewater; ocean and River inputs; the "wash out" by chemical fertilizers rainwater spread on industrial plantations.According to (Kies & Taibi, 2011; Kies et al., 2012; Kies & Kerfouf, 2014b; Bu et al., 2014; Kies, 2015; Elegbede et al., 2015) the concentrations of nutrients in surface waters vary regularly under the influence of border areas (watershed, streams, ocean ...). The discharge of the Cheliff River that is rich in nutrients to the sea of Mostaganem, could explain the high values of the NH4 +, observed in long dry season. The contents of NH_4^+, NO_2^- and PO_4^{3-} high, observed in the rainy season and floods, is explained by the massive arrival in the Bay of wastewater settlements, rainfall runoff, combined with water floods of the Cheliff River (Fig. 02-03 & Tab. 02), rich in nutrients (Kies et al., 2012; Kies, 2015). The pollution level in nutrients determined in this study is relatively high compared to the east side of Mostaganem rating compared to the estuary Cheliff; this classifies the Bay of Mostaganem and Cheliff River among eutrophic (Kies & Taibi, 2011; Kies et al., 2012; Kies & Kerfouf, 2014b; Kies, 2015).For parameters BOD_5, COD and SM in general, the water of the bay are heavily loaded with solid particles and matter in suspension. The highest values were obtained in February and April, during the long dry season and those in the lowest period of rains and floods. This could be explained by the fact that in rainy season, the water circulation becomes weak and suspended particles tend to settle. COD and BOD5 record the greatest values in February and April, during the long dry season, indicating organic contamination of the waters of the bay. The smallest values are obtained in periods of rains and floods.

To characterize the nature of the pollution and degradation of performance, the COD/BOD5 ratios were calculated (Tab. 02). According to (Kies et al., 2012) if the ratio COD/BOD5 is greater than 3, the effluent will be predominantly chemically biodegradable. This study shows that the reports COD/BOD5 are between 3.22 and 4.45; which corresponds to industrial wastewater characteristics with difficult degradation. The descriptive statistics that include all biological and physico-chemical data are presented in Table 02. Between the different stations (Cheliff River, Cheliff Estuary and the Bay of Mostaganem) and different months, the density difference was such that it was necessary to use a logarithmic ordinate for the graph. Graphics univariate quantitative data composed of 48 rows and 16 columns which were rescale from 0 to 100.

4. Conclusions

The results of this study show that the realm close to the Cheliff watercourse would be representative of reference conditions of the Cheliff estuary and also the bay of Mostaganem for its restoration. The class Diatomophyceae and Conjugatophyceae are indicators of pollution with ammonia, but the Dinophyceae are indicator of intense mineralization of the medium. The physicochemical and hydrobiological analysis of samples from the watercourse, the ocean and also the estuary in periods of flooding showed that Cheliff watercourse pours important quantity of pollutants within the watercourse mouth area. Contaminated waters issued by nine wilayas of the country are fed by the Cheliff River to empty into the Bay of Mostaganem. The pollutants are urban, agricultural and industrial.

The study discovered the presence of nitrogenous substances, phosphorus and sulfur; suspended matter (organic and inorganic) is significant. Consistent with the scientific observation conducted between January 2014 and December 2015, detected pollutants have adverse effects on wildlife and on the marine life of the bay of Mostaganem, notably within the area of the mouth of Cheliff. Owing to the winds of the East and coastal ocean currents that result, polluted waters are moving in times of floods to the west coast and might sometimes reach the beach of Sablettes (December 2015 wherever precipitation reached 156.5 mm). The large quantities of solid particles found in the water prevent the penetration of daylight, for this, the development of the flora is reduced to a minimum in the area of the mouth as is confirmed by the observation during marine's immersion. Additionally, it is probable that the flora like Posidonia oceanica meadows cannot be established within the space of the study due to the robust horizontal currents and the nature of the substrate (sandy bottom mixed with clay). This vegetable poorness so involves a really low diversity of fauna.

Companies Wilayas upstream of the Cheliff River minimize production charges by rejecting waste that can makes damage in the Wilaya of Mostaganem (downstream). So the problem of pollution from Cheliff watercourse isn't a matter of "all or nothing" however rather a case of "more or less". This can be explained by the fact that the results of the pollution increase with the degree of contamination and also the price of non-pollution decreases with it. This work showed the influence of Cheliff watercourse on the marine ecosystem, as well as negative effects on the phytoplankton and plants life, that has a real disturbance on abundance.

5. Recommendations

The intervention of the authorities is essential to reduce pollution at the optimum level. To reach acceptable levels, they should be equipped with policy instruments such as the imposition of a solution on polluters and victims of pollution which minimize costs that they bear together. Each Wilaya upstream to increase its interest cost of abatement and the Wilaya downstream to increase the cost of the damage; the introduction of compulsory treatment of wastewater from urban and industrial activities before they are released into the environment; promotion of scientific knowledge through research and information; dissemination of scientific knowledge and environmental education; revision of standards relating to water pollution, taking into account the concentration of the pollutant because the polluter can increase the amount of water that contains a polluting effluent that meets the standard, so they have consider the damage generated by the concentration of the pollutant per unit of time, not only the amount of the pollutant; establish a land use plan (and coastal) or physical planning; this instrument would, in relation to the possible establishment of new heavy and polluting industries, to prevent pollution of the coast of Mostaganem. It takes thorough foundation for economic demand and ecological data studies, namely climate change, the susceptibility of the soil and plant pollution, hydro-chemical, bio-chemical and hydro-biological. The economic argument should be directly related to the importance of the environment.

DOI: 10.1481/icasVII.2016.d25d

ABSTRACT

Landscape is characterised by interaction of natural processes and cultural feature. Human activities affect landscape and landscape linear elements such as hedges, dry stone walls, ditches, roads and railways influence biodiversity; landscape analysis requires an appropriate set of information able to describe land cover diversity and fragmentation. Since 2006, Eurostat carries out an area frame statistical survey on the state and the dynamics of land use and cover in the European Union called the LUCAS survey (Land Use/ Cover Area Frame Survey). The LUCAS surveys are completed in-situ every three years. LUCAS provides information for monitoring a range of socio-environmental challenges, such as land take, soil degradation, and the environmental impact of agriculture or the degree of landscape fragmentation. The latest LUCAS survey, carried out in spring - summer 2015, covers all the 28 EU countries and observations on more than 270 000 points. To this extent, we consider the latest available data collected by the LUCAS surveys in the years 2009 and 2012. The analysis can be generalised to LUCAS data 2015 when available.

The aim of the paper is to attempt of using the data collected by LUCAS survey for landscape analysis in an evolving system such as the EU countries, providing an appropriate set of information able to describe the landscape diversity and its fragmentation in agricultural land, jointly with the changes in land cover and in land use. In particular the paper shows an example of use of the informative capacity of LUCAS survey in describing and monitoring the variation of the territorial structural elements.

Keywords: landscape fragmentation, transect, data analysis

PAPER

1. Introduction

The impact of human activities on the land cover has grown enormously, being able to alter entire landscapes with important ecological consequences. A landscape refers to an area of land whose character and functions are defined by the complex interaction between natural processes (relief, soil type, water availability, climate, biological diversity) and cultural features (human intervention through agriculture, forestry, rural policies, construction and economic structures). European countryside is also characterized by structural linear elements that portray the joint role of nature and humankind on environment. The presence of grass verges, hedges, dry stone walls, ditches and other semi-natural linear elements is considered as an important factor to biodiversity, in some cases helping to promote ecosystem services (such as pollination or pest control), in others constituting negative barriers that could limit the movement of species. In this sense can be intended, for example, all those linear elements which have a dissecting nature (such as roads, railways and aerial cables), that are closely linked to population and infrastructure developments, and impact on biodiversity.

The analysis of these topics, in an evolving system such as the EU countries, requires exploiting an appropriate set of information able to describe the landscape diversity and its fragmentation in agricultural land, jointly with the changes in land cover and in land use. To this extent, we consider the data collected by the LUCAS (Land Use and Cover Area frame Survey) surveys in the years 2009 and 2012. The analysis will include LUCAS data 2015 when available.

LUCAS survey is carried out at EU level every three years; it is based on a sample of about 270 thousands geo-referenced points, selected from a frame of more than 1 million of points that belong to the intersections of a 2 square km grid built all over the EU territory. LUCAS is carried out by direct observations of surveyors in a small area centred on the selected point (with a width of 20 square meters). For each of them information on land cover (i.e. the bio-physical coverage of land, like natural areas, forests, buildings and roads or lakes) and of land use (i.e. the socioeconomic use that is made of land, like agriculture, commerce, residential use or recreation) is collected; it is allowed to get a main and a secondary land cover and land use codes. Moreover, the surveyors take a series of photographs of the point itself, and of what in all four cardinal directions (north,

[1] Contribution to the ICAS VII: Rough draft on gender and rural women's empowerment in relation to DW/rural employment.

south, east and west); some specific information are also collected as "ad hoc modules" added in each survey (top soil sample in 2009 and the transects in surveys 2009 and 2012).

The aim of the paper is to attempt of using the data collected by LUCAS survey for landscape analysis and to check the performances of the survey in describing and monitoring the territorial structural elements. The analysis is carried out considering the level “Country” because of the simplicity in presentation, even if the same methodology can be easily extended to regional level. The richness of the LUCAS classifications allows defining agricultural areas in different ways; in this context we referred to an extensive definition that considers the points belonging to Cropland and Grassland or characterized by a land use of agriculture (including fallow land, kitchen gardens) or forestry. The selections were made over the main or secondary land covers and land uses values. Moreover, in order to facilitate the comparison, only the countries that participated to the survey in both 2009 and 2012 are considered. These conditions led us to consider 23 countries and about 75% of their total area. In the following analysis, a set of indicators derived from the transects and concerning the richness and fragmentation of landscape are defined, calculated and synthetized with multivariate techniques on weighted data.

2. The Transect in LUCAS survey

Transect in LUCAS survey consists of a straight line walk of 250 meters in an eastwards direction from the point, where surveyors record the transition of the different land covers and of the linear elements, according to a specific classification in the sequence of their appearance (figure 1). Land covers are collected by means of the first digit of the standard LUCAS definitions (table 1).

Figure 1 -Transect information collected by LUCAS

Table 1 - Land cover classification, LUCAS 2009 - 2012

A	*Artificial land*	*E*	*Grassland*
B	*Cropland*	*F*	*Bare land*
C	*Woodland*	*G*	*Water*
D	*Shrub land*	*H*	*Wetland*

The linear features include 19 elements such as walls, hedges, roads, railway lines, irrigation channels or electric power lines; these features are taken into account if their width is larger than 1 meter (with the exception of walls ditches electric lines and fences) and at least 20 meters long. These elements could be grouped into five main subclasses, with a further distinction by considering a positive or negative impact on the biodiversity (as identified by experts in the topic) or classified according to their capacity to structure the countryside or to cause dissection of landscape (table 2). It has to be noted that the evaluation of the impact depends on the environmental context. Single bushes or single tree

Table 2 - Linear element classification, LUCAS 2009 – 2012

Linear element	Macro classification	type	Impact
Grass margins <3m	Green linear feature	structure	++
Heath/Shrub, tall herb fringes <3m	Green linear feature	structure	++
Single tree, single bushes	Green linear feature	structure	+
Avenue trees	Green linear feature	structure	+
Conifer hedges <3m	Green linear feature	structure	+
Bush/tree hedges/coppices, visibly managed	Green linear feature	structure	+++
Bush/tree hedges, not managed, with single trees	Green linear feature	structure	+++
Grove/Woodland margins (if no hedgerow) <3m	Green linear feature	structure	+++
Dry stone walls	Rock/stone linear elements	structure	++
Artificial constructions (other than dry stone walls)	Infrastructure linear elements	dissection	--
Fences	Infrastructure linear elements	dissection	--
Electric lines	Infrastructure linear elements	dissection	---
Ditches, channels <3m	Water linear feature	structure	++
Rivers, stream <3m	Water linear feature	structure	+++
Ponds, wetland <3m	Water linear feature	structure	+++
Rocks, outcrops with some natural vegetation	Green linear feature	structure	++
Tracks	Transport linear feature	dissection	--
Roads	Transport linear feature	dissection	--
Railways	Transport linear feature	dissection	--
Other linear elements	Other	dissection	0

could be positive (e.g. solitary trees in grassland) or part of a degradation process if remnants of tree lines. Avenue trees are positive for biodiversity, but completeness has to be taken into account. Conifer hedges are positive for biodiversity in boreal or alpine regions, where they are part of natural forest, and negative in Atlantic regions where they are part of gardens in residential areas. Visibly managed bush and tree hedges (pollarded) indicate a cultural landscape, that's well managed, probably rich on birds. Not managed vegetation deriving from abandonment can show plant species decline, but they can be good for larger mammals. Groves are mostly important for birds, butterflies and plant species.

Dry stone walls are relevant for plants, reptiles, insects and mosses, while other artificial constructions are barrier for natural species. Fences potentially constitute a bar and together with electric lines disturb landscape aesthetics. Water linear elements are in general positive for biodiversity, depending on the quality of the water or the vegetation along, or whether permanent or temporary water; ditches can be negative for the landscape (drainage of wetlands) and temporary ponds can be important habitat. Transport linear features (tracks, roads and railways) can be absolute barriers for invertebrates.

Land covers that characterize the transect are used to represent the richness of the landscape in terms of diversity, while the linear elements were considered as indicators of fragmentation. They can be calculated at elementary level or grouped according to the definitions reported in table 2 or by aggregations based on statistical analysis (see the next paragraph).

3. Dissection elements analysis

Generally synthetic indicators are previously identified and then applied to data to be analysed; they can be based, for example, on one or more classifications reported in table 2 as already done (Palmieri A, Dominici P, Kasanko M., Martino L., 2011). In this paper we propose a different approach: in the first place to analyse the data in order to identify relationships between variables and, on this base, to build up the indicators.

An analysis of the fragmentation (the variables in the first column of table 2) was made to verify the existence of a relation within the linear elements and between them and the countries, or, in other words, whether and how the fragmentation elements are able to shape groups useful to calculate synthetic indicators and to discriminate the countries; the analysis was carried out both on 2009 and 2012 survey data. To this purpose, the correspondence analysis (CA) (Benzécrì, 1973) was used. Starting from the table of cross frequencies of the linear elements by countries, CA allows to graphical identify the correspondence between the row categories (in our case the countries) with the column ones (the different kinds of linear elements). Such correspondence is obtained by projecting all the categories in a ĉcompromise spaceč(usually of dimension 2, i.e. a place). The coordinates of such projections are obtained by taking into account the row and the column profiles; this permits to take into account a metric that is not influenced by the different marginal totals.

To verify the effects of the years (2009 and 2012), we conducted a CA by considering the projections of the variables as estimated for the 2012 and, in the resulting space, we projected the countries according to the distribution of transects as observed in 2009.

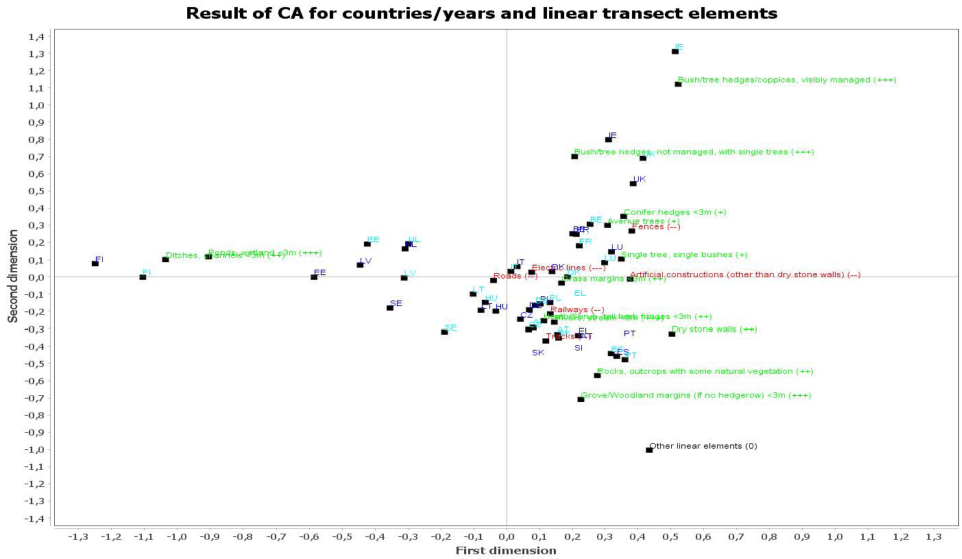
The first result obtained by the CA analysis allows identifying groups of linear elements that can summarise the fragmentation of the landscapes. In particular it is possible to create six groups, each of these defined by considering the projections as in figure 2. In particular:

- Ditches, channels ←3m, Ponds, wetland ←3m;
- Single tree, single bushes, Avenue trees, Conifer hedges ←3m, Bush/tree hedges/coppices, visibly managed, Bush/tree hedges, not managed, with single trees;
- Grass margins ←3m, Heath/Shrub, tall herb fringes ←3m, Rivers, stream ←3m, Dry stone walls, Rocks, outcrops with some natural vegetation, Grove/Woodland margins (if no hedgerow) ←3m;
- Tracks, Roads, Railways;
- Artificial constructions (other than dry stone walls), Fences;
- Electric lines.

For each group it was calculated an indicator that represents the relative frequencies of its linear elements on their totals; the indicators have been calculated on each point surveyed in the LUCAS framework.

Moreover, as second result, the CA allows us to describe the relations between the linear elements and the countries. In particular Finland, Estonia, Netherland and Latvia are grouped and characterised by ditches and ponds (it has to be noted that the rivers, initially classified in the same water linear feature are, instead, positioned in the opposite quadrant). Bush/tree, conifer hedges and avenues trees are features that seem typical of Ireland, UK, France Belgium and Luxembourg. Heath/Shrub, rivers,

Figure 2 – Projections of countries by year (2012 in blue and 2009 in cyan) and of the linear transect elements (in red those with a negative impact and in green those with positive impact) as resulting from the Correspondence Analysis



grove/woodland margins, rocks and fry stone walls characterize Spain, Portugal, Greece, Austria, Slovakia and Slovenia. The remaining countries/linear features are, instead, not well interpretable because projected near the barycenter of the axes, that represents the area in which the relations are not discriminant. Another interesting result of the CA relies on the fact that the countries maintain their relative position between the two years, showing a stability in their characterization.

4. The landscape diversity indicators

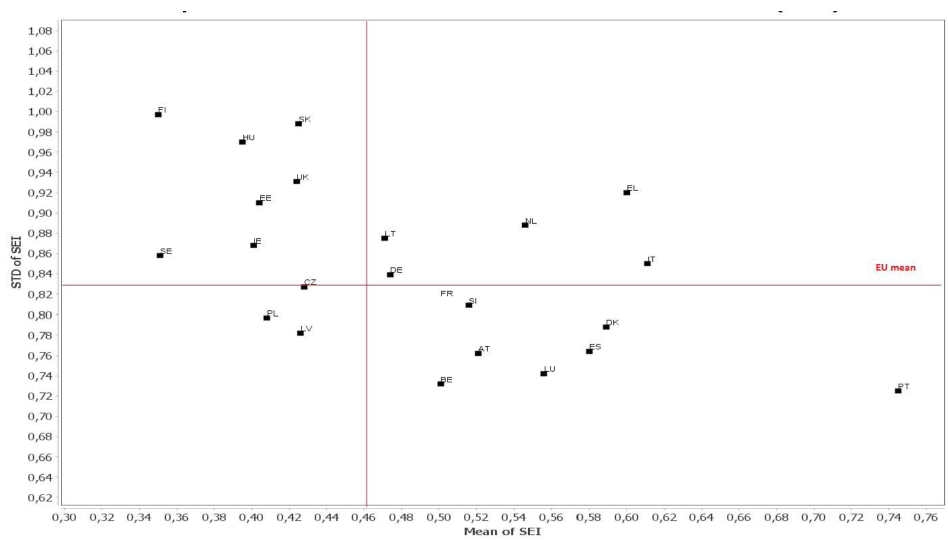
A direct measure of the degree of homogeneity or heterogeneity in terms of the physical coverage of the land can be drawn by the number of different land cover types (see table 1) observed in each of the transects surveyed.

The information on different types of land cover and their relative abundance (i.e. whether the same type of land cover recurs in a transect) can be summarised by means of two Shannon indices (Palmieri et al., 2011): the Shannon Diversity Index (SDI) and the Shannon Evenness Index (SEI).

The latter, obtained by dividing the SDI by its maximum value, is easier to read, as it varies between 0 (no diversity, i.e. a single land cover type) and 1 (maximum observed diversity combined with complete evenness).

To verify the discriminating capacity of SEI, further indexes are computed: 1) mean values at country level of SEIs, calculated for each point; their distribution is reported, for the year 2012, in the scatterplot in figure 3; 2) SEI standard deviations, taken as indicators of the heterogeneity of the index within the countries are also shown in vertical axis.

Figure 3 – Scatterplot of means and standard deviations of the SEI indexes for each country, as observed in LUCAS 2012 (the red lines identify the values for EU)



Analysing the SEI distributions for 2009 and 2012 it is possible to characterize the countries in four main typologies, considering those with a higher, or lower, value of the diversity index and, respectively, its variability. In particular Czech Republic, Poland and Latvia seems to have a higher homogeneity in the land cover with a less variability in respect to Finland, Hungary, Slovakia, UK, Estonia and Belgium, also characterized with a less diversity in land cover. Latvia, Netherland and Greece, instead, have a higher diversity index, but also more changing in their territories than the remaining countries. Because of its potentiality in discriminating the countries, SEI index is taken into consideration in analysing landscape together with dissection indexes.

5. The landscape analysis

As shown above, dissection as well as diversity indexes can be used separately to analyse the countries landscape but a different approach can be adopted. A further analysis has been carried out by considering together two sets of indicators; on one hand the six synthetic indexes, built up according to the grouping of linear elements identified in paragraph 3, and the SDI diversity index of land cover. On these seven indicators, a principal component analysis was carried out in order to obtain the latent variables (factors) representing the optimal combination of the indicators not affected by multicollinearity. The groups where identified by means of a disjoint cluster analysis (based on the K-means algorithm) applied on the resulting factors and the optimal clustering of the countries landscapes per year was obtained.

The analysis identified four clusters; they are characterized in terms of the original seven indicators by considering their mean value per cluster that more discriminate the groups; figure 4 reports the means for EU and for each cluster in the years 2009 and 2012.

Figure 4 – Mean values of the indicators for the dissection linear elements and for the SEI index as observed in EU and as obtained by the cluster analysis on the countries/years

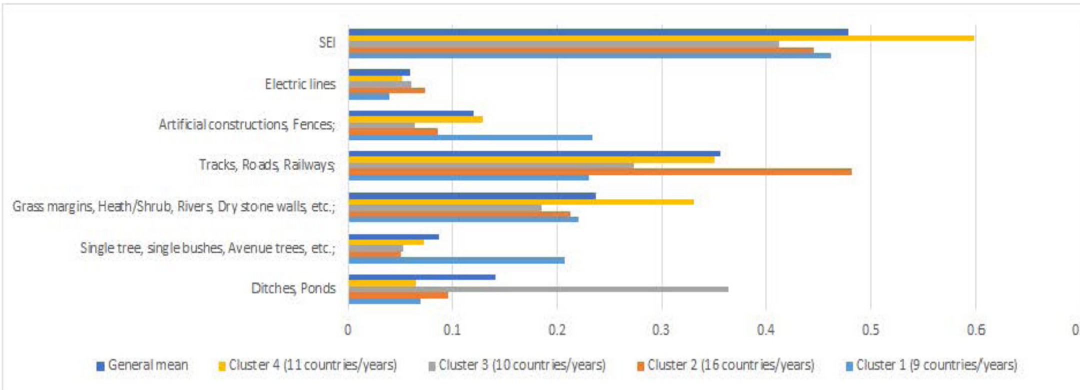


Figure 5 – EU countries according to the cluster to which they were attributed

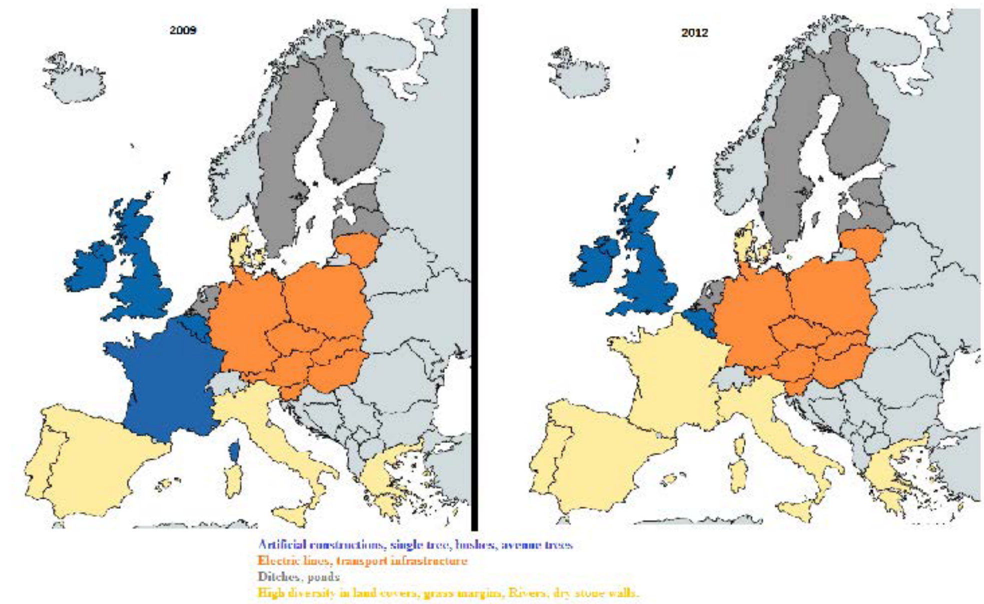

The analysis allows us to label the clusters in the following way:

- Cluster 1: Artificial constructions, single tree, bushes, avenue trees, medium diversity in land covers
- Cluster 2: Electric lines, transport infrastructure, medium diversity in land covers;
- Cluster 3: Ditches, ponds, lower diversity in land covers;
- Cluster 4: Higher diversity in land covers, grass margins, Rivers, dry stone walls.

Maps in figure 5 report, for the years 2009 and 2012, the different countries coloured according to the cluster in which they are classified. The maps show a stable classification among the two survey years except for France that passes from an ǍAtlanticčcluster to a ǍMediterraneančone. The country indicators in 2009 were close to the new group and so the change it is probably due to sample variations that in 2012 privileged the south points with regards to the north ones. Denmark, in both years, is classified in the “Mediterraneančcluster mainly because of its value of the Shannon index, which shows the diversity of land covers in comparison with the other countries/groups.

5. Conclusion

The paper shows how data collected by LUCAS survey, allow landscape analysis in an evolving system such as the European Union countries, and provide an appropriate set of information able to describe the landscape diversity and its fragmentation in agricultural land, jointly with the changes in land cover and in land use. In particular the paper describes how the application of multivariate statistical techniques is able not only to describe and discriminate different landscapes typologies in different countries but also to identify a set of indicators to support and complete the ones derived from the dissection elements classifications. The stable results obtained in correspondence and in cluster analysis could indicate that variations in point's selection and in data collection do not affect substantially the capacity of LUCAS in monitoring the EU landscape, even though a pure panel approach is to be preferred for a periodical monitoring.

The above analysis is a first attempt to exploit the potentiality of LUCAS using multivariate analysis on specific indicators derived from LUCAS primary data. The methodology can be fine-tuned using other indicators derived from auxiliary information collected by the survey; moreover the heterogeneity within countries, at level of regions and/or elevation classes, can be further studied in order to obtain a more analytical description of the EU agricultural area and probably a new picture of the variations over the time. We are including in the analysis the data from 2015 survey and results will be compared for different land cover classes; this will allow us to improve the system of indicators and to verify their dynamic. As far as regional context is concerned the efficiency of sample with panel structure has to be studied too.

LUCAS transects allow to study the richness of the land cover and of its dynamic though the years. The information could be used in estimating proper models to analyse agricultural systems when enriched with other information.

Other approaches for landscape observation, based on remote sensing or administrative sources are not included in this paper but the integration of such information could offer new opportunities in ameliorating the analysis. Both predefined and derived indicators, combined with suitable auxiliary information can be used for monitoring territory at macro level.

LUCAS micro-data are freely available to the user by direct download from Eurostat web site

ABSTRACT

Biodiversity affects the stability of ecosystem services, which in turn affects agricultural productivity and therefore global food security. The nature of the linkages between biodiversity and food security vary across temporal and spatial scales and are influenced by socio-economic drivers of agricultural systems. Based on existing literature, this paper outlines the relationships between biodiversity, ecosystem services and food security. It additionally reviews tools which can be used to integrate biodiversity and ecosystem services into analytic frameworks to allow a better understanding of the trade-offs between different agricultural systems and their ecosystem services provisioning, as well as the resulting impact on productivity and human well-being.

Keywords: *trade-off*, Agricultural systems, Ecosystem services, Model integration

PAPER

1. Introduction

There is increasing evidence that plant biodiversity increases ecosystem services (ESS) stability (Hautier et al. 2015), and that selection of appropriate land-use patterns and agriculture management practices not only increase productivity but also mitigate and enhance adaptation to climate change (Powers 2010; MA 2005). Conversely, poor production and management choices lower agricultural productivity and food security as a result of degraded land, scarcity and reduced quality of water, increased pest and disease risks, and loss of natural pollinators. Given this relationship between the health of ecosystems and economic development, including food and nutritional security, the global community adopted a sustainable development agenda at the 2015 UN General Assembly (UN 2015). This agenda includes the goals of sustainable agricultural production (under Goal 2); management of water (Goal 6); management and efficient use of natural resources (Goal 12); and protection, restoration and promotion of sustainable use of terrestrial ecosystems (Goal 15). The CGIAR similarly identifies improving natural resources and ecosystem services (ESS) as one of its high-level outcomes in its Strategy and Results Framework (CGIAR 2015) and has adopted a systems approach for its 2016-2022 research agenda. The establishment of these global development goals and frameworks for actions provide an opportunity to fully integrate biodiversity and ESS in the global agriculture research and development agenda, to not only improve food and nutritional security but also to achieve healthier agricultural ecosystems.

Understanding the multiple interactions between land use, management, environmental pressures and ESS is complex with interdependencies, trade-offs and tipping points. Understanding environmental, social and economic drivers requires transdisciplinary approaches. This paper explores some of the emerging approaches to integrate biodiversity and ESS into economic analysis of agricultural systems, particularly into those models designed to forecast the impact of potential investments and innovations on future productivity. Much of the discussions in this paper are based on a workshop convened at Bioversity International May 2015 (Rojas et al. 2015). In the following section, challenges faced in integrating biodiversity and ESS in economic models are discussed. The conceptual framework is then presented, highlighting the link between cropping patterns, practices and environmental outcomes. The next section discusses bio-economic models at different scales (from local to economy-wide). The paper closes with some discussions and conclusions for further work.

2. Challenge in integrating biodiversity and ESS in economic models

The productivity of agricultural ecosystems depends on ESS provided by natural ecosystems (Power 2010). According to the global initiative ďThe Economics of Ecosystems and Biodiversityč(TEEB), ESS are ďthe flows of value to human societies as a result of the state and quantity of natural capitalč(TEEB 2010). The Millennium Ecosystem Assessment (MA 2005) describes four categories of ESS: supporting services (e.g. soil formation, photosynthesis and nutrient cycling), provisioning services (e.g. fresh water, food, fuel and timber), regulating services (e.g. climate regulation through carbon storage and water cycling) and cultural services (e.g. recreation, spiritual, educational and aesthetic). Some examples of ESS related to agricultural ecosystems which affect productivity pertain to supporting services and include pollination, biological pest and disease control, maintenance of soil structure and fertility, nutrient cycling and hydrological services (Power 2010).

Biodiversity, among other factors, plays an important role in the provision of these services (MA 2005). Hautier et al. (2015) demonstrate a positive correlation between plant species biodiversity and ecosystem stability. Plant biodiversity affects soil nutrient content and therefore soil quality (Hajar et al. 2008; Ponisio et al. 2014; Mulumba et al. 2012). Selecting the right mix of crops rather than using one or a few dominant crops can dramatically increase crop water-use efficiency (West et al. 2014; Brauman et al. 2013). Biodiversity on farms and on landscapes provides broad genetic variations in plants and animals that is essential for adaptation and for resilience against future threats from pests and diseases (Heal et al. 2004; Hajar et al. 2008; Garrett and Mundt 1999). Increased crop diversity is shown to enhance pollinator health (Garibaldi et al. 2014; Isaacs and Kirk 2010). These ESS are also influenced by factors other than biodiversity and can be difficult to measure. Nevertheless there are ongoing efforts to identify metrics which can be used as indicators of these services (Biodiversity Indicators Partnerships 2015).

Biodiversity can be considered in two different contexts, intraspecies biodiversity and interspecies biodiversity. Intraspecies biodiversity is diversity within a single species while interspecies diversity is diversity of different types of organisms in a given ecological system. Both types of biodiversity are essential for stability in ESS and thereby for sustainable food production systems. The relevance of each biodiversity type, when used in analysis or in policy discussion, depends upon the scale at which the issue is being discussed or analyzed. The added complexity for analysis therefore involves consideration of context-specific types of diversity and the appropriate scale for the analysis.

Another important consideration from an economic and political point of view is the public goods nature of biodiversity and ESS. This means that they exhibit neither rivalry nor excludability. Rivalry refers to whether one agent´s consumption is at the expense of another agent´s consumption. Excludability indicates if some agents can be prevented from consuming a good by other agents (Perman et al. 2003). While some aspects of ESS such as pertaining to specific fields may be enjoyed privately by its owners, improved ESS resulting from preserving biodiversity can generally be enjoyed by all. Moreover, the costs of maintaining or enhancing agricultural biodiversity and ESS are usually incurred by individual landholders or operators and these are costs which occur in real time. The returns from these activities, which are enjoyed by all, however, may occur over a long period and may not cover the costs of the operator in the short term. Thus, inclusion of biodiversity and ESS into bioeconomic models requires addressing temporal and spatial challenges of private costs incurred in the short run for generating public goods in the long run.

Finally, the analysis of possible impacts of innovation, changes in biodiversity, and other interventions on ESS and, consequently, on agricultural productivity necessitates a systems framework and requires consideration across multiple scales. Interventions at the field and farm-level, including changes in biodiversity, affect the future flow of relevant ESS and, in turn, the agricultural productivity at any given site. Changes in policy or farm practices affecting the longer-term income potential of affected households, can cause a multiplier effect on future rural economy and even, in special cases, affect future national economy. Moreover, economically driven short-term land management decisions made by farmers at small scales can add up to drive ecological changes across whole landscapes across longer timeframes. Therefore, agroecosystems are intrinsically associated with natural ecosystems (Nicholls and Altieri 2004) and changes to agricultural landscapes affect the health of forests, wildlife, rivers, seas and other natural habitats. These changes in turn affect human activities and economic benefits associated with these habitats.

ESS depend on the interaction of multiple ecosystem types at different temporal and spatial scales, characterized by dynamic and non-linear relationships (Balbi et al. 2015; Bateman et al. 2012; Bennett et al. 2009), and the production of ESS in agricultural systems depends on the services provided by neighboring ecosystems (Power 2010). In recent years, significant strides have been made in analytic tools and computing capacity for work in this area (Rojas et al. 2015; Antle et al. 2015). These efforts have generally emerged from within different disciplines or, as in the case of integrated assessment models, have occurred in multidisciplinary teams. However, a concerted effort has not been made to model and study the trade-offs associated with agricultural production between productivity and environmental sustainability at multiple scales, taking into consideration agricultural biodiversity and ESS.

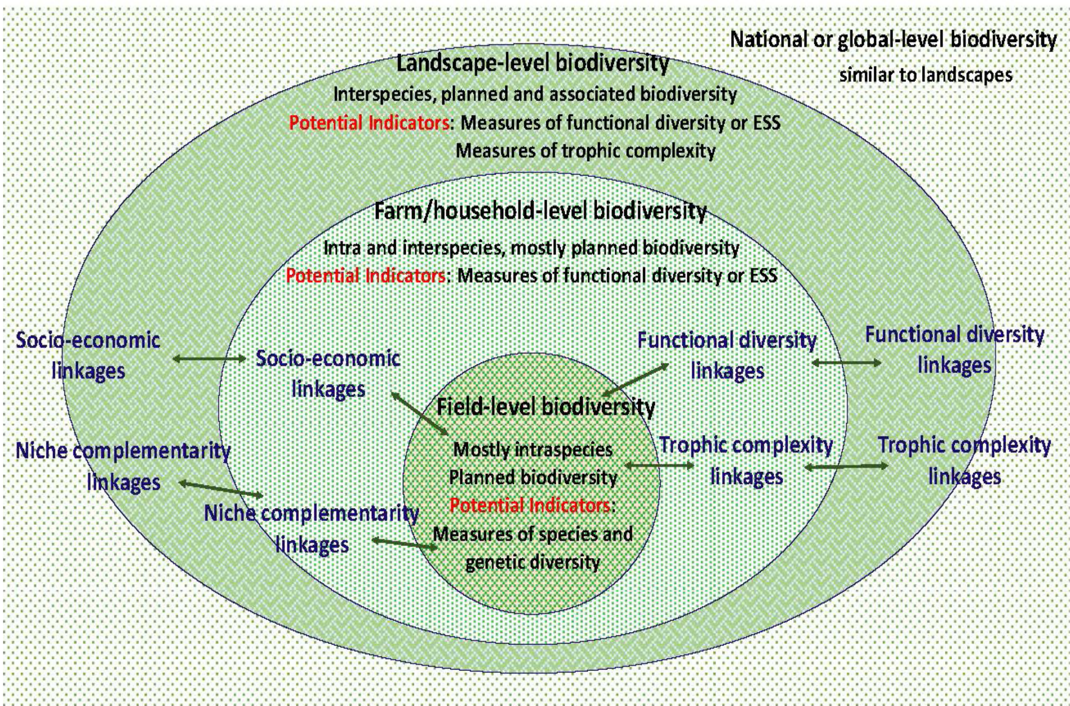
3. Conceptual framework for analysis

Nicholls and Altieri (2004) separated biodiversity in agroecosystems as *planned biodiversity* and *associated biodiversity*. Planned biodiversity is all life intentionally put in the ecosystem and varies with space, time, and other ecological conditions while associated biodiversity is all life that is attracted to, benefits from, and in turn contributes to planned biodiversity. The linkages between these are often established through *functional diversity*, the range of activities that organisms within an ecosystem perform. These include a variety of biological processes, functions or characteristics of a particular ecosystem, which connect a given agroecosystem to the health of the broader planned or associated ecosystems such as through ESS, for example soil quality, pollination or biotic and abiotic resilience. Another important linkage between planned and associated biodiversity is niche complimentarity which refers to the condition when different organisms use the same resource in different ways without directly competing with each other. Finally a third relevant aspect of connection between the two sets of biodiversity is *trophic complexity*, which indicates interactions between organisms at different levels of predation. These linkages between planned and associated biodiversity illustrate how the two systems, which could further extrapolate to socio-economic systems, are inter-connected. The precise relationships linking the two systems provide means of identifying measures for monitoring biodiversity and the possibility of using these measures as input in modeling exercises. For example, under certain conditions, information on soil quality, pollination, or a measure of trophic complexity can be used as either a reflection or an outcome of the existing status of biodiversity. The use of such measures would first need to be validated by studies which indicate their appropriateness for a given context.

Much of the past agriculture literature has tended to focus on planned biodiversity. Studies have mostly dealt with biodiversity within the context of 1 or 2 components of functional diversity, such as productivity (Li et al. 2009) or tolerance to biotic and abiotic stress (Costanzo and Bàrberi 2013). Yet it is known that practices on fields or a farm affect many components of biodiversity such as functional diversity, shift niche complementarity, and may consequently result in significant permanent changes to trophic complexity. Therefore models designed for the analysis of long-term agricultural productivity should consider analysis across multiple scales, taking into consideration the vertical linkages across scales as well as the horizontal linkages across sectors.

First at the field level, the effect of a choice of planned biodiversity on ESS and consequently its impact on productivity must be understood. At this level, activities and studies may focus on intra-species analysis, although inter-species is an important consideration in developing countries. Analyses additionally need to consider the connectivity between farm practices and non-cultivated areas within the farm and the impact of all practices on ESS (Fig 1). Second, how biophysical outcomes (including yield) of farming choices and practices affect social and economic dimensions are important aspects for consideration. These aspects may need to be examined at the farm or at the household level, with due consideration or incorporation of biophysical relationships. Third, the implications of choices made at the field and farm-level need to be fully examined at the agricultural sector level. This analysis needs to take into consideration how changes in planned biodiversity affect: the crop mix; implications for nutritional outcomes; the rural economy; and, as desired, the broader agro-economy and trade at the national and global level. Finally, agricultural sector level decisions and changes affect decisions, choices and outcomes in other sectors, including back on biodiversity and ESS. Also as earlier discussed, biodiversity status in planned agroecosystems affect biodiversity in associated non-agricultural ecosystems. Therefore the analysis of potential interventions at the field level need to be viewed within the broader economy-wide context.

Figure 1 – Conceptual framework for biodiversity assessment at different scales



As a basic conceptual framework any model designed for analysis of sustainable agricultural systems needs to incorporate the chain of linkages between changes in planned biodiversity and associated biodiversity, regardless of the scale of analysis. It is also useful to note that there can be multiple objectives along these chains, such as achieving food security, healthy diets, higher incomes, better livelihoods, resilient soils, sustainable use of water resources, and biodiversity in its own right as well as from a functional perspective. These outcomes occur at different scales. There are also multiple points at which interventions can be made, ranging from national-level interventions to field-specific interventions in agro-ecological systems.

Sustainable systems analysis needs to consider the choice of agricultural and land use activities and the resulting changes in linkage components such as functional diversity, niche complementarity and trophic complexity, and the trade-offs between these and the long-term productivity potential.

Using the concepts discussed by McGranaham (2014), such an analysis requires indicators of biodiversity measures at the field-level which can be related to functional diversity, and can be used as variables in most of the bioeconomic models. Measures of functional diversity associated with field-level changes in biodiversity are particularly well-suited in the analysis of field or agricultural sector models (Fig. 2). Among other indicators, functional diversity together with trophic complexity measures can be used as convenient indicators at the farm, household and economywide models. Given the current advances and efforts in data collection systems and data sharing platforms (Rojas et al. 2015; Antle et al. 2015), incorporation of appropriate indicators in modeling tools should be feasible.

Rojas et al. (2015) reviewed the literature to identify possibilities to harness existing capabilities to better incorporate biodiversity and ESS into economic analysis of agriculture systems. They developed a framework for assessing how well an existing model integrates these elements and whether there are scopes for improving it. Based on their approach, figure 2 summarizes key considerations in integrating biodiversity and ESS into analytic frameworks, with particular emphasis on linkages across scales and sectors.

Figure 2 – Conceptual framework for the model based assessment of the value of biodiversity

Vertical Linkages	Horizontal Linkages				
	Diversity-type		Assessment factors		Socio-economic consideration
Local-scale Field Farm Household Landscape	Mostly intra-species Intra and inter-species Intra and inter-species Intra and inter-species	↔	Crop yield, ESS Crop and livestock yield, ESS Food availability and demand, ESS Yield, ESS, community-level demand	↔	Benefits>costs at field level Joint benefits > joint costs at farm level Joint benefits > joint costs at household level Joint benefits > joint costs at community level
↕			↕		
Agricultural-sector	Mostly intra-species	↔	Relative demand, supply, prices nutrient, ESS	↔	Relative benefits/cost across commodities
↕			↕		
Economy-Wide	Intra and inter-species	↔	Relative demand, supply, and prices of food, and other consumer good; nutrition impact, ESS	↔	Impacts along value-chain, across commodities, across industry sectors, and across political boundaries

The conceptual framework, firstly, helps articulating linkages across scales and sectors. The effects of investments and interventions at the local scale, whether field, farm, household or local landscape, bubble up to higher scales and ripple across to other sectors. These linkages are not unidirectional. Changes made at the economy-wide level or at the agricultural sector level, for example a policy change, can in turn affect changes at the field, farm and household-level. The linkages in the analytic tool do not need to be hardwired into one single super-model. Rather, there can be soft linkages across models designed for different sectors and scales. Second, the framework helps to consider the requirements of modeling approaches designed for integrating biodiversity and ESS. This allows planning for necessary data collection during project design and implementation. Finally, given the existing linkages across scales, a key question in performing such analysis is whether the chosen approach allows for linking analysis across scales. It is likely that a modular configuration provides the versatility needed for adapting to different research objectives rather than one complex model with built-in linkages.

Assuming that a given modeling framework captures well the biophysical and socio-economic aspects, results from a given analysis must be examined within the context of other ongoing related work. Most models will rarely be able to integrate intra-household dynamics, particularly with respect to gender roles and decision making. Therefore the results from bioeconomic models must be examined with other ongoing analyses to explore gender and cultural aspects. Similarly models are simulated for certain selected scenarios and may not capture all complexities of all possible scenarios. Nevertheless, bioeconomic models are powerful tools for examining ex-ante and ex-post trade-off analyses between the impacts of a given innovation on productivity, nutritional outcome and ESS. The following sections briefly discuss the necessary steps in linking biodiversity to ESS, and integrating ESS into bioeconomic models at three scales of analysis as presented in figure 2.

4. Modeling the linkages between cropping patterns and practices to environmental outcomes

Agricultural economics profession has a long history of using different models which relate cropping patterns and practices to environmental outcomes. For example, Groundwater Loading Effects of Agricultural Management Systems (GLEAMS) model has been used in many earlier studies to examine the effect of agricultural practices and policies on groundwater (Boisvert et al. 1996). Models such as Soil and Water Assessment Tool (SWAT), which predict water availability and water quality have also been used in many studies (Douglas-Mankin et al. 2010). In recent years, there has been considerable effort within the biophysical science community to better understand the environmental impacts of cropping patterns and practices. Specific plot-level (Kumar and Nair 2007) and landscape-level (Swift et al. 2004) work has been undertaken to study the impact of agricultural biodiversity on environmental outcomes. In addition, there have been several concerted efforts to assess and value ESS. For example, TEEB has adopted a structured way to value biodiversity and ESS (TEEB 2010). ARIES, Artificial Intelligence for Ecosystem Services, provides a flexible suite of applications for mapping benefits, beneficiaries, and ESS flows (Villa et al. 2014). InVEST similarly estimates the biophysical provision of different ESS across a given landscape (InVEST 2015).

Bioeconomic models which are linked exogenously or endogenously (Janssen et al. 2010) to crop models can translate changes in ESS, crop-choices and management practices to crop yield. Many of these models use the DSSAT (Decision Support System for Agrotechnology Transfer) modeling system that comprises crop simulation models for over 28 crops (DSSAT 2015). Another common crop model is the Agricultural Production Systems Simulator (APSIM) software, a modular modeling framework which was designed to provide predictions of crop production in relation to climate, genotype, soil and management factors (Keating et al. 2003). Crop yields generated from such models can in turn be used as inputs to other bioeconomic models.

While efforts to estimate ESS from changes in biodiversity and land-use patterns are well-documented, these studies have not been systematically linked to economic analysis or always linked to specific field-level agricultural practices. Currently few analytical models capture complex behavior of (agricultural) ecosystems, and evaluate them at different scales (Balbi et al. 2015). Even simulation models, which take a more systems oriented approach, have focused on isolated processes and rarely examine effects of agricultural practices in multiple ecosystems (Balbi et al. 2015). Shepherd et al. (2013) conducted a review of data, from monitoring initiatives in sustainable intensification of agriculture, to examine past and ongoing efforts designed to inform decision-makers regarding trade-offs between food security, environment, and socio-economic goals. The authors identify weaknesses in many of the ongoing efforts but also point out that these weaknesses can be addressed. Among other solutions, they indicate the importance of data-sharing platforms to facilitate dissemination, reuse and learning. Similarly Antle et al. (2015) note that as growing demands are placed on agricultural ecosystems and landscapes, infrastructures are needed for supporting a comprehensive approach to data, knowledge, and its use for sustainable landscape management. The challenge therefore remains to leverage data, tools and skills present in the biophysical sciences to better link changes in crop choices and management practices to changes in the flow of ESS, which in turn affects productivity in subsequent years.

4.1 Bioeconomic models at local scale

Bioeconomic analysis at a local scale should include analyses of both productivity and environmental responses to varietal improvement or to other improved technologies. The impacts of a technology at a given locality can be analyzed at the field level, farm-level or at the household level, depending on the research purpose (Fig. 2). At the field level, the essential consideration in the past has tended to be whether, for a given crop, a given new technology is more profitable than the existing one. Farm-level analyses, similarly have tended to examine the profitability of a new technology taking into consideration all the enterprises on a given farm. While profitability and yield responses are important and essential considerations for wider adoption of a given technology, it is also important to analyze impacts on ESS to examine implications for long-term economic growth, environmental outcomes and sustainable food security.

Farm household models are a popular analytic tool for integrating household demand into the analysis of farm-level decision making (Louhichi et al. 2010; Kaimowitz and Angelsen 1998). These models are appropriate for analyzing the empirical relationship between farmer´s land use pattern, household preferences, and resource availability. They are capable of incorporating details regarding different crop and livestock systems and examining a number of technologies and potential impacts of a range of policy interventions (Louhichi et al. 2010). The models are particularly well-suited in applications regarding subsistence agriculture where production, labor allocation and consumption decisions are linked (de Janvry et al. 1991). These models can be applied to a single time period or over multiple years.

Figure 3 – Bio-economic models at local scale: strengths and weaknesses

	Strength	Weakness
Framework	Most operate using a 'bottom-up process' with the model based on detailed geophysical site-specific information.	Data requirement can be demanding.
Scope	It allows for site-specific trade-off analysis of productivity and environmental outcomes. Impact on human diets can also be incorporated.	Relating farm practices and crop choices to environmental outcomes can be difficult. Intra-household dynamics such as gender issues will need to be considered outside the model.
Domain	It is a good scale at which to analyze field-level activities in connection with farm or household level activities and try to link them to the immediate landscape.	Making these connections involves data issues. Some studies attempt to work with a few farms in a given landscape. Others start with large number of farms and reduce these to a few 'typical farms.'

Research has expanded to consider farm-level decision making within a landscape context. Given the scope for analyzing multiple benefits and costs, spatially explicit ESS provision modeling tools have increasingly become available. These tools describe multiple services or goals which a household or a farm can seek to optimize, such as agronomic, profit and environmental goals. These models are able to assess the impact of human activities on the provision and value of multiple services across space and time (Müller et al. 2010). At the moment however, the larger economic processes of market forces are often not incorporated in such models. Spatial models have high data requirements and limited spatial coverage, with infrequent capture of higher aggregation processes (Smeets et al. 2014).

Rojas et al. (2015) examined a number of farm and household-level models that are used for analyzing biodiversity and ESS. Based on this review, figure 3 presents their key strengths and weaknesses. While these models are useful to relate household-level decision making to its impacts, it is difficult to incorporate intra-household dynamics into the analysis. Factors such as gender-roles and nutritional impact on women and children, may need to be analyzed outside the models. Moreover, model scenarios must be selected and results interpreted taking into consideration these dynamics.

Given that the models are based on site-specific information, data needs can become cumbersome. There is also a challenge in deciding whether to make the model be true to a specific site or make the model more general and applicable across different sites. A possible solution is to adapt model prototypes, designed for specific farm or household typologies based on survey data, for use across different geographic sites covered by the same survey. Similarly, whether each component of the model, such as models for different crops considered, are endogenous to the model or exogenous can greatly change the level of complexity. It may be useful to design the model in a modular framework and enable linking different components as needed, rather than making a very complex single model which requires considerable investments for adaptation with each new use. However, a shared platform for data and for sharing analytic modules will significantly facilitate moving forward the research to allow integrating biodiversity and ESS into economic analysis.

4.2 Bioeconomic models at the agricultural sector level

Agricultural sector models belong to a set of models known as the partial equilibrium (PE) models which take into consideration only a part of the economy assuming the rest of the economy remains unchanged (ceteris-paribus condition). PE models incorporate both supply and demand of an industry or a sector of interest hence being able to capture market equilibrium processes. PE models are widely used for agricultural sector modeling because they offer the possibility of a comparatively detailed depiction of the sector while being comprehensive in spatial and commodity coverage and maintaining the capability of capturing market feedbacks taking place at relatively aggregate spatial scales. These models are powerful tools for assessing national/regional level policies, and also the impact of innovation within a commodity on the market price, demand and supply of other commodities.

Currently the agriculture economics profession has a wealth of information based on which model improvements can be undertaken to better integrate biodiversity and ESS into agriculture systems analysis. A commonly used tool IMPACT (International Model for Policy Analysis of Agricultural Commodities and Trade) is a global multi-market, dynamic model that provides long-term projections (up to 2050) of global food supply, demand, trade, prices and food security (Flachsbarth et al. 2015; Robinson 2014). The model covers 58 agricultural commodities including livestock, fisheries, crop processing for sugar, oil seeds and cassava, and biofuels production. Globally, agricultural production is depicted at the level of 320 spatial units or ďood producing unitsč(FPUs) based on 154 major river basins and 159 political regions or country boundaries. GLOBIOM is a global recursive dynamic model that integrates the agricultural, bioenergy and forestry sectors following a bottom-up approach based on detailed grid cell information on biophysical conditions, for agricultural production (including altitude, slope, soil characteristics, and the agro-ecological zone) and land use suitability, at a spatial resolution of 10 Km grid. Agricultural production is represented at a level of →200,000 spatial units (Havlík et al. 2014) for 18 globally most important crops, a range of livestock production activities, and forestry commodities as well as different bio-energy transformation pathways. Similarly MAgPIE (Model of Agricultural Production and its Impact on the Environment) a global, spatially explicit, recursive dynamic model uses a bottom-up approach and has a spatial resolution of 0.5°x0.5° which results in around 60,000 grid cells. This model covers 20 crops, 3 livestock, and 10 regions in the world (Lotze-Campen et al. 2010).

Figure 4 – Bio-economic models at the agricultural sector level: strengths and weaknesses

	Strength	Weakness
Framework	Most models are based on readily available national, global or regional data on production, trade and consumption and other uses. A few newer models are adopting the 'bottom up' approach of basing the model on site-specific information.	Integrating biodiversity and multiple ecosystem services to these models is relatively a new concept, and to date limited applications exist beyond some climate change analysis.
Scope	These models are well suited to examine inter-commodity market dynamics, both in local and global markets, including along value chains when included in the model, with changes in innovation or policy changes.	Relating farm practices and crop choices to profitability and environmental outcomes can be difficult. Intra-household dynamics such as gender issues will need to be considered outside the models. As the scope is limited to the agriculture sector, these models cannot directly consider impact on or from changes in other sectors of the economy.
Domain	These are relatively easy to use tools to compare the impacts of innovations across a number of countries and commodities, with simple disaggregation of bulk farm-gate product, semi-processed and processed products.	Relating environmental externalities can be incorporated in the models but currently the profession has limited applications. The models can be externally linked to household and economy-wide analysis, but this work is also currently under-developed.

While the above discussed models do not capture economic feedbacks between the agricultural sector and the rest of the economy (Fig. 4), agriculture sector models are an important tool and a necessary step for a comprehensive analysis of a given new innovation or a policy change within the agriculture sector. The model's aggregate spatial scale has limited representation and linkage with externalities and ESS, but model enhancements are being undertaken for greater consideration of site-specific biophysical information (Valdivia et al. 2012). For more comprehensive analyses, results from agriculture sector model can be linked to economy-wide models. In addition, results from analyses at other scales can be used to customize the model for specific scenarios.

4.3 Bioeconomic models at the economy-wide scale

The most common framework for analyzing innovation or policy changes using an economy-wide approach is the computable general equilibrium (CGE) model. These models cover production, consumption, input, and trade of all economic sectors for a given country, region or even for all countries worldwide. CGE models represent the optimizing behavior of all agents within the economy as producers, consumers, factor suppliers, exporters, importers, taxpayers, savers, investors, or government. This comprehensive coverage of economic processes allows assessing the full economic value to society of a public good such as biodiversity and ESS.

Important uncertainties and limitations to CGE modeling analyses are that the high level of aggregation conceals variations in and economic interactions between the underlying elements, and limits the degree to which bottom-up information and data can be effectively integrated within the larger model. Often the representation of specific commodities or agricultural technology and technological change can be limited. However, advances on bioenergy analyses have been made in some Global Trade Analysis Project (GTAP) model versions (Smeets et al. 2014), as well as assessments of ESS and biodiversity using CGE ICES (Intertemporal Computable Equilibrium System) model (Bosello et al. 2011).

Figure 5 – Bio-economic models at the economy-wide level: strengths and weaknesses

	Strength	Weakness
Framework	Model is based on aggregate national accounts data which is readily available.	High-level of data aggregation in the model only allows impact analysis at a very aggregate level.
Scope	It allows for analysis across all sectors of the economy, producers, consumers, suppliers of factors of productions, exporters, importers, taxpayers, investors, government. As such, it will also allow taking into consideration the impacts of biodiversity and ESS outside the agriculture sector.	As a complete consideration of biodiversity and ESS into such a model has not been attempted before, it will be a big challenge to develop the necessary data to include them into the model.
Domain	Given the public good nature of biodiversity and ESS, these models will capture comprehensively their economic value to society.	The model will not be able to capture the 'intrinsic value' individuals may place on biodiversity and ESS to just conserve them for future generations. As such it is likely that the estimated value will be an under-assessment of the true value.

Similar to the advances in agricultural sector models, significant advances have been made in CGE models. The recent version 8 of the GTAP database contains 57 commodities and 129 regions, including up to 12 agricultural commodities on the supply side and seven on the demand side. The forestry sector is included through a forest products commodity (GTAP 2015). Similarly, Modeling International Relationships in Applied General Equilibrium (MIRAGE) covers 113 regions of the world and up to 57 sectors (IFPRI 2015). MIRAGE was used to analyze climate change impacts in South-Asia (Laborde et al. 2011). A version of MIRAGE called MIRAGE-BioF was used to analyze biofuel policies, as well as to assess the impacts of trade and agricultural policies on income and poverty in developing countries (Valin et al. 2013). While these represent global models, there are ongoing efforts to improve economy-wide models at individual country-levels. For example, under the Nexus Project, which is a loose consortium of organizations engaged in building and using CGE models for African countries, an effort is underway to improve and expand the scope of analysis. Data coverage is currently being expanded to cover energy and water sectors and the inclusion of biodiversity and ESS is under consideration.

Economy-wide models allow calculating the costs and benefits accrued to society in general from investments in conservation of agricultural biodiversity and ESS. These models can take into consideration the indirect impacts, such as loss to tourism, recreation, hunting and fishing, from agricultural run-off and leaching from fields many miles away. The models can also be used to examine potential impacts under various policy options to conserve or enhance biodiversity and ESS, on different sectors of the economy. As indicated in figure 5, given the scale at which these models operate, it is difficult to precisely link the estimated impact to specific crops, fields or local markets. But, if linked to analyses in other sectors and to analyses at lower scales, a given policy can be fully examined to consider the impacts on productivity, biodiversity and ESS with linkages to specific crops, fields, landscapes and markets.

5. Concluding remarks

This paper has presented a conceptual framework for integrating biodiversity and ESS into economic analysis of agricultural systems. As global food security is intrinsically linked with biodiversity and ESS, it is critical that any analysis of the productivity impact of a given agricultural technology also includes its environmental footprints. The impacts of how biodiversity is manipulated at the field level can ripple horizontally across landscapes and vertically across economic scales, requiring linkage in analyses across these scales. While the paper does not devote significant time to this issue, the paper also points out the need for temporal consideration in analysis since the cost of preserving biodiversity and ESS are privately borne in the short-run, but its gains are publicly accrued over a longer timeframe.

The paper also points out the need to examine ESS impacts of crop choice and agricultural practices and link these impacts back to yield impacts in the long-run. Yield predictions can then be incorporated into economic models at multiple scales to examine future implications for food security, through the impact on productivity, biodiversity and ESS. It is important to consider the analysis at multiple scales in order to more comprehensively capture intervention impacts. At the local scale, the profitability of a given innovation can be considered in the context of a farm enterprise or at the household level, with linkages constructed to ESS flows. At the agriculture sector level, the given innovation can be examined in the context of a range of agricultural commodities and their domestic and international markets. At the economy-wide level, the impact of a given innovation on ESS can take into consideration the effects beyond the agricultural sector. Therefore the analysis at each scale complements the analysis at another scale, indicating the need to have analyses linked across scales.

Given the current state of science regarding geospatial data, computing and modeling capabilities, it is feasible to regularly integrate biodiversity and ESS into analyses which are designed to assess the food and nutritional security impacts of a given agricultural innovation. However translating this idea into practice is more complex. As discussed by Antle et al. (2015) linking the relationships between land management decisions and multiple outcomes is complex and requires coordination across a number of different stakeholders. The authors point to the need for infrastructure to support the management of agricultural landscapes. While efforts have been made to establish platforms for sharing data and tools, more can be done in this area. As shared platforms for data, analytic modules, tools and models are essential for integrating biodiversity and ESS into economic analysis of agriculture systems, a question arises regarding who funds it. Funding agencies and the research community need to explore different options for incentivizing the sharing of data and computer models. Antle et al. (2015) present some suggestions, including the role for private-public partnerships, within the context of the United States. Food security of any given country is linked to actions and well-being of other countries. In the context of challenges presented by climate change and degradation of ESS globally, any infrastructure for data sharing and facilitating analysis in the United States should also be linked to global data and research efforts. To confront the global challenge of food security and climate change we need a global effort to perform analyses that allows identifying the best options to increase agricultural productivity, while also maximizing the global availability of macro and micro-nutrients and minimizing the environmental footprint of agriculture production systems.

While underscoring the need to perform the trade-off analyses discussed in this paper, it has to be noted that these models are merely approximating very complex systems. In some areas we have a good understanding of the relationships and in others only an emerging understanding. The type of analysis advocated here will have inherent weaknesses and will need to act in parallel with other types of evidence – some of which will be qualitative. However, developing these analytical approaches will likely help facilitate transdisciplinary working and systems thinking. It will expose some of the areas where we currently lack understanding – identifying new research priorities, which in turn will lead to improvements in analysis.

MEASURING ENERGY EFFICIENCY IN AGRICULTURE AND BIO FUEL PRODUCTION

Session Organizer

Annalisa Zezza | CREA - Council for Agricultural Research and Economics | Rome | Italy

ABSTRACT

Energy efficiency can enhance sustainability, support strategic objectives for economic and social development, promote environmental goals and increase prosperity. Measuring energy efficiency of agriculture and biofuel production is crucial when planning energy policies aimed to partially replace fossil fuels and to lower green house gas emissions. Reducing the dependency on non-renewable energy sources relies both on the use of renewable energy and on the improvement of energy efficiency in productive processes. However absence of solid data, lack of standard methods, presence of multiple objectives – among other factors – complicate the evaluation of energy efficiency of agriculture and biofuel production. Moreover the rapid expansion of biofuel production has generated considerable interest and a variety of approaches to understand the impact of biofuel growth on the global food economy. The session will discuss criteria and methods related to energy efficiency assessment in agriculture and biofuel production. Specifically, the session will focus on the following areas: 1. Assessment methods of energy efficiency in agriculture and biofuel production; 2. Evaluation of the energy and environmental efficiency of the primary sector at country/regional level and for different farming systems; 3. Analysis of the impact of biofuel growth on the global food economy. The session will welcome thematic papers focusing on these three areas. Methodological studies concerning constraints and difficulties for energy efficiency measurement such as data gaps/needs and implications for Institutions involved in agriculture statistics will be welcome as well.

Abstract

The agro-food sector is characterized for demanding a significant amount of energy in its industrial processes. According to the Joint Research Centre of the European Commission, the amount of energy necessary to cultivate, process, pack and bring the food to European citizens' tables accounts for 26 % of the EU's final energy consumption in the same year (Monforti-Ferrario et all 2015). In the Mediterranean area, the agro-food sector is highly represented by Small and Medium Enterprises (SMEs) which demand innovation and practical solutions to greening the supply chains. In contrast, SMEs are often reluctant to change production behaviours due to limited financing alternatives, lack of information on the most fitting technologies or gaps in knowing benefits without affecting the quality of the final products.

Aiming at assisting agro-food SMEs of the Mediterranean area, the project Sinergia[2] has contributed to identify innovative processes, address energy efficiency patterns in the productive chains and guarantee a wide replication of the technological solutions for energy saving and CO2 reduction. Sinergia pools the experience of 10 Mediterranean partners who jointly developed an Energy Self-Assessment Tool (ESAT) to help SMEs to better know their own energy consumption features and to identify energy saving potentials. The project is financed in the framework of the EU Cohesion Policy through its European Territorial Cooperation (ETC) objective. The aim of this paper is to analyse the effects and contributions of ETC to the increase of energy efficiency levels in agro-food sector. The paper analyses Key Performance Indicators (KPI) of reference and highlights how ETC exercises can address data availability challenges.

Keywords: Energy efficiency, Agro-food sector, SMEs, Mediterranean

1. Introduction

Over the recent years, market trends and environmental pressures make clear that an essential requisite for future growth and competitiveness of the European agro-food industry are not only the investments in the global network of commodities and distribution channels but also to extend the paradigm of sustainability in the food processing from the big corporations to the SMEs. This aspect is particularly important if we observe it from the energy side. Although agro-food industry is considered as a low-energy intensity sector, some steps in the value chain are characterised by consuming high levels of energy to transform, process, cook, warm, dry, cool and store the final food products.

In the Mediterranean region, agro-food industry is one of the largest and more productive sector, mostly composed by small and medium enterprises with limited resources and unqualified personnel for addressing greening practices in the supply chain innovation. Furthermore, SMEs typically consider additional investments not as a way to improve their energy efficiency but as a loss or major change in their product market characteristics and quality already assimilated by target consumers.

The purpose of Sinergia is to help the Mediterranean agro-food industry to spark green energy practices. One of the most innovative aspects of the project is the proactive method offered to the agro-food SMEs to make them feel closer to the knowledge poles in the field of energy and to stimulate investments to improve the environmental footprint of food processing. Sinergia tackles the energy challenges by designing friendly instruments to increase the SMEs' awareness and introduce innovation in the energy efficiency processes. These instruments are designed to cover monitoring and selection of the most fitting technologies to the energy managers' across the whole investment life cycle.

This paper focuses on Sinergia project as an example of European Territorial Cooperation where several partners of different Mediterranean countries have addressed a common challenge by giving a unified response through collective action. To this respect, the added value of ETC is of significant importance for the agro-food sector as it allows sharing knowledge, good practices and motivating exchanges between experts and entrepreneurs of several Mediterranean countries.

2. European Territorial Cooperation, joining efforts to support the Mediterranean agro-food sector.

In the European Union, the Cohesion Policy finances initiatives to reduce disparities among member states and regions who evidence different growth progression as a result of heterogeneous market dynamics and trends. European Territorial Cooperation is part of the EU Cohesion Policy and promotes collaborative actions in response to common challenges. In the Mediterranean area, ETC addresses some of the common challenges normally by following a three-phase approach consisting of: (1) diagnosis and strategies to be addressed commonly by partners of different territories, (2) testing activities and demonstrative actions to validate future and higher interventions and (3) transferability and capitalization actions based on the amplification of previous test and results towards concrete policy changes (Gómez and Stephanedes, 2015).

Results of European Territorial Cooperation are not normally seen as infrastructure-oriented achievements. Instead, ETC contributes to the delivery of reports and analysis based on state of the art, legislation tendencies and changes, roadmaps, guidance materials for several public targets, communication and awareness raising campaigns, establishment of local working groups, international conferences, events to facilitate exchanges between public and private sector, political Memorandums of Understanding and provision of evidence for improving local, regional and national policies (Gomez Prieto, 2015).

Concerning the agro-food sector in the Mediterranean area, over the period 2007-2013 the European Territorial Cooperation instrument contributed to the support of several stakeholders through different initiatives in areas such as innovation and transnational collaborative platforms (Agro-environmed, 2013), promotion of sustainable diets and agriculture traditions (Fooding, 2011), simplification of technical and administrative procedures and operation for Horticultural Perishable Products (E.H.P.P.C, 2011), exchange for technology transfer in the agro-biotechnologies (Agrobiotech exchange, 2005) and energy efficiency advice to SMEs (Sinergia, 2015)

According to the nature of ETC, achieved results should be considered as interface of new interventions in same or similar thematic and targeted territories. Although project outputs are of varied nature they could be used individually or collectively to define starting points, references or baselines of future projects and initiatives. This approach is part of the so-called capitalisation strategies promoted at programme and project level.

3. The Sinergia project, increasing energy performance by transfer innovation.

Sinergia is an ETC project implemented by the transnational programme Interreg MED. The project is coordinated by the Italian National Agency for New Technologies, Energy and Sustainable Economic Development (ENEA) and engages the participation of eight partners representing research centres, federations, clusters and agencies of Spain, Italy, France, Greece, Slovenia, Croatia and Turkey committed to the development of agro-food sector in the Mediterranean area.

The main mission of Sinergia is to promote the technology transfer to the SMEs of the agro-food industry in order to (1) identify innovative processes and address energy efficiency patterns in the productive chain (2) guarantee a wide replication of the technological solutions for energy saving and CO_2 reduction undertaken by the different agro-food divisions and productive clusters in the involved MED regions and (3) strengthen the competitiveness of the agro-food industry in the Euro-Mediterranean and global markets.

To achieve the objective, the project developed 50 pilot cases addressing concrete technological options to boost better energy performances in SMEs, with high potential of replication to strengthen competitiveness and sustainable resource management of agro-food industry in the Mediterranean area. The following case addresses for instance energy efficiency practices in a winery of Greece.

Case study on Energy efficiency practices in a Greek winery

Company description and products. Brintzikis is a Greek winery and produces 500 tons of wine annually wine from locally grown grape varieties. It is the first winery in Greece with zero carbon footprint, thanks to its two ground source heat pumps systems coupled to photovoltaic panels. Production process includes grape collection from the vine trees, transport to the winery, production of must, cold static decantation, separation, alcoholic fermentation, aging, storing and bottling.

Energy use. Heating needs are limited to 5 days in winter in order to maintain wine storing temperature at 12 °C. Cooling is needed during the wine production season in September for treatment of must after pressing and removal of grape solids, static decantation and alcoholic fermentation of the must. Additional cooling is needed in order to maintain the wine aging as well as a storing room temperature at 18 °C during from May to October. Electricity is also needed for lighting, driving motors at the pressing system and filtering units, as well as for pumps and fans.

Renewable Energy technology installed. Heat, cool and chill are provided by a pair of ground source heat pumps (57 kWth heating and 53 kWc cooling each). One of them provides base load and the second provides peak load. At times when both heating and cooling are needed in the plant, one GSHP provides heating and the other cooling, operating in maximum efficiency due to the favourable temperature prevailing at the bore hole heat exchangers (BHE). The GSHP units are connected to a ground heat exchanger which delivers 16 °C water to the GSHPs in heating mode during winter and 20 °C water in cooling mode during summer.

Electricity is provided by photovoltaic panels placed at the roof, which sell all generated electricity to the grid at a guaranteed feed-in tariff according to national regulations. The PV panels generate 150 MWh of electricity annually exceeding plant needs of 100 MWhe.

Annual energy savings. Useful energy delivered by the GSHPs is estimated at 152 MWhc for cooling plus 17 MWhth for heating. The corresponding electricity consumption is estimated at 32 MWhe, resulting in energy savings of 137 MWh annually. In addition, the PVs provide another 150 MWhe of renewable energy every year. It must be noted that correction of the power factor does not result in energy savings, but only in cost savings.

These pilots demonstrated in one hand the variety of industrial processes and energy consumption patterns in the Mediterranean agro-food sector. Even if we talk about similar food items, feta cheese production in Greece entails a particular process that cannot be compared to the elaboration of Mozzarella in Italy or Banon in France. On the other hand, small and medium entrepreneurs are normally more sensible towards the preservation of traditional industrial processes rather than modernising the practices by introducing energy efficiency measures that could bring both economic and environmental benefits.

Sinergia project also implemented a set of tools to promote technology transfer in agro-food industries of the Mediterranean. Concretely, an energy efficiency simulator, a food energy tech database, help desks and an energy self-assessment tool were designed to stimulate energy efficiency practices in SMEs and demonstrate that final products can be elaborated with the same quality and less energy consumption. In this paper, analysis is concentrated in the Energy Self-Assessment Tool[3].

4. The Energy Self-Assessment Tool and key performance indicators

The Energy Self-Assessment Tool (ESAT) was designed to stimulate energy efficiency patterns in the productive chain of SMEs' industrial processes. The tool is based on an free-accessible software[4] which was developed to process a set of information about SMEs' energy cost/consumption and production data. Users can enter data about energy performance associated to food production into a software that provides a diagnosis regarding the energy efficiency of the site by comparison with appropriate benchmarks. ESAT allows to evaluate higher margins of energy performance improvements and supports enterprises in their choices.

As for the functioning, ESAT was designed to work on two operative levels: the first one is a preliminary check-up consisting on a simple and quick process to calculate SME performance indicators and compare them with reference values for the same sector. Here, the tool requests for basic information in order to deliver indicators related to working hours per day, energy bill and averages. In the second level, a comprehensive energy check-up, based also on preliminary information, allows the system to properly identify when and where the higher energy consumptions occur along production process. This second level assists SMEs to identify specific energy consumption by analysing all energy vectors consumed and energy techs installed.

The Energy Self-Assessment tool not only allowed to determine quantitative values of energy consumption in targeted SMEs of Mediterranean agro-food sector. The obtained results were also visible through the increase of awareness about SMEs energy consumption not only by entrepreneurs but also by policy makers and other relevant stakeholders. Comparison on SMEs energy performance, energy consumptions assessment for each segment of the production chain and simulation of major energy efficiency scenarios were also part of the associated results.

The key performance indicators addressed by Sinergia were linked to the needs and demands of the agro-food industry as one of the largest and most important manufacturing sector in the Mediterranean area. Although mostly composed by SMEs with limited resources and qualified personnel for investing in research and innovation, the Mediterranean agro-food sector counts on great innovation potentialities leading to improve energy efficiency levels of industrial processes.

After diagnosis analysis and surveys addressed to representatives of SMEs, these KPI were jointly defined by project partners as a way to identify common solutions. Concretely, the defined KPI were: energy consumption per square meter, energy cost per square meter, energy consumption per volume produced and energy cost per volume produced.

[3] Details of these tools are available at: http://www.sinergia-med.eu/index.php/my-energy-efficiency-simulator

5. Discussion and key messages to stakeholders and policy makers

In previous sessions, it was demonstrated how European Territorial Cooperation contributed to improve energy efficiency levels in the Mediterranean agro-food sector. Sinergia project in particular addressed key interventions towards the support of SMEs in order to modify energy consumption practices. However, some observations and results obtained through project operation are valid for policy dimension at local, regional and national level. The following messages are addressed to policy makers and stakeholders committed to the improvement of the Mediterranean agro-food sector:

Moving companies towards sounding energy efficiency diagnosis. Making the agro-food companies, in particular the SMEs, aware about their potential energy efficiency upgrade is definitely the first step to achieve reasonable energy efficiency levels. Assisting SMEs to run an initial self-diagnosis of their energy consumption patterns is the way to convince them to investigate market alternatives as well as to identify suitable low carbon technologies fitting with specific industrial processes. Decision support systems such as ESAT represent a concrete support to any SMEs as it offers a set of energy performance reference values for the selected agro-food divisions and technologies, helps enterprises to pre-evaluate the potential benefits, maps out the innovation hubs and the available local RES and E-services. Tools like ESAT encourage the agro-food companies to wisely approach their own energy performance problems and deal with the EU directive on energy efficiency which promotes the energy diagnosis in the EU SMEs.

Improving the industrial associations' innovative services for the greening of the supply chain. Most of the agro-food companies are not fully aware of the transformation of the EU market towards the single market for green products. In the meantime, large agro-food corporations have started requiring green standards to their supply chain, selecting mainly sub-providers able to meet clear environmental criteria. In this perspective, the green innovation challenges not only the enterprise at individual level but the whole agro-food local productive system (clusters of companies located in the same territorial background). The agro-food associations should be widely supported in order to enhance the efforts to provide their members with a vision over the future market trends and new services, with the goal of promoting the large scale introduction of eco-innovation model analysis in the agro-food sector and stimulating targeted investments.

Assisting agro-food companies to get oriented across the numerous sources of information. The access to good quality and scientific-based innovative ideas to improve the environmental performances of the agro-food industry is one of the main challenges to stimulate the green innovation of this sector. However, the enterprises, especially small and medium sized ones, must be supported in order to fully exploit the advantages offered by heterogeneous, numerous and complex information sources. SMEs often do not have a sufficient capacity to understand what technology options could better fit with their own production patterns and to calculate the cost/benefits of the investment in the full life cycle. Key elements to meet new SMEs' requests of information are the various tools available online to enable two-way information flows, starting from the simplest to the more evolved, that attract the companies making it possible to obtain useful information about the opportunity of new energy technologies. Therefore, the use of organized and structured tools allows SMEs to achieve an high level of innovation, but this process should be guided by technology intermediates and skilled specialists to better fulfil the companies' expectations.

Introducing innovation within the traditional food processing systems. Food and Drink sector shows relative slowness to pursue innovation, including the integration of new clean technologies into the industrial processes. Among the main challenges for stimulating innovation in agro-food, the following ones are the more recurrent: risks of investment towards innovation, failure rate of innovation projects (technical management, business support) during the process, legal and administrative barriers, insufficient protection of confidential information/knowledge related to the food processing, inflexible legislative framework for research and innovation and bureaucratic system of public funding schemes. Furthermore, SMEs typically see financing possibilities as a way to improve their traditional longstanding manufacturing processes rather than introducing innovative elements in the production chains.

Smart specialisation as a driver of innovation and interregional cooperation. Agro-food is one of the main economic pillar in the Mediterranean area and it is recognized as priority of smart specialisation in most of the concerned Regions. The introduction of eco-innovation model analysis in the agro-food sector, both to reduce the environmental stress factors in the value chain and to support the competitiveness of the agro-food SMEs requires synergies between regional strategies. To this regard, the European Commission has recently[5] launched a Smart Specialisation Thematic Platform on Agro-food. The platform promotes innovation-driven investments and cooperation around new agro-food growth opportunities.

Training and skills are fundamental! On one hand, the specialization of the educational systems, from the technical colleges to the universities, to meet the demand of new green skills and green jobs shall be pursued by encouraging new forms of public and private collaboration on the labour market. On the other, the enrichment of the vocational training with topics for the development of skills on eco-innovation, the innovation management and the sustainability issues are necessary to assure a correct implementation of priorities. Initiatives among agro-food federations, high education, R&D and specialized market/skills organizations should be promoted to increase the professional capacities in energy diagnosis and green energy projects in agro-food enterprises.

Creating alliances and inter-disciplinary networks. Agro-food sector in the Mediterranean area needs reorientation towards eco-innovation driven businesses in order to face the world-wide competition and effectively contribute to reach international post-Kyoto goals. Opening up to strategic intervention from technical, political and financial perspective strongly depends on the participation in European and international networks, economic forums, technology platforms and project partnerships. New and traditional cooperation on technology tendencies and novelties as well as in low environmental footprint patterns shall be conveyed within specific agro-food supply chains and be implemented by enterprises. National and European Agro-food cluster's vision in favour of sustainability has to be deeply promoted also across the small and medium agro-food stakeholders. In this perspective, the mechanisms for bottom-up participation and transnational think-tank in profiling the "vision to sustainability and competitiveness" should be enhanced.

Transposing new energy and clean technologies to the market. Developing close-to-market research projects focused on energy efficiency, renewables and clean technologies is necessary as a supplementary way of transposing research into market by introducing new high-tech applications for the agro-food enterprises. The elaboration of new projects under targeted financing programmes should be inspired by the advances and results derived from EU Technology Platforms. Concept and approach should be characterized by innovation (research-driven innovation and innovation in business models, design, branding and services that add value for users especially for SMEs) and engagement of all actors (R&D performers, final beneficiaries, intermediates) in the innovation

[5] Official launching of the Agro-food platform took place on 1st June 2016, Brussels as a joint initiative between DGs Agricultural and Rural Development, Regional and Urban Policy, Research and Innovation and Joint Research Centre.

cycle. A special attention should be devoted to the implementation of demonstrative pilots, being the key-factor to accelerate the propagation of successful case studies to the market.

6. Conclusions

European Territorial Cooperation has contributed to greening the Mediterranean agro-food sector through several initiatives. Sinergia project in particular has demonstrated that although the variety of industrial processes, techniques and traditions, Mediterranean stakeholders and policy makers might converge on joint action to provide collective answer to the energy efficiency challenge of related industries. Additionally, the public-domain character of achieved results and outputs, allow to prepare, design and implement further related interventions by integrating what has been already analysed, elaborated and concluded.

Decreasing energy consumption is one of the main options to make agro-food companies green and competitive. Reliable, scientific-based and independent tools of public use like ESAT might motivate the interest of agro-food SMEs to get a first screen of the possible company-based energy efficiency interventions. This tool, along with other Sinergia outputs, allowed to clarify SMEs' concerns related to: What are the best available technologies in the fields of energy efficiency for specific agro-food SMEs in specific food processing area? Are there any other example, best practices or successful case studies to get inspiration in the Mediterranean Region? Is my personal energy consultant aware about the newest applications?

Many of the problems faced by the EU agro-food sector cut across the territories of the MED areas characterized by similar climates and geo-morphologies for the land use in agriculture as well as socio-economic conditions and effective solutions. require an integrated approach and cooperation between the various authorities and stakeholders involved in order to ensure a cohesive and sustainable development of the sector. The know-how of Mediterranean SMEs is usually based on a specific and traditional products. Small entrepreneurs typically consider potential investments to improve their energy efficiency as a loss in the low price approach or as a major change in their product market characteristics already assimilated by consumers. Therefore, more focused intervention to assist Mediterranean SMEs on greening their daily processes is necessary.

ABSTRACT

Agriculture accountsbetween 2 and 3 percentof national energy consumption even if direct and indirect energy usesconstitutean important part of farmer's costs. Furthermore, the considerable increase of energy prices in the past years, affected significantly farmers, generating disturbing effects on production costs.

This paper present a novel approach to estimate energy impact on operating costs at farm level.To point out the impact of global energy costs of Italian farms, "Energy Impact Matrices" (EIMs) were defined through an analysis of national Farm Accountancy Data Network (FADN), collecting data concerning the costs of direct (electricity, fuel, gas) and indirect (seeds and plants, fertilizers,pesticides and herbicides,) energy uses for each Type of Farming (TF) and Economic Size Class (ESC) of farms.

The EIMs obtained, show the differences for each intersection TF/ESC referred to the percentage weight of energy expenditures on operating costs of farms, highlighting those cases with values above national average.

The results of the analysis are useful to identify specific agricultural sectors where adopt measures at regulatory level - addressing public funding and investments - as well as at private level, promoting actions forreducing energy coststhrough management approaches such as energy audits.

Keywords: Farm Accountancy Data Network,energy costs,energy impact,energy audit.

1. Introduction

The Italian national Authority for electricity gas and water services (AEEGSI) highlighted,in its 2015annual report,a total agricultural consumptions of 2,69%, the 0,47% from electricity, the 0,12% from gas, the 2,09% from oil and the0,01% from renewable sources.Although it can be considered a small percentage of national consumptions, for farmers it represents a topic issue, as direct and indirect energy uses, have an high incidence on total farm inputs.

Furthermore, in the stream of consumption of 500-2.000 MWh/Year (most representative in Italy) prices are over EU average for 20% (except, taxes and charges) and of 26% considering the gross price (AEEGSI, 2015).

Energy consumption in agriculture can be direct – as with gasoline, diesel, petroleum, natural gas, electricity - or indirect as with fertilizers (Sands R. et al. 2011). The impact of costs related,on farms activity, depends strictly from type of farming and economic size.

In the past years Italian agriculture has been affected by an increasing of production costs, that, in 2011, reached about 5%, with peaks of 19% for feed and agricultural fuels.

Coldiretti, one of the most representative Italian farmers organization, estimated 200 million euros of additional costs for the whole agricultural sector.

This high level of costs concernedespecially energy intensive activities such as livestock companies, those ones needing energy to heatgreenhouses (such as flowers, vegetables and mushrooms) and for drying forages for animals, in addition to all those with energy demanding processes with high level of mechanization.

Such increasing of energy price was due by a combination of external dynamics, mainly the constant growth of oil prices from 2009 to 2012 and the charges in energy bills due to incentives for renewable energy production,near to 10 billion euros in 2012.Those factors entailed energy price variability, hampered farmers to make reliable predictions on their own energy costs andgenerated unexpected additional expenditures,whose incidence can vary between different type and size of farms and between farm to farm belonging to the same category.

For this reasons,energy efficiency-basedmanagement approaches can led to farm’s competitiveness, considering also that, with the future climate change and population growth,pathway for improving energy efficiency and reducing environmental footprint need to be identified (Khan et al., 2009).

This paper analysesthe impact of energy costs of Italian farms, using “Energy Impact Matrices” built through an analysis of national FADN. The FADN methodology - often used to estimate sustainability indicators at farm level like “Sustainability Farm Index” (SuFI) (Longhitano et al. 2012) or energy use and energy use efficiency of specific set of specialized dairy farms (Meul et al. 2007) - classifies farms in Type of Farming and Economic Size Class.

By referring to the concept that we can’t manage what we don’t know, this kind of analysis is an useful tool to identify specific targets in the agricultural sector to use energy efficiency as driver for farm’s performance improvements, both under economic and environmental perspective(Fabiani, 2014).

In addition, this kind of assessment can provide the building blocks for a national energy efficiency plan, where, one of the focus is better approach to energy management farms. Similar approaches have already been undertaken by some European countries (i.e. see the

Plan de Performance Energetique- PPE, in France. http://agriculture.gouv.fr/ministere/le-plan-de-performance-energetique-2009-2013-des-exploitations-agricoles).

2. Materials and methods

2.1 Farm Accountancy Data Network

The Farm Accountancy Data Networkwas launched in 1965 and established by the Council Regulation number 79/65/EEC.It is an yearly survey carried out by the Member States of the European Union and represents an important tool for the evaluation farms' income and the assessment of the Common Agricultural Policy (CAP) impacts. The FADN is a unique source of microeconomic data harmonized at European level, i.e. the bookkeeping principles are the same in all countries, as well as established by Council Regulation 79/65 (the legal basis for the organization of the network).

The scope of the FADN survey covers only farms whose size exceeds a minimum threshold[1] so as to represent the largest possible proportion of agricultural output, agricultural area and farm labour, only for market orientated farms. For Italy the threshold that farms must meet to join the FADN sample was set equal to 4000 euro ofStandard Output – SO[2].

The services responsible for the operation of the FADN, collect every year accountancy data from a sample of farms in the European Union. Farms are selected to take part in the survey on the basis of sampling plans established at nationallevel in the Union. The methodology applied aims to provide representative data along three dimensions: regional, economic size and type of farming.

The main purpose of the survey is to gather accountancy data for the determination of incomes and business analysis at farm level. The information collected concerns approximately 1000 variables and is transmitted by Liaison Agencies to the EU. The FADN database, widely recognized as an efficient tool to estimate environmental performance and footprints (Westbury, 2011 and Dalgaard, 2006),contains, among other, data on energy costs related to direct uses (divided inelectricity, fuel, gas) and to indirect consumptions (seeds and plants, fertilizers, pesticides and herbicides) for each Type of Farming and Economic Size Class.

Data collected at farm level are aggregated in a set of standard groupings and, for each accounting year, the standard results are computed at the level of the European Union and for each Member State.

In this work FADN data were aggregated as follow (Table 1):

- Types of Farming (TF), 8 classes:a farm is classified as specialist if the Standard Output (SO) of one of the farms productive activities (or more than one if the activities are related) represents over two thirds of the total SO of the farm, otherwise it's classified as Mixed.

[1]Thresholds of economic size establishing the minimum size of agricultural holdings included into FADN field of observation differs between Member States.

[2]The Standard Output (SO)is the average monetary value of the agricultural output at farm-gate price of each agricultural product (crop or livestock) in a given Region. The SO is calculated by Member States per hectare or per head of livestock, by using basic data for a reference period of 5 successive years; for example, SO 2007 covers the calendar years 2005 to 2009. The SO coefficients are calculated for more than 90 separate crop and livestock items. This large number of items not only reflects the diversity of agriculture within the European Union, but also indicates the level of detail that is required to ensure that the results of the FADN and of other surveys are comprehensive and reliable. (FADN website).

- Economic Size Classes (ESC), 8 classes:the economic size of an agricultural holding is measured as the total SO of the holding expressed in euro[3].

Table 1:*Types of farming (TF) left, and Economic Size Classes (ESC- €) right*

Classes	Type of Farming
1	Fieldcrops
2	Horticulture
3	Wine
4	Other permanent crops
5	Milk
6	Other grazing livestock
7	Granivores
8	Mixed

Economic Size Class	Description
I	< 4.000 euro
II	from 4.000 to 8.000 euro
III	from 8.000 to 25.000 euro
IV	from 25.000 to 50.000 euro
V	from 50.000 to 100.000 euro
VI	from 100.000 to 500.000 euro
VII	from 500.000 to1.000.000 euro
VIII	> 1.000.000 euro

2.2 Methodology of analysis and Energy Impact Matrix (EIM)

The analysis of this work is based on theFADN2013 database, the last update available. For eachtype of farming and economic size class,“Direct energy”, “Indirect energy” and “Globalenergy”(direct + indirect) costswere considered andcorrelated with the farm economic index“Operating costs”.Operating costs represent those costs linked to the agricultural activity of the holder and covers the categories “Off farms consumption factor” (seeds, plants, fertilizers, pesticides and herbicides, water, electricity, fuel, feed and forage), “Other costs”(such as commercialization and transformation expenditures, overheads and land related costs), and “Third party services” (rental expenses, health costs, insurance, etc.).

The first part of the analysis allowed us to define the national average value of direct, indirect andglobal energy costs and their impact (%) on operating costs for each intersection of TF and ESC. The followingTable 2presents an example for ESC I.

Table 2: *Example ofDirect, Indirect and Global energy costs and impact of ESC class I.*

Type of Farming (TF)	EconomicSizeClass (ESC)							
	I							
	Farms	A-Operating Costs	B-Direct Energy	Impact % (B/A)	C - Indirectenergy	Impact % (C/A)	Global Energy (D=B+C)	Impact % (D/A)
Field Crops	12	2.506,00	754,72	30%	657,42	26%	1.412,14	56%
Horticulture	0	-	-	NA	-	NA	-	NA
PermanentCrops	4	1.462,25	568,26	39%	503,75	**34%**	1.072,01	**73%**
Grazing livestock	4	1.711,25	717,68	**42%**	82,50	5%	800,18	47%
Granivore	0	-	-	NA	-	NA	-	NA
Mixed Cropping	2	3.156,50	1.890,75	**60%**	330,50	10%	2.221,25	**70%**
Mixed Livestock	0	-	-	NA	-	NA	-	NA
Mixed Crops-Livestock	0	-	-	NA	-	NA	-	NA
Italy	***22***	***2.230,86***	***817,36***	***37%***	***495,23***	***22%***	***1.312,59***	***59%***

In the definition of the EIMs only values consistently higher then national average were considered using the statistical criteria of "Average Coefficient of Variation" to highlightthose intersection TF/ESC with an high incidence (red values). The Coefficient of Variation (CV) represents a standardized measure of dispersion of a probability distribution. It is often expressed as a percentage and defined as the ratio of a group of data's standard deviation σ to its mean μ:

$$CV = \frac{\sigma}{\mu} \text{ with } \mu \neq 0$$

The CV shows the extent of variability in relation to the average of the population. When its value is high, it means that the data has high variability and less stability, when is low, it means the data has less variability and high stability.In this work CV was calculated as the average of the coefficients of variation of each group identified for TF and ESC.All percentage value obtainedapplying CV criteria, representing high incidence for those specific intersection TF/ESC, generated the three Energy impact matricesfor costs related to direct, indirect and global energy use on operating costs.

3. Results

The analysis performed implies some important assessments: energy costs seems to affect Italian farms in relation to specific farm economic dimension and for giventype of farming.Considering direct energy impact matrix (Table 3), field cropsis the most affected class, presenting values above national average, especially in the last 3 economic size classes (VI, VII, and VIII). Considering also the agricultural surfaceavailable for those classes, it is probably due to the high use of tractor and field machinery, with high fuels consumption. The economic size classes where an high weight of direct energy costs is most widespread is the second class (SO form 4.000 to 8.000 Euro), characterized byhorticulture, permanent crops, grazing livestock, mixed cropping and mixed crop-livestock. A consistent impact of direct energy use costs appears also for the VIII economic size class, particularly for horticulture and mixed-livestock. Also this evidence seems to be correlated with the farms size as,for instance,large size greenhouses for horticulture require high electricity and gas consumption for cooling, as well as large surfaces for mixed-livestock farms have great direct energy consumption, mainly electricity for irrigation of forage crops often associated with livestock,milking and stable activities.

Table 3: *DirectEnergy Impact Matrix*

	EconomicSize Class (ESC)							
Type of Farming (TF)	I	**II**	III	IV	V	VI	VII	VIII
Field crops						**23%**	**20%**	**21%**
Horticulture		**25%**						17%
Permanentcrops		**26%**						
Grazing livestock	42%	**30%**						
Granivore								
Mixed cropping	60%	**23%**						
Mixed livestock			31%					16%
Mixed crops-Livestock		**29%**					19%	
Italy	***37%***	***19%***	***27%***	***24%***	***22%***	***18%***	***14%***	***10%***

Concerning indirect energy consumptionscosts (Table 4), a strong correlation between farm size and operating costs is clear.Five TF classes out of eight(field crops, horticulture, permanent crops, mixed cropping and mixed crop-livestock) present a percentage impact even four time above the national average in the VIII ESC. Horticulture is clearly the he specific type of farming most affected by indirect energy consumptions, presenting high levels of impact for all economic size classes except the field crops.Similar results can be recordedalso for field crops, mixed cropping and the for permanent crops. The fact that such kind of farms are significantly affected by indirect energy costs probably depends on the huge quantity on chemical inputs needed, especiallyfor big farm sizes.

Table 4: *IndirectEnergy Impact Matrix*

	EconomicSize Class (ESC)							
Type of Farming (TF)	I	II	III	IV	V	VI	VII	**VIII**
Field crops			44%	46%	49%	48%	51%	**53%**
Horticulture		**53%**	**53%**	**48%**	**54%**	**52%**	**44%**	**48%**
Permanentcrops	34%	27%				30%	29%	**30%**
Grazing livestock								
Granivore								
Mixed cropping		35%		39%	43%	51%	63%	**45%**
Mixed livestock								
Mixed crops-Livestock								**27%**
Italy	***22%***	***22%***	***35%***	***33%***	***31%***	***26%***	***18%***	***12%***

Table 5 presents the results for global costs; it highlights that concerning the economic size classes, the occurrence of an impact above national average, appears mostly for all economic size classes,except for the first and the third one: four times for ESC II, VI, VII and VIIIand three times for IV and V.This seems to show once again a direct correlation with farmssurface, a part from their specialization, with peak values between 70% and 80% in classes VI, VII and VIII for field crops and mixed cropping.

Horticulture and mixed cropping (seven classes on eight are over average), but also field crops (from III to VIII class) are the type of farming most affected and considerably sensible to energy.

Table 5: *Global energy Impact Matrix*

	EconomicSize Class (ESC)							
Type of Farming (TF)	I	**II**	III	IV	V	**VI**	**VII**	**VIII**
Field crops			72%	73%	74%	**72%**	**71%**	**74%**
Horticulture		**79%**	**74%**	**69%**	**74%**	**69%**	**57%**	**66%**
Permanentcrops	73%	**54%**				**49%**	**46%**	
Grazing livestock								
Granivore

Mixed livestock								
Mixed crops-Livestock		**46%**						**38%**
Italy	***59%***	***41%***	***62%***	***57%***	***53%***	***44%***	***32%***	***22%***

4. Conclusions and recommendations

This kind of analysis is an useful tool to identify specific targets in the agricultural sectors most affected by energy expenses, where to obtain better operational results in terms of environmental and economic performances.

Results suggest that reducing energy costs is a crucial topic for future policy strategiesaddressed at improving energy efficiency and competiveness of farms.

Acknowledgements of regulatory framework on energy management and technical approaches in use, such as certifications systems (adoption of EMS – Energy Management System) allow us to consider energy audit as the right tools to evaluate farm's energy consumptions andincrease the level of knowledge on energy uses in agriculture.

The general audit technique, is based on the *Deming Cycle* which represent a continuous improvement methodology with four stages: plan, do, study, act (Dean and Evans, 1994)[4].

Performing an energy audit in a given structure means to do an objective analysis of energy management so it is an essential tool for achieving a reduction in energy consumptions and hence, costs.

[4]Specifically, the audit technique is referred to the traditional procedures adopted for quality and/or environmental management systems derived from ISO 19011:2003 "Guidelines for quality and/or environmental management systems auditing".

It could be useful to look at other experiences, where, in order to be properly developed and spread, energy audit has been included in a nationalenergy performance plan for agriculture, as happened in France with the *Plan de Performance Energètique*(PPE)[5].

To reach such important objectives, farmers should be fully aware of their potential and research institution and policy makers can play a central role in increase the level of public awareness.

[5]It was an holistic plan, integrated with France Rural Development Plan, made of eight axis and aimed at getting a better knowledge of energy consumption and production on French farms, spreading farm energy audits in great numbers. It also promoted research and innovation activities encouraging partnerships of public institutions with the private sector and allowed the awareness on energy efficiency as a long term issue (http://agriculture.gouv.fr/ministere/le-plan-de-performance-energetique-2009-2013-des-exploitations-agricoles).

ABSTRACT

Recently there has been a growing interest in multifunctional farms. In this paper we focus on some characteristics of the Italian agricultural holdings which produce renewable energy. To better investigate this topic it is necessary to integrate data collected in two sample surveys: the Farm Structure Survey and the Survey concerning Economic Outcomes of Agricultural Holdings. The paper presents a particular approach to the integration problem; the integration permits a deeper investigation of the characteristics and the economic performances of the interest agricultural holdings by analysing relationship between variables not jointly collected in a single survey.

Keywords: agriculture surveys, hotdeck imputation, statistical matching, multifunctional farm.

1. Introduction

Recent studies show an increase of the multi-functional Italian farms, i.e. holdings carrying out diversified activities such as tourism activities, contractual work, processing of farm products and renewable energy production, among the most popular ones. The focus of this paper is on activities related to the production of energy for self-consumption and/or for sale, and their corresponding earnings. The information about the production of renewable energy have been collected in occasion of the 2010 Italian Agriculture Census, and more recently by the 2013 Farm Structure Survey. Unfortunately these structural surveys are not able to catch revenues of such activities. These information can be retrieved from the survey on the Economic Outcomes of Agricultural Holdings, which is carried out annually on a sample basis. Unfortunately this latter survey does not collect data on costs and revenues related to the production of renewable energy. For this reason a deeper analysis of the phenomena requires an integration of the data collected in both the surveys.

The paper will describe a first approach for integrating the two surveys in order to investigate the economic characteristics of agricultural holdings producing renewable energy. In particular Section 2 describes the data sources, while the integration process is described in Section 3. Section 4 provides some results concerning the phenomena under investigation.

2. Data sources on agricultural holdings

The Farm structure survey (FSS) is regulated at European Union level and provides harmonised data on agricultural holdings (AHs), including: number of holdings, land use and area (main crops), livestock, farm labour force (by age, gender and relationship to the holder), type of activity, economic size of the holdings, other gainful activity on the farm, system of farming, machinery, organic farming. It is run at regular intervals, every three years on a sample basis while every 10 years it coincides with Agricultural Census. FSS data are also used in other policy areas such as environment, regional development and climate change. In addition to the contents, the regulation defines also coverage and precision requirements as well as the sampling strategy: stratified random sampling where the stratification shall include the size and type of the AHs. Italian 2013 FSS edition sampled 44,168 holdings (the sampling frame was the 2010 Agriculture Census list consisting of about 1.6 millions of AHs), out of which 40,166 were active and respondent. The number of holdings considered in the present work is of 39,656, where new holdings have been disregarded.

The economic performances of Italian agricultural holdings are investigated annually by means of the sample survey on "Economic outcomes of agricultural holdings" (EOAH). In practice it consists in two independent surveys carried out on two non-overlapping subpopulations: the medium-large sized AHs are investigated via the Farm Accountancy Data Network (FADN) survey, while smallest farms are observed by means of an ad hoc survey with a relatively short questionnaire. The size of the farms is measured in terms of Standard Output (SO; the gross agricultural output expressed in monetary terms): in 2013 holdings with SO (derived using 2010 Census data) greater or equal to 4,000€ were included in the FADN target population. Such a two-fold survey is carried out jointly by Istat and Crea, the liaison agency as far as FADN is concerned. The variables observed in EOAH consists mainly in costs and revenues of the AHs. The data being considered in this paper are those referred to 2013 accountancy year; the sample consisted of about

19,000 holdings (15,000 for FADN and 4,000 for the remaining part of the population). The available data refer to about 11,000 responding AHs; however for practical purposes in this study we will refer to a slightly smaller subset, consisting of 10,757 units, obtained by discarding the new holdings emerged after splitting or fusion of sampled AHs.

3. Integration of the data sources

For the sake of simplicity, in this Section the EOAH survey will be denoted as *A*, while FSS will be denoted as *B*. The union of the two surveys ($A \cup B$) returns the situation illustrated in Figure 1.

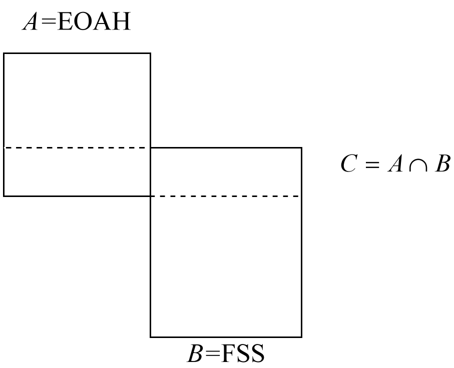

Figure 1: *Union of EOAH and FSS surveys.*

In practice, *A* consists of $m_A = 10,757$ AHs while *B* includes $m_B = 39,331$ units; their intersection, $C = A \cap B$, provides a non-empty set with $m_C = 3,724$ AHs; these results were obtained after a file merging based on error-free AH identification code.

The subset *C* contains all the variables observed both in *A* and *B*; given its non-negligible size, it would allow in-depth analysis of phenomena involving variables not jointly observed in a single survey. In our case the interest is in the relationship between revenues of holdings and the presence of equipment for energy production. The revenues are observed in EOAH survey (*A*); the attention here is on revenues due to some unclassified other gainful activities, denoted as *Y*. The presence of equipment for renewable energy production is observed is FSS (*B*) and hereafter will be denoted as *Z* (1='Yes'; 2='No').

The units in *C* permits the investigation of the relationship between *Y* and *Z*, but it is not straightforward to generalize results to the whole population of Italian AHs. First of all, the probabilistic sampling design underlying both the surveys (stratified random sampling) tends to assign higher probability of being included into the sample to large AHs, for this reason it is expected that the intersection set *C* includes medium-large size farms, but, since more than 3,700 have been randomly included in both surveys, a deeper analysis of the structural characteristics must be performed. Moreover, two equivalent alternative set of survey weights (weights derived as the inverse of the probability of including a unit into the sample, usually corrected to account for unit nonresponse and coverage errors) can be used to derive estimates from *C* : those arising from *A* and the ones from *B*. For instance, Table 1 provides the results of crossing the variable *Z* and a categorized Y variable denoting the presence of 'other' revenues (1 if $y_k > 0$ and 2 otherwise), where the word 'other' refers to unclassified revenues not due to sales of agricultural products nor to activities like tourism, processing of food products etc.; in practice Y includes production of renewable energy but not solely refer to that.

Table 1: *Estimated joint distributions of Y and Z derived from the intersection of the two surveys.*

	Subset *C*, *A* weights			Subset *C*, *B* weights			*Y* distribution	
	Z=1	*Z*=2	Tot.	*Z*=1	*Z*=2	Tot.	Estimated in *A*	
Y=1	0.40	2.71	3.11	0.38	2.24	2.62	*Y*=1	***5.95***
Y=2	1.19	95.70	96.89	0.96	96.42	97.38	*Y*=2	***94.05***
Tot.	1.59	98.41	100.00	1.34	98.66	100.00	Tot.	***100.00***
	2.07	***97.93***	***100.00***	***2.07***	***97.93***	***100.00***		

In general, the joint distributions of Y and Z, estimated with the different weighting systems, seem quite close; but if we look at the marginal distributions the results are not satisfactory; as far as Y=1 is concerned, the obtained estimates, 3.11% and 2.62% respectively, are far from the "reference" estimate 5.95% derived considering in the whole survey A (in italic-bold text there are the marginal distributions of Y and Z estimated from the whole survey they are directly observed, A and B respectively). This gap confirms the idea that C cannot be considered a representative sample of the population of Italian AHs. Indeed, by looking at the main characteristics of the AHs belonging to the various subsets, it seems that C tends to over-represent small-medium farms.

Table 2: *Main characteristics of the agricultural holdings observed in both the surveys.*

Source	No. of units	**Weighted averages**					
		LSU		UAA (in ha)		SO (euros) Census	
		A weights	*B* weights	*A* weights	*B* weights	*A* weights	*B* weights
A-C	7 033	10.4		5.9		38,616.2	
C	3 724	6.6	4.9	4.8	4.5	27,362.0	26,122.4
B-C	36 207		9.3		5.6		33,616.8
Whole sample (*A* or *B*)		8.4	8.4	5.3	5.4	32,639.9	32,230.4

*computed considering aggregated livestock categories

In particular, Table 2 shows that AHs in C provide estimated average values of *utilized agriculture area* (UAA), *livestock size unit* (LSU) and SO smaller than the remaining units, thus indicating that using C as base for inferences would provide a picture of medium-small AHs. For this reason it is not advisable to perform inferences using solely C, even in the hypothesis of modifying the survey weights of units in it, e.g. by using Renssen's (1998) weights' calibration approach, in order to obtain a representative set, in terms of size, of the whole population of AHs. Furthermore weights' calibration performed on C may be problematic because of the relatively small number of units if compared to the possible constraints to be set.

In order to make inference valid for the whole population the problem can be tackled by resorting to the approaches developed to integrate survey data that are commonly denoted as *statistical matching* or *data fusion* (cf. D'Orazio *et al.*, 2006), by using the set C as the joint information. Statistical matching techniques are developed to integrate survey data related to the same target population with the scope of investigating the relationship between variables not jointly observed in a single source. Integration is based on the information shared by both the sources. The situation described in Figure 1 corresponds to a particular framework, commonly encountered when integrating data concerning business or agricultural units In this case, the challenge is to perform the matching by exploiting the information in C (see e.g. Ballin *et al.*, 2008, 2009; Torelli *et al.* 2009). An approach suitable to manage such a situation is the Rubin's (1986) *file concatenation*, where the base of the inference is $A \cup B$. For this purpose two steps are necessary (i) computation of a new set of weights for each unit in $A \cup B$, to account for the probability that a single AH is included in survey A, in B or in both; and (ii) imputation of the target variables in subsets where they are missing. The first step is not straightforward (cf. Ballin *et al.*, 2008) and however the Rubin's procedure is thought to integrate theoretic samples by means of direct survey weights available for the whole population, while in practice the data sources include just responding units and the corresponding weights obtained by correcting direct survey weights to compensate for representativeness problems. The second step can be tackled in different manners, and, in our case, the problem is that of imputing variables available in $B - C$ which is very large ($n_{B-C} = 36,207$) if compared to $A - C$ ($n_{A-C} = 7,033$). The main risk is that of imputing unreliable values whose marginal distribution does not correspond to the reference one.

A viable way of working may be that of applying nonparametric procedures based on *hot deck imputation* methods. These methods consist in imputing the missing variable into the *recipient* data source by selecting suitable donors from the other data source, the *donor*. The recipient data set filled in with the missing information, called *synthetic data source*, becomes the base for final inferences. Imputation relies on the information shared by both the data sources (cf. Section 2.4 in D'Orazio *et al*., 2006). The common practice consists in choosing as recipient the smallest data source while the other one plays the role of donor.

In our integration problem, applying the standard version of hot deck matching procedures, would mean imputing in A values of Z observed on the donor units in B, based on some variables (X) shared by both the data sources. Unfortunately, the available common variables X are not good predictors of the target variables Y and Z, and, in any case, such a way of working would not allow to exploit the information in the subset C, in particular with respect to the relationships between the variable Z and those only observable in set A. For these reasons we decided to consider only A and use C as a donor for the remaining units for A (subset $A - C$) where Z was missing, even if the donor data set is smaller than the recipient one. The method chosen for imputing Z (production of renewable energy) in $A - C$, is a particular version of *random hot deck*; in practice for each recipient unit with a given legal form (company or not) the $k = 10$ closest donors sharing the same legal form are searched in C, then one of the donors is randomly picked up (cf. D'Orazio, 2016); closeness between recipient and donor units is measured in terms of a Euclidean distance and the algorithm is based on an approximate nearest neighbour (ANN) research tree, a balanced box-decomposition BBD tree (cf. Arya et al., 2015). The distance is computed on the following variables: geographical area (North-West, North-East, Centre, South and Islands); costs for purchasing electric energy, gas, etc.; amount of 'other' revenues; overall revenues.

To get an idea about the reliability of the imputation procedure we check whether the marginal distribution of the imputed variable Z is coherent with the "reference" one, i.e. estimated from the whole survey B. The Table 3 provides the different estimates; in survey B, where the variable is originally observed, the estimated percentage of units producing renewable energy is about 2% (about 30,000 over 1.5 million of AHs); two alternative estimates can be derived from C, according to the chosen weighting system (i.e. weights from A or from B); in both the cases there is a tendency to underestimate the percentage of AHs producing renewable energy. Finally, considering A after imputation of missing values for the subset $A - C$, it comes out an estimate of 2.55% units producing renewable energy; a value that slightly overestimates the fraction estimated in survey *B* (2.07% is the reference estimate). This result seems quite good and, more in general, it can be said that the imputation procedure provides in EOAH survey (*A*) a reasonable estimate of the distribution of *Z* (production of renewable energy).

Table 3: *Marginal distributions of the Z variable estimated from different datasets.*

Z	Survey *B*	Subset *C* (weights *B*)	Subset *C* (weights *A*)	Synthetic *A* (weights *A*)
1	2.07	1.34	1.59	2.55
2	97.93	98.66	98.41	97.45
Tot	100.00	100.00	100.00	100.00

4. Analyses on the synthetic dataset

The synthetic data set obtained by imputing the production of renewable energy (Z) in survey *A* allows a series of analyses involving *Z* itself and some economic variables observed just in *A*. First of all it is possible to check the presence of association between the production of renewable energy and the presence of "other" revenues, i.e. not attributable to revenues categories of AHs explicitly listed (sales of products, animals, transformed products, aquaculture, tourism, etc.).

Table 4: *Joint distribution of presence of 'Other' revenues and production of renewable energy.*

	Prod. Renewable energy		
	Yes	No	Total
"Others" revenues > 0	9 934	80 080	90 015
Row. rel. freq. (%)	*11.0*	*89.0*	*100.0*
Col. rel. freq. (%)	*25.8*	*5.4*	*6.0*
"Others" revenues = 0	28 567	1 393 574	1 422 142
Row. rel. freq. (%)	*2.0*	*98.0*	*100.0*
Col. rel. freq. (%)	*74.2*	*94.9*	*94.0*
Total	38 502 *2.5* *100.0*	1 473 655 *97.5* *100.0*	1 512 157

Table 4 shows that the fraction of AHs having nonzero vales for "other" revenues is higher for those having equipment for renewable energy production (25.8% vs. 5.4%). In addition, among the AHs that produce renewable energies, those that declare other non-agricultural revenues are roughly one third of the ones having only agricultural revenues (25.8% vs 74.2%). This suggests that within Italian agriculture the production of renewable energy is more likely to be employed to lower costs and because of other benefits, including rural development support, rather than for the direct sale of energy, thus representing an additional gainful activity producing other revenues.

Table 5 goes more in detail by considering the overall revenues. It can be seen that the marginal distribution of the revenues ("row pct" in Table 5) changes passing from AHs with production of renewable energy to those without; in particular, the share of revenues due to non-agricultural activities (column non-agr. 'other') in the first case is much higher (8.4%) than in the second (2.3%). Furthermore, even if among the AHs that declare other revenues only 11% of them produce renewable energy, these AHs cover the 36.9% of revenues deriving from other non-agricultural activities, thus showing that the gainful activity linked with the sale of energy is much more profit-making than other gainful ones. Moreover when comparing average revenues due to sales of products (transformed or not), the AHs without installations for the production of renewable energy (which contribute for the 95.4% of total revenues vs 90.2) in average gain 42.5 thousands of Euros, less than one third of the average revenues of the same type achieved by holdings with production of renewable energy (140.0 thousand of Euros). This result confirms that AHs producing renewable energy tend to be "larger" in terms of revenues than the remaining ones.

Table 5: *Production of renewable energy and revenues of agricultural holdings*

Production of	No. of	Agriculture		Non-agr. (exc. "other")		Non-agr. "Other"		**Overall revenues**	
renew. energy	Holdings	tot.*	ave.**	tot.*	ave.**	tot.*	ave.**	tot.*	ave.**
Yes	38 502	5 390.2	140.0	83.4	2.2	499.3	13.0	**5 973**	**155.2**
row pct		*90.2*		*1.4*		*8.4*		*100.0*

row pct		*94.7*		*2.1*		*3.2*			
col pct		*100.0*		*100.0*		*100.0*			

*Millions of Euros; **Thousands of Euros

Finally, Table 6 provides some results concerning the costs incurred by the AHs. The attention is just on the costs for electricity, gas etc. and on the overall costs. In particular, the average cost for electricity is much higher for the holdings producing renewable energy (about 6 times higher); this result seems a consequence of the fact that AHs producing renewable energy are "larger" than the other ones in terms of costs, in fact their overall costs are larger too (in average 7 times greater than the holding not producing renewable energy). As a consequence the incidence of cost of electricity with respect to overall costs is smaller for the farms producing renewable energy (3.9% vs. 4.5%).

Table 6: *Production of renewable energy and some costs of agricultural holdings*

Production of	No. of	Electricity, gas		Overall costs		Electr./
renew. energy	holdings	*tot.**	*ave.***	*tot.**	*ave.***	Overall
Yes	38 502	121.0	3.1	3 140.9	81.6	3.9%

*Millions of Euros; **Thousands of Euros

5. Conclusions

So far in Italy some characteristics of farms producing renewable energy cannot be easily investigated due to the absence of a single data source providing all the interest information. In fact, Italian Farm Structure Survey (FSS) collects data concerning production of renewable energies for self-consumption and/or sale while EOAH collects information on revenues and costs but not the presence of such a production activity. The integration problem within this framework has been tackled by applying statistical matching techniques suitable to deal with two different sources. The intersection of the two samples, i.e. the common complete available information on subset *C*, has been used as donor in a nonparametric imputation procedure. Under these assumptions, revenues and costs-observed in EOAH have been investigated after having imputed the presence of - the production of renewable energies. Results clearly suggest that Ahs producing renewable energy are characterized by much higher overall revenues than others, even in terms of other non-agricultural revenues as hypothesized, but also in terms of agricultural competitiveness, since average agricultural revenues are more than three times higher when compared with other farms. Furthermore this practice lowers cost associated to electricity. More in general, it seems that the sale of energy is still a minor reality for Italian farming, but economic performances of agricultural holdings that produce renewable energy are on average much higher than those who do not, thus this practice should be encouraged, and the growing phenomenon also deeper analysed.

ABSTRACT

The Global Bioenergy Partnership (GBEP) is an international initiative that brings together public, private and civil society actors to cooperate on a voluntary basis in the areas of bioenergy for sustainable development, climate change mitigation, and food and energy security as per the mandate of the 2005 G8 Summit. FAO is a founding partner of GBEP and hosts its Secretariat since its establishment in 2006. In 2011, GBEP agreed on a set of 24 science-based, technically sound, voluntary and highly relevant indicators concerning the sustainability of all forms of bioenergy. The measurement of these indicators can inform policy-makers and other stakeholders in countries seeking to develop their bioenergy sector to help meet national goals of sustainable development. Measured over time, the indicators will show progress towards or away from a nationally defined sustainable development path.

To date the GBEP indicators have been applied in a number of countries to various extents including Japan, Germany, Indonesia, Colombia, the Netherlands, Ghana and Argentina, and several others have announced their intention to perform the assessment or are already carrying out the assessment including Kenya, Ethiopia, Viet Nam, Paraguay, the United States of America, Jamaica, Italy and Brazil.

In this paper the results of and lessons learned from the “Pilot testing of Global Bioenergy Partnership (GBEP) indicators for sustainable bioenergy in Colombia and Indonesia” will be shared.

Keywords: Bioenergy, Sustainable development, Colombia, Indonesia.

1. Introduction

The production and use of bioenergy is growing in many parts of the world as countries seek to diversify their energy sources in a manner that helps promote sustainable development. Modern bioenergy can provide multiple benefits, including promoting rural economic development, increasing household income, mitigating climate change, and providing access to modern energy services. On the other hand, bioenergy can also be associated with risks, such as biodiversity loss, deforestation, additional pressure on water resources, and increased demand for agricultural inputs, land, and commodities.

The Global Bioenergy Partnership (GBEP), an international initiative established in 2006 and of which FAO is a founding partner, has developed a science-based, technically sound, and highly relevant set of 24 indicators (Table 1) that can inform policy-makers and other stakeholders in countries seeking to develop their bioenergy sector to help meet national goals of sustainable development. Measured over time, the indicators will show progress towards or away from a nationally defined sustainable development path.

The indicators were intentionally crafted as a voluntary tool to report on the environmental, social and economic aspects of sustainable development. Each indicator was developed with three parts: a name, a short description, and a multi-page methodology sheet that provides in-depth information needed to evaluate the indicator.

Table 1: Indicator names.

GBEP INDICATORS		
Environmental	**Social**	**Economic**
1. Lifecycle GHG emissions	9. Allocation and tenure of land for new bioenergy production	17. Productivity
2. Soil quality	10. Price and supply of a national food basket	18. Net energy balance
3. Harvest levels of wood resources	11. Change in income	19. Gross value added
4. Emissions of non-GHG air pollutants, including air toxics	12. Jobs in the bioenergy sector	20. Change in consumption of fossil fuels and traditional use of biomass
5. Water use and efficiency	13. Change in unpaid time spent by women and children collecting biomass	21. Training and requalification of the workforce
6. Water quality	14. Bioenergy used to expand access to modern energy services	22. Energy diversity
7. Biological diversity in the landscape	15. Change in mortality and burden of disease attributable to indoor smoke	23. Infrastructure and logistics for distribution of bioenergy
8. Land use and land-use change related to bioenergy feedstock production	16. Incidence of occupational injury, illness and fatalities	24. Capacity and flexibility of use of bioenergy

In order to establish the feasibility of these indicators and enhance their practicality as a tool to support policy-making towards sustainable development of bioenergy, it was suggested to pilot test them, supporting countries with required technical and financial assistance.

As of July 2016, the GBEP indicators had been implemented in nine countries (i.e. Argentina, Colombia, Egypt, Germany, Ghana, Indonesia, Jamaica, Japan and Netherlands) and another dozen countries committed to implement or were in the process of implementing them.

With this paper, the results of the "Pilot testing of Global Bioenergy Partnership (GBEP) indicators for sustainable bioenergy in Colombia and Indonesia" will be shared.

The overall objective of the project was to pilot the GBEP sustainability indicators in Colombia and Indonesia, and build the capacity of these two countries to apply the indicators and use them to inform the sustainable development of their bioenergy sectors.

The project aimed to:

- assess and enhance the capacity of the two countries to measure the GBEP indicators and use them to inform bioenergy policy-making; and
- learn lessons about how to apply the indicators as a tool for sustainable development and how to enhance the practicality of the tool.

2. Results of the pilot testing

2.1. Main findings in Colombia

The testing of GBEP sustainability indicators in Colombia focused on ethanol from sugarcane and biodiesel from palm oil. The testing provided Colombia with an understanding of how to establish the means of a long-term, periodic monitoring of its domestic bioenergy sector based on the GBEP indicators. Such periodic monitoring would enhance the knowledge and understanding of this sector and more generally of the way in which the contribution of the agricultural and energy sectors to national sustainable development could be evaluated. Furthermore, the testing in Colombia provided a few lessons learnt about how to apply the indicators as a tool for sustainable development and how to enhance their practicality. These lessons learned, which were shared and discussed with neighbouring countries at regional level, as well as the trainings carried out during the project showed the importance of these activities in the measurement of the GBEP Indicators and in the facilitation of South-South cooperation.

2.1.1 Sustainability of bioenergy in Colombia

A number of environmental, social and economic issues associated with the sugarcane-based ethanol and palm oil-based biodiesel supply chains were identified during the testing of the GBEP indicators in Colombia.

On the environmental side, fertilizer and pesticide applications were identified as key sources of GHG emissions and water pollution along both supply chains. Few data could be found on this, due to the limited extent of ongoing monitoring and analysis of water quality in Colombia. Therefore, despite the limited interest in this issue expressed by Colombian stakeholders during the testing of the GBEP indicators, further data collection and analysis would be needed on the impacts of bioenergy feedstock production and processing on water quality. In parallel, good practices that reduce fertilizer and pesticide application while improving efficiency and profitability, such as Integrated Plant Nutrient Management and Integrated Pest Management, should be promoted. Wastewater is another source of GHG emissions and water pollution along the sugarcane-based ethanol and palm oil-based biodiesel supply chains. In this case, methane capture and use should be promoted, including through carbon offset programmes, as is already being done in the palm oil industry in Colombia.

In addition to water quality, issues related to water availability and use in bioenergy feedstock production were identified. In particular, water withdrawals for sugarcane production (including for ethanol) in the *Cauca* watershed might trigger medium-high water stress in dry years. Therefore, irrigation efficiency should be closely monitored and improved technologies and management practices promoted. Finally, with regard to soil quality, both the *Valle del Cauca* (the main sugarcane production area of Colombia) and the Northern region of the *Caribe*, where oil palm is cultivated, show high susceptibility to salinization.

On the social side, in addition to the aspects already discussed above, other issues were explored, for instance with regard to the quality of the jobs associated with biofuel feedstock production and processing. Overall, compared to the average agricultural worker, sugarcane and oil palm workers seem to benefit from a higher level of formalization of employment, better wages and benefits and better protection against occupational risks. Another interesting aspect relates to the business models and the level of smallholder inclusion along the biofuel supply chain. During the last decade, there was an important transformation in the palm oil supply chain in Colombia, with the emergence of the so-called *Alianzas Productivas Estratégicas.* The *Alianzas* are strategic business partnerships formed by small-scale producers, which organize themselves in order to improve their access to credit, strengthen their bargaining power with the mills, and ensure a secure market for their produce thanks to contracts with the latter. As of 2010, around 16 percent of the planted area of oil palm was under an *Alianza*, up from less than 1 percent in 1999. In addition to having contributed to the growth of the palm oil sector, these strategic business partnerships have been quite effective in strengthening the inclusion of smallholders in the palm oil supply chain and in increasing their profitability. The *Alianzas* should be further researched and analyzed and the potential for their future expansion in the palm oil supply chain and eventually in the sugarcane supply chain should be explored.

With regard to the economic aspects, the Colombian biofuel sector can count on a high level of productivity in feedstock production, especially with regard to sugarcane, with an average annual yield among the highest in the world (i.e. 120 t/ha). From an energy balance perspective, Colombian sugarcane-based ethanol and palm oil-based biodiesel supply chains are rather efficient compared to the production of other first-generation liquid biofuels. This is true especially for sugarcane-based ethanol systems, which use the energy content of the biomass rather efficiently, through co-generation of electricity and steam from bagasse, in addition to the sugar and ethanol output.

While the gross value added generated by the biofuel industry in Colombia is relatively small compared to the GDP (e.g. 0.031 percent in the case of ethanol in 2010), the demand for goods and services associated with this industry was found to trigger multiple indirect and induced effects on the economy, including in terms of employment.
Furthermore, even though in 2009 ethanol and biodiesel accounted for only 1.05 percent and 0.7 percent respectively of the total primary energy supply (TPES) in Colombia, these biofuels substituted fossil fuels worth 103 million USD (ethanol) and 215 million USD (biodiesel) in 2012. However, the contribution of these biofuels to energy security was limited by their lack of diversity in terms of feedstock and geographic location, exposing their production to risks related to pest outbreaks and adverse weather conditions, especially in the case of sugarcane-based ethanol. Bagasse, which is a co-product of sugarcane processing used for cogeneration, contributed 3.49 percent to TPES in 2009. On other hand, in Colombia, where woodfuel was still accounting for 8.7 percent of TPES in 2009, modern bioenergy technologies have not played a significant role yet in displacing traditional uses of biomass and in providing access to modern energy services.

2.2. Main findings in Indonesia

The testing of GBEP sustainability indicators in Indonesia focused on palm oil-based biodiesel, reflecting the indications emerged during discussions with relevant stakeholders in Indonesia and the relevance of biodiesel within Indonesia's modern bioenergy mix. The testing provided Indonesia with an understanding of how to establish the means for a long-term, periodic monitoring of its domestic bioenergy sector based on the GBEP indicators. Such periodic monitoring would enhance the knowledge and understanding of this sector and more generally of the way in which the contribution of the agricultural and energy sectors to national sustainable development could be evaluated. The testing in Indonesia also provided a series of lessons learnt about how to apply the indicators as a tool for sustainable development and how to enhance their practicality. These lessons learnt, which were shared and discussed with neighbouring countries at regional level, as well as the trainings carried out during the project showed the importance of these activities in the measurement of the GBEP Indicators and in the facilitation of South-South cooperation.

2.2.1 Sustainability of bioenergy in Indonesia

A number of environmental, social and economic issues associated with palm oil-based biodiesel supply chains were identified during the testing of the GBEP indicators in Indonesia. In Indonesia, the growing demand for palm oil, including as biofuel feedstock, has triggered a supply response, in the form of an expansion in the harvested area of oil palm. Thanks to this increase in production, there was no diversion of palm oil from the food market to the biofuel market, as confirmed also by the data available in national and international statistics. According to FAOSTAT, between 2008 and 2012, the supply of palm oil for food increased in Indonesia. However, the land-use changes associated with the oil palm expansion have given rise to a range of environmental, social and economic impacts.

In 2010, around 8.4 million hectares were planted with oil palm in Indonesia, of which 91.6 percent in the islands of Sumatra, Kalimantan and Papua. Between 1990 and 2010, about 6.35 million ha of land were converted to oil palm in these three islands.

According to the Life Cycle Analysis (LCA) of GHG emissions that was performed during the project, under indicator 1, this expansion led to the conversion of high carbon stock areas (e.g. forests, timber plantations, etc.), causing significant emissions of carbon dioxide. In addition, about 1.25 million ha of peatland were drained and converted to oil palm cultivation, resulting in high, continuous GHG emissions from peat decomposition. Overall, the results of the LCA confirmed that land-use change, especially from forests, is the most important contributor to total GHG emissions from the Indonesian palm oil industry.

Other important consequences of land use change associated with oil palm expansion are habitat loss and impacts on biodiversity. As of 2010, 17 percent of Indonesian oil palm plantations were found in High Conservation Value areas.

Another important source of GHG emissions along the palm oil supply chain is the methane released by the anaerobic fermentation of palm oil mill effluent (POME). As of 2012, only around 5 percent of the over 600 Indonesian palm oil mills were equipped with methane capture systems. An analysis of the economic viability of these methane capture systems should be conducted and, if necessary, measures to promote their wider adoption might be considered.

In addition to land-use change and the associated effects in terms of GHG emissions and biodiversity, a number of other environmental issues were assessed and analyzed.

With regard to soil quality, in East Kalimantan, soil erosion affects oil palm production areas. Concerning soil organic carbon, data is scarce due to the lack of periodic monitoring.

Regarding water quality, it was found that large quantities of pollutants, mainly nitrate and phosphate, are discharged into the bodies of water near the oil palm plantations. As a result, in several areas pollutant concentrations in rivers often exceed the thresholds set by law, particularly around smallholders plantations on peat soils. Further and more refined investigations of pollutant loadings in the internal waters in Indonesia due to biodiesel feedstock production are needed, including mathematical modelling of material transport. With regard to non-GHG airborne pollutants, the low level of mechanization in oil palm cultivation results in relatively low emissions of such pollutants. Concerning tailpipe emissions, tests have demonstrated that biodiesel can significantly reduce the emission of most non-GHG pollutants when compared to fossil-based diesel, showing the potential environmental and health benefits of a shift from traditional fuels to biofuels, especially in densely populated urban areas.

With regard to social sustainability, in addition to the food security implications mentioned earlier on, other issues were explored as well, for instance with regard to the income effects and the number and quality of jobs associated with biofuel feedstock production and processing. As explained above, the increased in the demand for palm oil for biodiesel in Indonesia has triggered a supply response, leading to a significant expansion in the planted area (and subsequently harvested area) of oil palm. This has resulted in a considerable increase in the number of people employed in palm oil production. Regarding the quality of the jobs created in this sector, compared to the average agricultural worker oil palm workers seem to benefit from a higher level of formalization of employment, better wages and benefits, and better protection against occupational risks. The increase in the demand for palm oil for biodiesel production has also provided additional income-generating opportunities for agricultural producers, including smallholders, who accounted for around 35 percent of total palm oil production in Indonesia in 2012.

With regard to land tenure, a few cases of land conflicts were reported in literature, including in the context of oil palm plantations, with lack of adequate legal recognition of customary rights to land identified as one of the main causes.

Last, but not least, concerning energy access, it was found that to date modern bioenergy has not played a significant role in providing access to modern energy services and in displacing traditional uses of biomass, which still accounted for over 18 percent of the Total Primary Energy Supply (TPES) in 2012.

With regard to the economic sustainability aspects, the Indonesian biofuel sector appears to be cost-competitive. However, yields have been stagnant for many years, whereas higher yields have been obtained in experimental trials thanks to the research and development of improved varieties and management regimes.

While the gross value added generated by the biofuel industry in Indonesia is relatively small compared to the GDP (e.g. 0.026 percent in 2012), the demand for goods and services associated with this industry has been reported to trigger multiple indirect and induced effects on the economy, including in terms of employment.

From an energy balance perspective, the Indonesian palm oil-based biodiesel supply chain is rather efficient compared to the production of other first-generation liquid biofuels. However, there appears to be room for further improvement in the feedstock production phase of the supply chain (particularly in the case of independent smallholders), as well as for the refinery component of the processing phase.

Furthermore, even though in 2012 biodiesel accounted for only 0.19 percent of the total primary energy supply (TPES) in Indonesia, this modern bioenergy led to around 282 million USD of estimated savings from avoided oil imports and generated 657 million USD of export revenues.

With regard to the logistics of the biodiesel supply chain, distribution to the easternmost provinces of the archipelago, namely Papua and Maluku, may be difficult due to the lack of efficient infrastructures and this is considered the main cause that has prevented the country from fulfilling the B10 mandate in 2012. Distribution hurdles are also found in the two main producing islands, i.e. Sumatra and Kalimantan. The latter, in particular, suffers from limited availability of processing facilities and poor internal distribution routes (e.g. dirt roads and shallow ports). For this reason, large quantities of feedstock need to be transported in relatively small batches from Kalimantan to Sumatra. In order to meet higher biofuel mandates, these logistical issues are expected to be thoroughly assessed and managed.

3. Conclusions and recommendations

During the pilot testing of the GBEP indicators, both in Colombia and Indonesia, only partial analyses could be conducted due to the limited data available. Filling these data gaps will be essential in order to enable an effective monitoring of the GBEP indicators in the future and thus assess over time the sustainability of bioenergy production and use in the two Countries. Data gaps were particularly significant for the social sustainability indicators. In order to fill these gaps, surveys should be carried out. In addition, as already mentioned above, as the bioenergy sector continues to expand and higher biofuel mandates are considered, it is essential to monitor land-use changes associated with bioenergy feedstock expansion, given the important implications that land-use changes can have for a range of environmental, social and economic sustainability issues. Remote sensing, field visits and stakeholder consultation are complementary tools that should be used in order to study and analyze the land-use changes associated with bioenergy feedstock expansion.

Furthermore, as anticipated above, the pilot testing in Colombia was focused on sugarcane-based ethanol and palm oil-based biodiesel and, to a certain extent, cogeneration from bagasse, while the pilot testing in Indonesia was focused on palm oil-based biodiesel. This reflected the indications emerged during discussions with relevant stakeholders in the two countries. However, as different bioenergy technologies start being deployed in both countries, the impacts associated with these technologies should be assessed as well. In Colombia, in particular, wood fuel still accounts for an important share of total primary energy supply (TPES) and rural households rely heavily on fuel wood and charcoal for heating and cooking. Traditional uses of biomass are inefficient and lead to a number of detrimental environmental and health effects. Therefore, the potential for displacing these traditional uses of biomass with modern bioenergy technologies and for providing access to modern energy services through them should be explored and promoted, and the resulting environmental, social and economic effects should be assessed.

Regarding the long-term measurement of GBEP indicators in Colombia and Indonesia it is recommended to involve all relevant stakeholders in the process, ranging from relevant government departments/ministries (e.g. those dealing with agriculture, energy, environment, rural development, food security, infrastructure, etc.) to producer associations, universities and NGOs. Stakeholder engagement and ownership of the process is key in order to get access to the necessary data and information, receive inputs and feedback, discuss and interpret the results, and ultimately inform policy discussions and decisions.

In addition to this, a network of focal points within each relevant organization could be considered in the future as a means to strengthen institutional coordination and stakeholder engagement for regular national activities related to bioenergy.

With reference to the objective to enhance the practicality of the GBEP indicators, during the testing in Colombia and Indonesia it was realized that more clarity and guidance from GBEP would be needed regarding both methodological and practical issues related to the implementation of certain indicator methodologies. An implementation guide would be needed in order to complement the GBEP report on the sustainability indicators.

On this matter, further guidance would be necessary, in particular, on the complex and crucial issue of the attribution of impacts to bioenergy production and use. For each indicator a range of suitable approaches should be identified and illustrated in detail providing specific examples, and the pros and cons of using one approach versus another should be discussed.

Furthermore, in order to significantly reduce the time, skills and cost required to measure the GBEP indicators, an Excel and/or web-based application should be developed. This would allow users to easily enter all data required for the 24 indicators into one single data entry sheet and to get a set of results for each indicator based on the related methodologies. In addition to the aforementioned benefits, this process would also simplify considerably the data collection process, and it would allow to easily save and share the results and to re-run the tool over time with up-to-date information.

Last, but not least, given the global nature of the GBEP indicators, the report containing the methodology sheets should be translated into other official languages of the UN beside English, e.g. French and Spanish. This would greatly facilitate the dissemination and implementation of the indicators in developing countries around the world.

SUSTAINABLE DEVELOPMENT FRAMEWORKS AND AGROENVIRONMENTAL INDICATORS

Session Organizer
F. Tubiello | FAO | Rome | Italy

ABSTRACT

Agriculture plays a fundamental role in climate change, both as a driver at local to global scale through land use change and emissions of greenhouse gases, and as a sector that will be significantly exposed to climatic damage in coming decades, with possible negative impacts on food security. This session investigates the role of statistical information, existing and required in coming years, in support of sound decision making towards reducing climate change threats within sustainable rural development strategies, with adaptation, mitigation and food security dimensions rolled into a consistent package. Papers are invited investigating the application of agri-environmental indicators for monitoring progress within the climate change convention and the SDGs, with a focus on applicability to developing countries.

This session will present four selected papers on the following topics on the use of agrienvironmental statistics: Adaptation of food systems;

- GHG reporting and analysis;
- National mitigation plans;
- Climate change and food security indicators within the System of Environmental and Economic
- Accounting for agriculture, forestry and fisheries (SEEA-Agriculture)

ABSTRACT

East Kalimantan economy is heavily relied on natural resource sectors. Aside from a gigantic output produced, the economy also creates a significant amount of emission. In the long term, this situation is believed could create environmental risks for East Kalimantan Province. Therefore, East Kalimantan Government has formulated Regional Action Plan in Reducing Greenhouse Gas (RAD GRK) in 2012 for all sectors. The document provides framework for reducing emission and implementing green economy policy in East Kalimantan Province. This paper evaluates emission reduction target of Provincial Emission Reduction Plan (RAD-GRK) in East Kalimantan Province, Indonesia. Using Input-Output Table of year 2013, which disaggregates the agriculture sectors into several subsectors, and employing optimization model; this paper assesses the possibility of achieving the emission target. The paper shows that implementing emission reduction target, as well as maximizing level of output, hampers the economy to reach both economic and environmental targets. There is a trade-off between economic output and emission reduction. Moreover, it shows that there is macroeconomic cost of emission reduction policy for East Kalimantan economy. Even though there is a trade-off in terms of economic output, agricultural sector tends to contributes more to the economy. It implies that in order to achieve the emission target, there is a necessity economic structural transformation towards agriculture sector.

Keywords: *Emission reduction, Trade-off, Optimization, Agricultural sector output*

1. Introduction

Nowadays, natural scarcity and degradation has become an issue discussed in many countries. Natural resources, renewable and unrenewable, have been intensively exploited without considering its impact on environmental quality. Meanwhile, climate change and global warming are haunted the earth and they reduce the earth ability in providing resources for human needs. Therefore, there has been a transition on development paradigm from business as usual (BAU) to sustainable development.

Sustainable development was introduced by the UN World Commission on Environment and Development (Brundtland Commission) in 1987. It is defined as a societal development "… that meets the needs of the present without compromising the ability of future generations to meet their own needs". The idea of sustainability combines three goals, economic power with ecological responsibility and social justice. Moreover, the concept of sustainability that connects the economic activity of people with the nature as resource provides the idea that economic processes must be sustainable if long-term development goals shall not be sacrificed to short-term prosperity. Sustainable development is also defined as the increase of utility or welfare per capita along the time or the increase of a set of development indicators (Pearce, 1996).

UNEP (2011) stated that in order to deliver the goal of sustainable development, one economy should implements a green economy policy. Green economy is defined as: "*One that results in improved human well-being and social equity, while significantly reducing environmental risks and ecological scarcities. It is low carbon, resource efficient and socially inclusive. In a green economy, growth in income and employment should be driven by public and private investment that reduce carbon emissions and pollution, enhance energy and resource efficiency, and preven the loss of biodiversity and ecosystem services*".

National Development Planning Agency (BAPPENAS) states that there are four pillars in achieving sustainable development. There are social, green economy, environment and governance. In Indonesian context, the concept of green economy is applied through green growth program. Green growth program is a new approach to achieve several goals in order to create sustainable development in Indonesia. The notion of the program is to stimulate green growth that recognizing the value of natural capital, increase resilience, building local economic and that is inclusive and fair. There are five dimensions of green growth: (1) sustained economic growth, (2) greenhouse gas emission reduction, (3) social, economic and environmental resilience, (4) inclusive and equitable growth and (5) healthy and productive ecosystems providing services. Therefore, although it is not explicitly stated, the concept of green economy in Indonesia is believed to be similar with the concept of inclusive green economy.

As a response to the national policy of green growth, East Kalimantan Government takes an active part by launching Kaltim Green (Kaltim Hijau) Program on 7th January 2010. Kaltim Hijau is defined a condition where East Kalimantan is equipped by policies, system of government and development programs that provides social and ecological protection, long term assurance of welfare and security for people of East Kalimantan, as well as environmental sustainability. Moreover, East Kalimantan Government has formulated Regional Action Plan in Reducing Greenhouse Gas (RAD GRK) in 2012 for all sectors. East Kalimantan Government has also developed Strategy and Action Plan for REDD+ (Strategi dan Rencana Aksi atau SRAP REDD+). The documents are providing framework for reducing emission. However, some challenges remain in implementing inclusive green economy policy in East Kalimantan.

Firstly, East Kalimantan economy is heavily relied on natural resources. This puts East Kalimantan as one of biggest emitter in Indonesia. In 2008, East Kalimantan Province emits 255 million ton CO_2e as a result of its economic activities. Therefore, some alternative sectors aside from natural resource-based sectors should be considered as exit strategy to the East Kalimantan economy. In other words, there is an urgent need to make an economic structural transformation shifting from natural-resource-based sectors dominance into others.

However, some empirical studies show that there is an economic cost by implementing emission reduction policy. Fan et. al. found that there is a positive correlation between emission reduction and output or value added decline. The higher the target of emission reduction, the bigger the output decline. Moreover, the decrease of the output occurs because of activity restriction of the sectors that have high emission intensity, and these sectors are dominant sectors in the economy (Yang 2000).

This paper focuses on assessing the inclusive green economy in East Kalimantan Province to shed more lights on the existing situation and the potential regarding its sustainable development. Moreover, it analyzes the impact of emission reduction target policy to the economy in terms of output and also measures the economic cost of the policy. The organization of the paper is as follows. In the next section, there is a discussion about emission reduction in agricultural sector. It elaborates how agriculture and emission are related and agricultural contribution in creating emission. Section III explains models used to measure economic trade-off due to emission reduction in East Kalimantan. Section IV reveals the economic optimal structure of East Kalimantan that may provide a pathway to sustainable development and shows the economic cost that occurs due to the policy implementation. Last section will summarize the findings of the previous sections and discuss possible effects as well as some recommendations in order to minimize the economic cost of the emission reduction policy.

2. Emission Reduction in Agricultural Sector

East Kalimantan economy is characterized by highly-dependent on natural resources, such as mining sector, which produces oil, gas and coal. Based on its structure, in 2015 mining sectors contributes more than 44 percent of total the economy. Compared to previous years, its contribution decreases overtime. This indicates that East Kalimantan Province economy slows down and its growth would be unsustained.

However, these dominant sectors contribute to the carbon emission so that they make East Kalimantan as the third largest emitter Province in Indonesia. Mining sector contributes significantly in creating emissions. Based on analysis result carried out by Mc Kinsey Company, DNPI (National Council of Climate Change) and East Kalimantan Government (2011), dominant sectors, such as forestry, mining and coal, as well as oil and gas, are main sectors that create CO_2 emission. In 2010, from the total of 251 million ton of CO_2e, 90 percent of emission is produced by those sectors, or called as land use sectors especially forest land use (Figure 1).

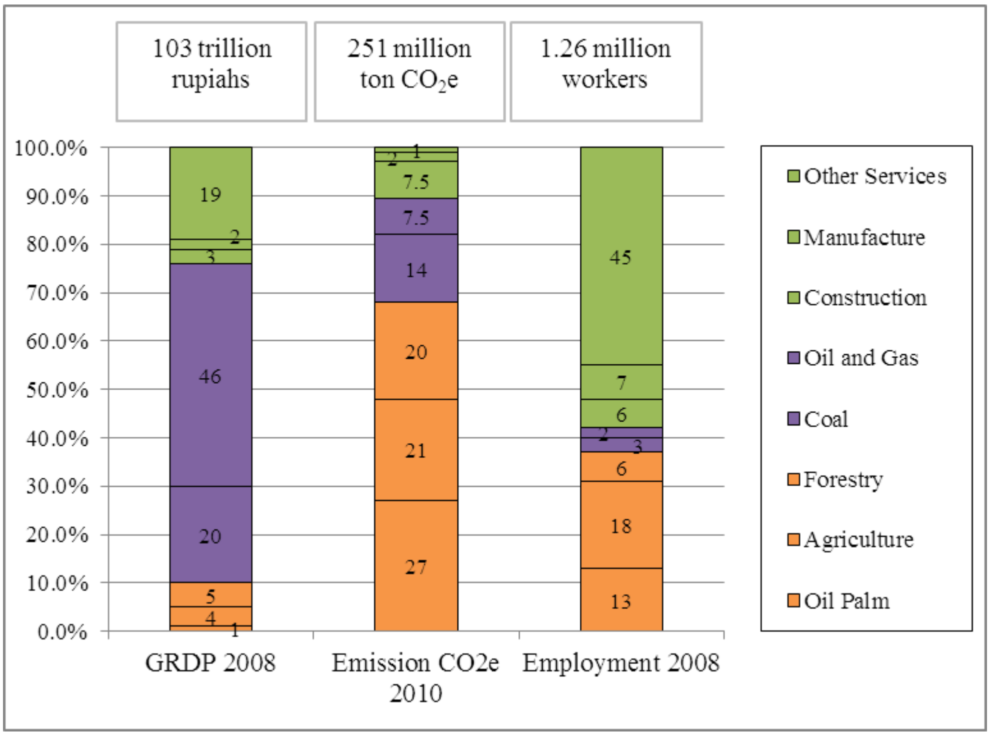

Figure 1. GRDP Distribution at Constant Price Year 2008, CO_2e Emission Year 2010 and Employment Year 2008 by Sector

In contrary, agricultural sector tends to increase overtime, from around 5 percent in 2010 to more than 7 percent in 2015. The increase of agricultural contribution to the economy due to expansion of the oil palm plantation in East Kalimantan. The area of oil palm plantation consists of 85.9 percent from the total planted area of estates in East Kalimantan. The oil palm plantation rises overtime and it reached around 1 million hectares in 2014.

However, the rise of the agriculture sector, especially in oil palm plantation sector, is likely followed by an increase in emission intensity. Government of East Kalimantan calculated emission generated during period 2007-2020 and documented in the Regional Action Plan of GHG Emission Reduction (RAD GRK). The calculation is based on assumption that the economy applies the strategy of business as usual (BAU). It shows that there is a sharp positive trend of generated emission. Land sector is the biggest emitter, especially mining sector.

Land sector is classified according to its land use, such as mining, forest, housings, open area, mangrove, and swamp; including agricultural activities, for instances estate and crops. Carbon stock of each classification has been calculated based on its land cover. If there is a land conversion, carbon stock difference will be calculated as a base in measuring emission that is produced because of the conversion in the land sector.

The calculation of emission in land sector is based on land use planning using assumptions what land use would be in 2020. There are 21 classifications in land use planning, such as food estate, protected forest, production forest, road, industrial estate, crops, wildlife preserve, housings, and peat land. There are some scenarios of emission reduction applied to each sectors. First scenario is conserving primary and secondary forest, while rehabilitating opened area to thicket area. Second scenario is pushing private sector to plant in opened area. Third scenario is conserving forest area. Fourth scenario is applied on plantation area, that is planting oil palm on the opened and bush area, and total plantation area is conserved. Fifth scenario is encouraging establishments accelerates reclamation and replanting so that in 2020 about 50 percent of mining area has been recovered. Sixth scenario is reforestation so that 30 percent of opened area can be converted to be bush area.

Seventh scenario is conserving area by applying eco-friendly practices. Eighth scenario is conserving area.

Method used in estimating emission and making projection is Land Use Planning for Low Emission Development Strategy (LUWES). Firstly, based on changes in land use or its canopy, total emission produced is predicted. Then, applying scenarios on the 21 plans of land used accordingly, total emission is measured and projected up to year 2020. This calculation shows the total amount of emission due to land conversion caused by development activities in East Kalimantan.

Estimation result shows that plantation is responsible for largest amount of emission, that is 29.94 percent and it is followed by mining which produces emission up to 12.81 percent from the total emission. However, it also significantly contributes to the total emission reduction when the scenario of emission reduction is applied. Plantation would contribute to 75.61 percent of the total reduction, while mining would reduce 7.95 percent of emission.

3. Method

Goal Programming (GP) is employed to analyze what is the impact of emission reduction policy on the economy in terms of output level. Moreover, GP model also estimates the economic cost of the policy when it is applied. Furthermore, the model provides a new alternative economic structure that is considered to be "green" as the emission reduction policy is applied to the economy. Therefore, GP model formulates an appropriate or optimal economic structure that is considered to be more environmental friendly.

Adopting Cristóbal model (2012), Goal Programming model can be applied in order to find the optimal economic structure that consider three goals that are social, economic and environmental to achieve IGE. In matrix form, Goal Programming model is formulated as follows:

$$\textit{Minimize } f = P_i . d_1^+ + P_i . d_2^+ + \dots + P_i . d_n^+$$

Subject to:

$$(I - A)X + \boldsymbol{d_1^-} - \boldsymbol{d_1^+} = \boldsymbol{a}$$

$$\hat{L}X + \boldsymbol{d_2^-} - \boldsymbol{d_2^+} = \boldsymbol{b}$$

$$\hat{E}X + \boldsymbol{d_3^-} - \boldsymbol{d_3^+} = \boldsymbol{c}$$

Where: X is the total output; $\hat{L}$ is a vector of direct impact coefficient of output on the employment; $\hat{E}$ is a vector of direct impact coefficient of output on the emission; P_i is rank or priority. i = 1, 2 or 3.

For economic objective, the target level refers to the output level in 2013 or it is equivalence with 1.59 percent of economic growth. The level of employment in 2013, that is 1,378.61 thousand labors, is used for social objective. As environmental objective in the model, emission target data taken from RAD-GRK is used, 563.29 million Ton CO_2e, and the classification of emission sector is modified to match IO classification. Additionally, IO Table of East Kalimantan Province Year 2013 is employed as constraints for GP model to represents level of technology in the economy of East Kalimantan.

The result of the model is expected to provide new economic structure of East Kalimantan that satisfies the economic, social and environmental goals. Moreover, the model will allow us to find the effects on output in different sectors of a reduction in the emission levels. Furthermore, the model provides a role model of systematic procedure for examining the different goals that policymaker must implement in order to achieve IGE in East Kalimantan.

4. Optimal Economic Structure toward Sustainable Development: a Goal Programming Application

Economic transformation requires changes in the structure of the economy. However, an appropriate economic structure that is in line with IGE has not been provided. To formulate appropriate or optimal economic structure, it would need to firstly identify what are challenges and potential natural resources that are available in East Kalimantan economy. Moreover, other factor such as human capital is also should be taken into account in formulating the optimal economic structure.

To achieve sustainable development condition, therefore development in an economy should simultaneously consider among economic objective, as well as social and environmental objectives. Goal Programming model can be employed in assessing the achievement of an economy toward sustainable development. Moreover, model output suggests the new alternative economic structure that is optimal in order to achieve sustainable development. The result of the GP model is given in Table 1.

Table 1 the Impact of Emission Reduction on Output

No.	Sector	Output 2012 (Billion Rupiahs)	Output 2013 (Billion Rupiahs)	Maximize Value Added		Minimize Emission	
				Optimal Output (Billion Rupiahs)	Change Contribution Relative to 2012 (%)	Optimal Output (Billion Rupiahs)	Change Contribution Relative to 2012 (%)
1	Food Crops	7.11	7.25	7.24	0.021	7.24	0.021
2	Oil Palm	3.55	3.89	3.04	-0.081	3.89	0.054

27	Other Services	1.84	2.06	2.02	0.029	2.03	0.030

No.	Sector	Output 2012 (Billion Rupiahs)	Output 2013 (Billion Rupiahs)	Maximize Value Added		Minimize Emission	
				Optimal Output (Billion Rupiahs)	Change Contribution Relative to 2012 (%)	Optimal Output (Billion Rupiahs)	Change Contribution Relative to 2012 (%)
Natural-Resource Based Sector		431.95	422.54	421.86	-1.600	330.06	-16.159
Non Natural-Resource Based Sector		198.56	216.67	214.73	2.565	215.14	2.630
Total		630.53	639.20	636.60	0.963	545.21	-13.531

In general, there is a decline in the output level due to the emission reduction policy. First scenario is carried out by maximizing output level as first priority. It shows that there is a reduction in the output level by 33.45 percent compared to the output level in 2013. In 2013, East Kalimantan economic growth was 1.59 percent, however, if the policy of emission reduction is applied then there is a slower growth occurs in the economy. The economic growth would be expected to be only around 1.15 percent. Meanwhile, the environmental objective of emission reduction cannot be achieved. By considering output level as a priority policy, the emission level is 599.67 million ton or 6.5 percent higher than the level of emission target.

In details, significant output reduction share are given by natural-resource-based sectors, such as Oil and Gas (1.96 %), Coal (6.67 %), Oil Refinery Products (4.93 %) and LNG (5.20). These sectors are biggest emitter in the economy, and given the policy implementation, they contributes more to the total output reduction. This finding is similar to a study carried out by Cristóbal (2012) that is all output level declines in the Spain economy when the environmental policy of emission reduction is implemented. This indicates that there is a trade-off between emission reduction policy and output level. Moreover, aside from Coal sector, the highest shares to the total output reduction are given by industrial sectors, Oil Refinery Products and LNG. This result is also similar with study in Canada where the industrial output should reduce to meet the Kyoto Protocol target (Lixona *et al*. 2008).

Furthermore, second scenario is applied to the model by putting environmental objective as top priority provides the expected result of emission reduction. However, the economic cost is bigger compared to the result of previous scenario. The economic output is lower compared to the output level in 2013, it is a difference of 13.53 percent, when the emission reduction policy is being implemented and put as the priority. This decline is equivalence to a contraction in the economy, an economic growth of -9.04 percent.

The result shows that in general there are output declines in all sectors of the economy, and some sectors are recommended to have zero level of output, especially services. Natural-resource-based sectors, such as Coal, Oil Refinery Products, and LNG contribute more to the emission reduction compared to other sectors. Moreover, the shares are higher compared to their shares of the first scenario. This indicates that these sectors are quite responsive to the emission reduction policy.

In addition, the result shows there is a shift in the sectoral emission structure in East Kalimantan when the emission reduction policy is implemented. Due to the significant output reduction of the natural-resource-based sectors, there is also a significant in the emission reduction, especially from Oil and Coal sector activities, whereas there is an increase in the other sector emission, such as agriculture. This indicates there is a transformation in the economy from natural-resource-based sectors to the agricultural sectors, such as food crops and palm.

This finding is confirmed by Figure 2. In general, it shows that emission reduction policy tends to change the economic structure of East Kalimantan Province compared to baseline data on

2012. If the policy is applied while maximizing value added, there is a decline in natural resource contribution to the economy, and a greater contribution of the non-natural resource-based sectors. More significant contribution is given by non-natural resource-based sectors when emission reduction policy is applied while minimizing emission is prioritized. This implies that dominant sectors in East Kalimantan economy are significant emitters. Therefore, in order to achieve green economy, there has to be a slowdown in production activities of these sectors.

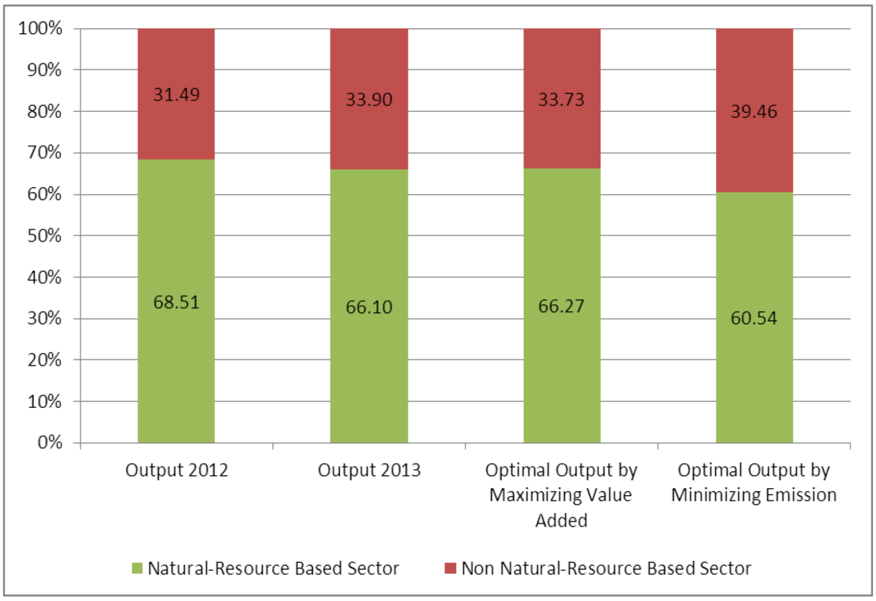

Figure 2. Structural Transformation of East Kalimantan Province due to Emission Reduction Policy

Figure 3 shows that there is structural change when an environmental objective is taken into account in the economy. In terms of output level, applying emission reduction policy causes a lower output level compared to the level of it should be that is output level in 2013. However, it may be successful in reducing emission level. Although in first scenario of maximizing value added, the level target of emission still cannot be achieved, the level emission is lower compared to the level of emission when Business as Usual practices applied in the economy and East Kalimantan economy still experiences a positive growth. Whereas, if second scenario is applied, there would be an even lower output level compared to output level in 2013, and East Kalimantan economy experiences negative growth. However, the level emission targeted can be achieved by applying this scenario.

These scenarios suggest that in order to achieve a greener East Kalimantan, emission reduction policy should be applied. However, there are consequences in applying this policy, lower output level that may cause a slower growth or even a negative growth of the economy. Aside from a slowdown in the economy, model also suggests that there has to be a structural transformation in East Kalimantan economy. In order to ensure a sustainable development, there is a necessity to shift from natural resource-based economy into non-natural resource-based economy, such as agricultural or industry.

Figure 3 shows that as the policy is applied, there is a tendency that agricultural sector contributes more to the economy. As the economy moves to more environmental practices, agricultural sector contributes more to the economy. This because emission intensity produced by agricultural activities is relatively lower than one produced by natural resource-based sector. This indicates that development in agricultural sector may benefit and support to create a green economy of East Kalimantan.

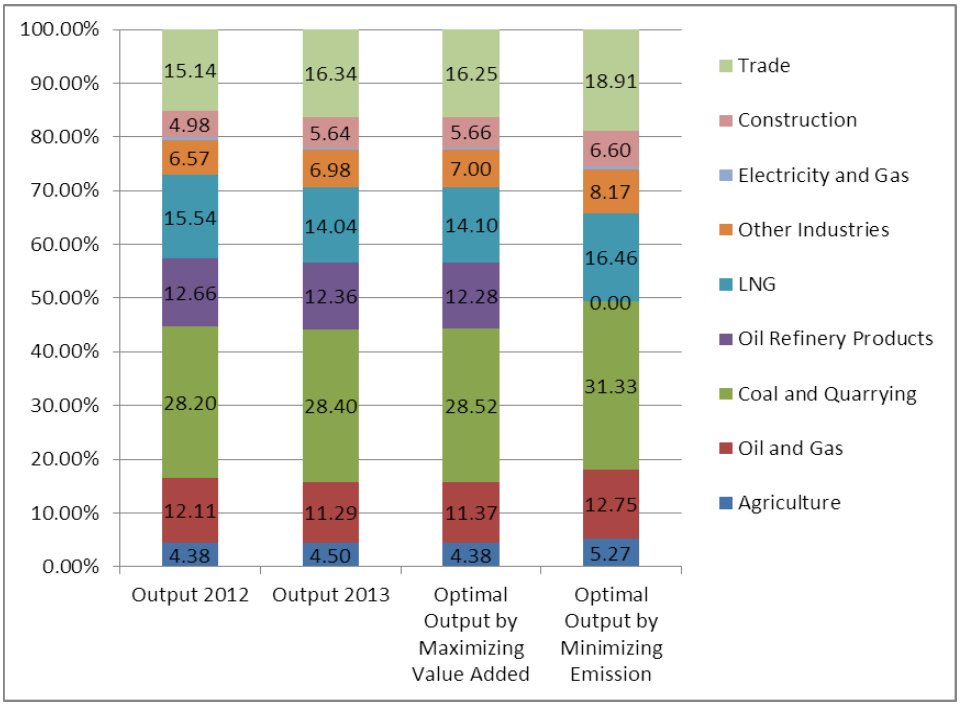

Figure 3. Economic Structure of East Kalimantan Province due to Emission Reduction Policy

5. Concluding Remarks

East Kalimantan economy is heavily relied on natural resources. It creates externalities. East Kalimantan becomes one of biggest emitter in Indonesia.

The performance of greenness aspect of East Kalimantan is indicated by emission intensity and energy intensity. During period 2000-2012, there is an increase in the emission intensity assuming that economy applies BAU practices. Moreover, there is also a tendency to use more energy per capita overtime. This suggests that the sustainability would be threatened given that there is no other new energy reserve found. Furthermore, DEA model indicates that East Kalimantan becomes less efficient overtime in terms of utilizing its natural resources and environmental management.

Emission reduction policy is believed to be a way in achieving sustainable development by creating a greener economy. However, there is economic cost in applying the policy. There is trade-off between emission reduction and output level. As it is expected, natural-resource-based sectors contributes more to the total output reduction. This implies that there is a contraction in these sectors; hence it reduces more emission compared to other sectors. The economic cost is even bigger when environmental objective of emission reduction becomes first priority. Therefore, it should be considered alternative policies in order to outweigh the incurred cost.

By applying the environmental policy, there is a change in the economic structure of East Kalimantan. A significant decrease in the output level of natural-resourced-based sectors implies that there is a transformation towards agriculture, especially palm plantation. Moreover, this indicates that there is an opportunity for East Kalimantan economy to be less dependent to the natural-resources-based, as well as be greener. Thus, this implies that sustainable development in East Kalimantan can be achieved by developing agricultural sector.

ABSTRACT

The effects of climate change in Ghana pose a threat to sustainable development, hence food security. Phenomena including drought, prolong dry season, flooding, storms and increased temperatures have become prevalent in the country, with several implication for food production. Particularly, the small-scale farmers in the country who account for about 80% of domestic agricultural production have limited resources to invest in appropriate technologies in order to adapt to the changing climate variability. In the Talensi district several staple cereal crops as well as tubers are affected by the shortening of the growing season. Small-holder farmers in the district have considerably relied on traditional knowledge for the production of food in the communities in the mist of this variability. World Vision Ghana with support from World Vision Australia started the implementation of a climate change project in the district in 2009 with the aim of improving the resilience of the people through improved adaptive capacity of small-holder farmers. This paper seeks to understand the synergistic relationship between the autonomous practices by the indigenes and the planned adaptation measures in shoring up food security in the communities. Focus group discussion, individual and group interviews were adopted to collect data from respondents in three purposively sampled beneficiary communities. Findings from the study revealed that bridging indigenous knowledge with the planned approaches leads to higher food crops yields and thereby strengthening the adaptive capacities of beneficiaries in these communities. These findings imply that planned adaptation programmes need to identify and incorporate indigenous knowledge and practices into their activities in order to achieve greater success.

Key words: Food security; resilience; indigenous knowledge; smallholder farmers

1.0 INTRODUCTION

Conventional agricultural land preparation activities in the research area are often slash and burn at the beginning of each farming season prior to planting which contribute to land degradation. This manifests in declining agricultural yields and loss of environmental services such as wild foods that traditionally subsidized household diets, wood stocks, etc. World Vision Ghana (WVG) with support from World Vision Australia (WVA) started Farmer Manage Natural Regeneration (FMNR) project with the aim of improving the livelihood of the people through improved adaptive capacity of small-holder farmers in 2009 in the Talensi District o the Upper East region. The project approach involved blending the planned ideas with the local approaches that were adopted by the small scale farmers. This paper is a presentation of the bridged points of the project and its impact on the output of the small-scale farmers in the region.

1.1 BACKGROUND

In Ghana, underlying structural factors of vulnerability such as population pressure, declining ecosystems, poverty, conflict, vulnerable rural livelihood activities amongst others have been exacerbated by climate change leading to increase in human vulnerability to environmental factors, (IOM …). In recent years, annual rainfall volumes have been declining, forest cover and the associated indigenous biodiversity and arable soils disappearing. The net result is a population that is staggering between food crises with shorter recovery periods, (WVI, 2012), thus posing a threat to sustainable food security, (WFP, 2013). Effects of climate change including drought, prolong dry season, flooding, storms and increased temperatures have become prevalent (CC DARE (…), affecting the activities of the small-scale farmer. Integrating adaptation into development strategies will address the impact of climate change thereby reducing pressure on natural resources, improve environmental risk management, improve the resilience of people, and increase the social well-being of the poor, (United Nations 2013).

Adaptation practice is both planned and autonomous. Planned approaches are consequence of deliberate policy and project decisions while autonomous approaches are more reactive to the changing climatic conditions. People in hazard-prone areas have adapted to the effect of climate change using their own capabilities, skills, knowledge and technologies to improve resilience and self-sufficiency, (Ensor and Rachel, 2009). Because of the frequent occurrence of climate extreme events, local people have developed extensive reactive beneficial skills, knowledge, and management systems that enable them to interact with their environment which sustains the livelihoods that they depend on, (IPCC, 2012). These knowledges have sustained rural societies and their environment in many parts of the world for centuries, (Ensor and Rachel, 2009). Little of these approaches have been incorporated into formal climate change mitigation and adaptation strategies, (Nyong, et al 2007).

Small-scale farmers in Ghana account for about 80% of domestic agricultural production, and about 84% of farming households in the upper east region, (WFP, 2013). However they have limited resources to invest in appropriate technologies in order to adapt to the changing climate variability. They have considerably relied on traditional knowledge for the production of food in the communities, (Arndt et al 2014, Nyong et al 2007). The main objective of the study is therefore to understand the synergistic relationship between the autonomous and planned adaptation measures in shoring up food security in the beneficiary communities of the FMNR project.

1.2 METHODOLOGY OF THE STUDY

The study assessed the synergy between planned and autonomous climate change adaptation approaches by small-scale farmers in the Upper East Region for improved output. Primary data was collected from the communities and complemented by secondary information from the district and the program office level. The research adopted mixed approach but with much emphasis on participatory research approach, (Chambers, 1994). This approach was adopted because; community-based inquiries can provide more knowledge about changes in a situation, (Anirudh et al, 2004). The approach was used to illicit information from small-scale farmers on the approaches adopted and its effect on their outputs. Three farming communities (two beneficiary communities and one non-beneficiary) were purposively sampled. Primary data as well as both published and unpublished secondary data were used to provide the basis for analyses and conclusion of the study. Focused group discussion; community group discussion; observation, in-depth interviews and questionnaires were used to collect the data. Both qualitative and quantitative techniques were adopted to analyze the data.

2.0 THE STUDY AREA

The three communities studied are located in the Talensi District of the Upper East Region of Ghana. About 84% of the households in the region are farmers as compared to 45.8% in the country (GSS, 2013). Also, about 90% of the inhabitants livelihoods depend on climatic condition and about 49.1% of the inhabitants are food in-secured (WFP 2013). The climatic condition is tropical and has two distinct seasons – a wet season with erratic rainfall that runs from May to October and a long dry season that stretches from November to April. The mean annual rainfall ranges between 88mm-110mm with the maximum being 950mm while the maximum temperature is 45°C in March and April with a minimum of 12°C in December (DMTDP, 2014). The visible environmental problems in the district include: deforestation; silting of water bodies; soil erosions and Bush fires which are mainly caused by poor agriculture practices, charcoal production, activities of herdsmen, hunting, honey tapping and surface mining.

2.1 RESULTS AND DISCUSSION

Farmer Managed Natural Regeneration (FMNR) is a technique that improves lands that have been degraded leading to loss of biodiversity and soil fertility. It encourages regrowth from the stumps of cut-down trees, protects and prunes the regrowth into new trees. The approach has a 100% success rate of trees survival. It can be implemented as an on-farm agroforestry activity or managed as a community forests. The two beneficiary communities of interest implemented the two approaches: community forestry; and on-farm mixed agroforestry. The community forests are protected from agriculture activities, over-exploitation, and it's managed by the communities' FMNR Lead Farmer Groups. The groups are made up of 20 Lead Farmers each who are responsible for pruning and protecting the site and its regrowth. In return, they are allowed to harvest their off-cut as firewood and other natural resources such as grasses. The on-farm approach is a mixed agroforestry practice that allows the farmers to prune shrubs on their farms to become trees. Other complementary activities implemented by the project include: education on behavioural change; skills and occupational training; provision of improved and drought tolerant crops; climate information gathering and communication amongst others. The autonomous approach adopted by the farmers before the project included: wage labour temporal migration; assets portfolio diversification; changing production technology; occupational diversification; formation of farming associations amongst others.

2.2 CONVERGENCE OF THE TWO ADAPTATION APPROACHES

This section analyses the convergence of the two approaches adopted by the beneficiary communities. FMNR and the autonomous approaches converged at most points that resulted in the benefits of the project.

2.2.1 Production technology (Composting, mulching and soil conservation)

Prior to the implementation of the project, farmers in the beneficiary communities valued and practised organic fertiliser techniques inputs such as manuring and mixed farming. Farmers gathered animal droppings during the dry season and spread it on their lands during the lean season before ploughing. They also piled up household scraps over the year, and then scattering the pile over a small area, such as a vegetable plot during the lean season. These local approaches were improved by the project by training farmers on composting and its application in the communities. The improved technique involved collecting the stalks and debris and transferring it into a pit dug on the field (which preserves moisture in the dry season, permitting decomposition), then adding smaller quantities of manure, leaves, weeds and household waste and allowing it for some time before spreading it on the farm. Prior to the project, all crops stalks would be burned off annually after harvesting which exposed the land to erosion and degradations. The expansion of improved composting has made organic fertiliser available to more household without sufficient number of livestock. The project approach also included leaving crop stalks on fields to prevent erosion and; encouraging livestock and birds to graze and defecate on the farms. These techniques are used to increase soil fertility and crops yields by farmers.

2.2.2 Livelihood diversification

As a way of minimizing the effects of climate change on their livelihoods, local people diversified some of their livelihood activities including sale of convenient items in the villages; processing of shea butter; occupational diversification amongst other activities. To help improve on the livelihoods of these people, the project supported the Lead farmers to create Group bank savings account; establishment of village savings and loans associations (VSLA); support of two bullocks for field ploughing and income generation activities, bee keeping etc. The groups were further trained in association management skills, and encouraged each group member to build up a capital reserve for future farming investments by saving a little of their income with the VSLA. The bullocks provided affordable traction or service for members and a source of income generation by hiring them out to other farmers. Through the VSLA, the members mobilized savings from the group members and offered business capital to group members which was used to expand their businesses such as shea-butter extraction, selling of salt, pepper, gari amongst others at the community levels.

2.2.3 Communal pooling

The farmers in the communities formed associations and groups which were used to support each other in their farming activities. Members of the groups benefited from the entire group through rotational services among members. These groups were useful for the project since the lead farmers who were responsible for the community forestry was dependent on this background. Through this group climate information was easy to spread from one member to another since they constantly met to take decision on the community forestry. The groups also served as grounds used to demystify traditional fear that growing trees causes the planter to die as well as demonstrated that trees do not suppress crop growth when pruned effectively and the suppression of bushfires that does not expose the land to harsh weather conditions. Planting of trees especially economic ones like mango, shea and dawadawa was encouraged through the groups.

2.2.4 Market exchange

Some community members had started selling various items in the communities and beyond to supplement household income and provide basic needs for the family. These items included the sale of wild fruits, soap, pepper, salt and the introduction of new items in the communities as well as the sale of seeds and other farm inputs. The project improved these processes by introducing training on business management practices such as record keeping; customer care; group dynamic etc. The introduction of bee keeping in the communities and the training on bush fire suppression increased the sale of honey in the communities and the sale of fruits. The collective decision-making and agreements have strengthened the unity and collaborative spirit of the project communities to fight bush fires which is yielding positive results on the environment and their crops yields.

3.0 BENEFITS OF THE PROJECT

An assessment of the benefits of the project during the survey revealed that numerous benefits were achieved as a result of the synergetic approach that was adopted by the project. These benefits are enumerated below.

3.1 IMPROVED SOIL FERTILITY AND CROPS YIELDS

In all the focused group discussions of the FMNR adopters, participants revealed that the key benefits of the project was improved soil fertility and increased crops yields. One of the farmer groups indicated that;

"The applications of compost, agroforestry, bushfire suppression and mixed farming have resulted in increased in soil fertility. We use to burn the stalks after harvesting but now we leave them to decay into the soil as well as use some of it for composting. Previously we cleared the entire shrubs on the field but now we prune the shrubs and the leaves drop back on the land which increases soil fertility. Also the mixed farming allows the droppings of the animals to fertilize the farm lands. In the past, the traditional notion was that trees affect the growth of crops negatively. But we have come to realise that it is untrue. Rather, where there are trees and they are well pruned, soil fertility increases, leading to good crop yields." (Tongo-Beo Men)

This information was corroborated with the World Vision Ghana office who revealed that 94% of the project beneficiaries revealed an improvement in soil fertility, of which about 75% indicated that it was improving a lot and has resulted in increase in crops yields. The non-adopters in the observed community indicated that their soil fertility was decreasing. According to them, they had started learning how to prepare composting since they saw the change it was bringing in the yields of those communities that adopted the FMNR approach.

"We have also started learning how to prepare composting. This is because we are seeing how it is improving the yields of our colleague farmers in Yameriga and Tongo-Beo. The soil fertility is decreasing drastically and there is nothing we can do to improve on it than to try what the others are doing and it is helping them" (Kaare community leaders).

The FGDs at the communities and the KIIs at the implementing agency offices attributed the increased in soil fertility to: FMNR increased leaf-drop, wind protection and run-off; bushfire suppression; elimination of field-burning; grazing livestock in the dry season; and improved Compost' technique.

"Some of us have our outputs increased by three folds, for instance, I used to get three to four basins of sorghum from my field. After applying compost, manure and not burning the stalk on my field I got close to three bags on the same field [equivalent of 12 basins)" (Yameriga Lead farmer)

A corroboration of the output levels of crops at the District MOFA Monitoring and evaluation Office revealed that between 2009 and 2010, the average output of maize increased from 1.95metric tonnes/hector to 2metric tonnes/hector while vegetable crops increased from 2.39metric tonnes/hector to 5.2metric tonnes/hector between 2009 and 2013 in the district. The increment was dominated by the FMNR project communities. The benefit of the improved crops yields contributed to improved household food security and income as well as creating a cost saving to the household.

3.2 IMPROVED ACCESS TO FODDER AND LIVESTOCK SECURITY

Fodder for domestic animals in the Upper East Region of Ghana has become very scarce. This is because, the bushes are burnt in the dry season and since the dry season has become so long, it becomes difficult to get feeds for the animals. Cattle, sheep and goats get lose as a result of the scarcity. The animals travel long distances in search for food in the dry season. In the two beneficiary communities that the research covered, fodder in those communities are progressively increasing and reducing the number of animals that get lose in the dry season. They also indicated that their animals are fatter and healthier and have up to 3-4 times market value than the animals in the non-beneficiary communities. This is because the community forest and the individual farms that are not burnt serve as feeding grounds for these animals. The animals do not wander around looking for feeds. The implication is that more time is saved as young boys have more time to attend school as they spend less time herding their cattle and ruminants in the forest and the grown-ups also spend more time on other activities than looking after the herds.

"Our animals no longer roam far for pasture because there is ample feed around. The grasses in the community forest are not burnt. The landscape is also cooler and attracts animals all over the surrounding villages that come to graze. Our animals look more healthy and fatter such that we can bargain for a better price when they are offered for sale." (Tongo-Beo Lead Farmers)

"We sell our animals to cater for household needs like children's school fees; health; buy consumables for the household. Animals are very important assets in our lives. Previously some of our animals used to die due to hunger, but with the introduction of FMNR, there's more pasture for animals and they don't roam far. We didn't know and we were always burning the bush, but now we don't burn the bushes and our animals feed there. Children now spend more time in school than looking for animals in the bush. We also spend less time looking for the animals in the dry season. They are always around the community forest all time grazing" (Yameriga Chief)

As compare to the non-beneficiary community that was survey, the Tindana and elders complained that the chance of their animals being stolen by people outside their communities is higher. They spend much time looking for their animals which wander around for food in the dry season. Some end up being stolen while others too loses their market value because they do not get enough fodder to feed.

3.3 IMPROVED DIET: WILD FRUITS AND ANIMALS (BUSH MEAT)

The study revealed that there is increased in availability and access to local wild foods such as fruits, nuts and wild animals such as rabbits and partridges in the beneficiary communities. The increase in the access leads to increase in access to diet which translate to increase in nutritional values for both children and grownups. The major cause of this achievement is due to the suppression of bushfires which allows mature fruit trees to bear fruit, and also serve as habitat for the wild animals. When the information was corroborated with WVG and district level MOFA, it was revealed that about 46% of the project beneficiaries observed that the FMNR practices have generated more wild fruits and food in the communities. The community members also expressed that there are more wild animals which are used for bush meat and improves household diet. The improved diet and income is also as a result of the project supplementing bush meat with breeder rabbits to some lead farmers.

"*Some wild animals that were almost extinct are returning in the forest. For some time now we have begun experiencing the return of wild animals such as partridge, birds, rabbits and mice. These animals are hunted for and used as food in the household as well as sold for additional household income in the family" (Yameriga chief).*

3.4 INCREASED ACCESS TO NATURAL RESOURCES SUCH AS CONSTRUCTION MATERIALS AND FIREWOOD

In the research area, over 95% of the households depend on fuelwood and charcoal for their household energy. Construction materials are also mainly local materials like rafter, grasses (for thatch) and wood for other building purposes. This study revealed that access to these materials improved in the beneficiary communities over the period. The firewood is gotten from the pruned branches while some of the matured branches are harvested for building or construction materials.

"We prune the trees and use the pruned branches for firewood. We also cut the dried branches on the trees and use them for firewood. Because we don't burn the forest too, the grasses are there all year round and they are much taller than before. We harvest those grasses and use them to roof our buildings. We also select and cut the matured branches and use them as rafters" (Yameriga Chief).

"In the past, we used to travel long distance to obtain grasses for thatch. These days we don't go far and get the grasses for the thatch. A lot of time is saved and we are able to do other activities other than using the whole day to search for the grass" (*Tongo-Beo Lead Farmers*).

This situation was different in the non-beneficiary community (Kaare). They still face the challenge of spending much time to look for rafters and grasses to roof their buildings.

"*We travel long distance to look for rafters and grasses to roof our buildings. One can spend the whole day searching for only two bundles of grass", (Kaare Tindana and elders).*

Corroborating this information with the WVG office and the MOFA district office revealed that FMNR beneficiary households harvest four times more rafters from their own fields, and twice as many harvest firewood from their own fields than the non-beneficiary communities in the project area.

3.5 PROTECTION FROM CLIMATIC EXTREME EVENTS LIKE STORM

Climatic extreme such as storm is very frequent and causes devastating effects to crops and lives. The severe winds can rip off the roof of buildings; cause wind erosion; level or push crops on the ground and even push down trees including economic trees. The community forest and the agroforestry practices on the farms serves as wind breaks and the consequence of the effects of storm have reduced in the project communities. The fire suppression has also increased the quantity of leaves on the farms which checks erosion when there is heavy rain.

"Previously there used to be heavy storm that carried away our crops and rip off our buildings. Though we still experience heavy storm, it doesn't affect our crops like before. The trees serve as wind breaks and reduces the effect on our lives. The time we used to spend on reworking on our roofs and buildings after storm is no more. Times are saved and use it on other activities including farming. Leaves of trees also prevent soil erosion. The leaves also serves as mulching and the land does not dry in time" (Yameriga Lead Farmers).

4.0 CONCLUSION AND IMPLICATION

Bridging autonomous adaptation with the planned approaches leads to higher commitment and therefore improves on outcomes that go a long way to strengthen the adaptive capacities of beneficiaries. The indigenous and planned approaches converged at various points and this has resulted in increased commitment in the implementation of the project leading to higher achievement in the outcomes of the project. Local adaptation approaches are relevant for food security and environmental protection and should be identified and incorporated in planned approaches. These findings imply that planned adaptation initiatives need to use consultative and participatory process to identify and mainstream context-relevant autonomous and indigenous knowledge and practices in order to achieve greater success and increase sustenance of outcomes.

ABSTRACT

Assessing the integration of environmental requirements into agricultural practices is a difficult exercise, aimed at evaluation of the state of the environment, the interaction between agriculture and environmental outcomes, as well as of the influence of other factors, such as general market trends, technological development and weather events.

Measuring the impact of agriculture on environment for designing, implementation and evaluation of economic policies aimed at its mitigation is crucial. Relevant and timely information on the response of agricultural practices to data requirements for designing and monitoring the environmental policy became mandatory. To meet these high demands, international and national organizations accelerated the transition from the development of agri-environmental indicators to the actual production of such data.

Farm Structure Survey (FSS) is one of the main tools for collecting data for the calculation of agri-environmental indicators in European Union (EU)'s member countries. Starting with FSS 2010, Romania integrated in its survey program the required information for calculation part of the agri-environmental indicators according to Eurostat standards and recommendations. Having in view the deficiencies related to data collection, still a number of limitations need to be overcome for the set of agri-environmental indicators to become fully operational. However, for analyzing the relationship between agriculture and environment and for identifying main trends in this evolving interaction, efforts are done to gather supplementary information, scattered among various institutions, to improve, develop and compile the entire set of indicators needed, according to Eurostat recommendations. Administrative data sources can fill important gaps, but efforts should be done to obtain more added value, improving such data in line with statistical requirements and georeferencing principles. From this perspective, FSS, even if confronted with increasing and more complex data demands, became a core instrument for collecting primary data on environmentally related farm management practices indicators.

The paper presents a brief overview on data needs and availability at national level for assessing the farm management practices in Romanian agriculture, aiming to appraise the set of agri-environmental indicators related to soil management practices towards environmental sustainability based on FSS data.

Keywords: agri-environmental indicators; soil management practices; soil conservation methods

1. Introduction

Agricultural production systems based on intensive farming led to increased pressure on the environment. The dynamic relationship between the processes taking place in agriculture and environmental phenomena grounds the “sustainable agriculture” concept. The series of reforms of the Common Agricultural Policy (CAP) that have taken place in the 1990s, 2000, 2003, 2008 and 2013, led to a ‘greening’ of the CAP (O. Oenema et al. 2011).

Implementation of agri-environmental measures started in 1980 on own initiative of several Member States of the EU. This initiative was taken by the European Community in 1985, by Article 19 of the Council Regulation (EEC) No 797/85 of 12 March 1985 on improving the efficiency of agricultural structures, but remained optional until 1992 when it was introduced as “accompanying measure” of the CAP for all EU Member States. Subsequently it became subject of a specific regulation[1], encouraging farmers to carry out environmentally beneficial activities on their land, and Member States were required to introduce agri-environment measures “throughout their territory”. In 1999, the Agri-Environment Regulations were incorporated into the Regulations for Rural Development[2], as part of the CAP reform “Agenda 2000”. Compliance with the rules of conditionality (cross-compliance) accompanying the single farm payment scheme (stated during CAP Reform for 2007-2013), introduces a cross-cutting approach support system for farmers, which is based on accomplishing of the strict conditions to be met for getting the aid requested from the community. All farmers receiving direct payments must comply with a “list of priorities”, which refers to respecting different European standards in the following areas: (i) environmental protection; (ii) food security; (iii) animal health and welfare.

Agri-environment measures are the main tools for implementing the environmental policy for fulfilling environment objectives established through the Rural Development Programs (RDP). They are accompanying the mechanism of single farm payment scheme and are a key instrument

[1] Council Regulation (EEC) No. 2078/92 on agricultural production methods compatible with the requirements of the protection of the environment and the maintenance of the countryside.
[2] Council Regulation (EEC) No 797/85 of 12 March 1985 on improving the efficiency of agricultural structures.

for achieving environmental objectives agreed in the development programs at EU level. Agri-environment measures are proposed by Member States or regions and submitted for approval to the Commission according to Regulation 1698/2005 as part of their RDPs.

For the assessment of trends over time of (i) the effects of agriculture on the environment, and (ii) the effectiveness and efficiency of agricultural and environmental policy measures, and for monitoring the implementation of agri-environment measures, a set of 28 agri-environmental indicators (AEIs) were identified in the Commission Communication COM(2006) 508 and subsequently approved by the Agricultural Council.

Following the analysis of data requirements for the calculation of agri-environmental indicators, Eurostat has identified a total of 97 different types of data, of which 25 are related to surface. Twenty types of data can be obtained from the Farm Structure Survey (FSS) and 12 from the Survey on Agricultural Production Methods (SAPM). In addition to FSS and SAPM there were identified 43 other different data sources.

In some EU member states the SAPM was surveyed as a sample survey, in others as a census, while the FSS was carried out as a census in all countries in 2010. The SAPM was in most countries carried out at the same time as the FSS 2010.

2. Analytical framework

Given the flexible framework offered by OECD model DSPIR (Driving forces - Pressures - States - Impacts - Responses), the 28 AEIs were identified under DPSIR analytical framework[3]. Most sets of indicators presently used by nations and international bodies are based on DPSIR-framework or a subset of it (Gabrielsen&Bosch).

Farm management practices are defined as decisions and operations practices that shape the effective management of farms, such as land preparation (soil cover and methods of preparing the soil for cultivation) and the type and capacity of manure storage farm manure and slurry. In order to assess the relations between farm management practices and environment, under the DPSIR domain "Driving Forces" sub-domain *Farm management*, there were defined three main agri-environmental indicators[4]: (i) Soil cover - AEI 11.1, (ii) Tillage practices - AEI 11.2 and (iii) Manure storage - AEI 11.3.

2.1 Soil cover – AEI 11.1

Conservation agriculture encompasses a set of complementary agricultural practices which minimize alteration of the composition and structure of the soil. Soil conservation is one of the ways to reduce land degradation due to soil erosion, pollutants, pesticides etc., contributing, at the same time, to enrich soil organic matter by soil cover in winter. Conservation agriculture tries to keep the soil covered with a cover crop or with crop residues. Soil cover can improve soil fertility and reduce erosion risk while, thereof, preventing leakage of nutrients and pesticides.

[3] http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=COM:2006:0508:FIN:EN:PDF
[4] http://ec.europa.eu/eurostat/web/agri-environmental-indicators/analytical-framework

This indicator provides information on the periods of the year when soil is covered with: (i) normal winter crops (winter crops), (ii) protecting crops / crop cover or intermediate, (iii) residues of crops or (iv) soils uncovered.

The AEI *soil cover* can be measured by the following indicators[5]:

Main indicator:

Share of the year when arable land is covered with plants or plant residues.

Supporting indicators:

• The share of arable land covered by winter crops (winter cereals and winter rape or grass)

• The share of the arable crops covered by annual green crops.

• The share of arable land covered by maize.

FSS, SAPM and Crop Statistics are the main sources of information for AEIs with reference to farm management practices classified. Data on farm management practices are not collected regularly. These data were required for the first time in the SAPM, held together with the FSS in 2010 (year of agricultural census in EU Member States).

2.2 Tillage practices - AEI 11.2

Tillage practices refer to cultivation operations carried out between harvest and the next sowing operation /cultivation. It is included only the area of the main crops. The sum of land under conventional tillage + conservation tillage + zero tillage = arable land - arable land not sown/cultivated during the reference year. Arable land which is not sown/cultivated during the reference year can be areas under glass or other protective cover, temporary grasslands, leguminous plants, industrial crops like hops or aromatic plants etc.

Tillage practices are defined as the share of arable surfaces under conventional tillage, conservation tillage (reduced cultivation) and zero tillage (direct sowing), and is measured by the following indicators[6]:

Main indicator:

The share in total area of arable land of the arable land on which there were practiced the following cultivation methods: (i) conventional plowing (ii) cultivation of conservation (iii) zero tillage and (iv) not tilled.

Supporting indicators:

Arable areas under conventional tillage, under conservation tillage and under zero tillage.

2.3 Manure storage - AEI 11.3

AEI on manure management provides information on manure storage facilities on agricultural holdings and related storage capacity, which depends on the time required for storage and the number and type of animals.

[5] http://ec.europa.eu/eurostat/statistics-explained/index.php/Agri-environmental_indicator_-_soil_cover
[6] http://ec.europa.eu/eurostat/statistics-explained/index.php/Agri-environmental_indicator_-_tillage_practices

The storage capacity for manure can be measured by the following indicators[7]:

Main indicators:

- Share of holdings with livestock which have manure storage facilities in total holdings with livestock.
- Share of holdings with different manure storage facilities.

Supporting indicators:

- Share of manure applied with different application techniques and manure incorporation time
- Share of animals in different housing systems

There are delineated the following types of storage facilities:

- Storage facility for solid manure (dung): impermeable surface with drain insulation, with or without roof;

- Storage facilities for liquid manure: watertight tank, open or covered, or lined lagoon;

- Storage facility for semi-liquid manure (suspended) slurry tanks, open or covered, or lined lagoon.

This indicator is primarily of relevance for emission of ammonia (NH3) and nutrient leaching losses from animal manures. The main indicator is related to storage facilities and supporting indicators to spreading of manure or slurry and to housing facilities

3. AEI on farm management practices in Romania

Agri-environmental indicators related to farm management practices were calculated based on the results of FSS and SAPM carried out in Romania in 2010 (full scope survey).

3.1 Soil cover – AEI 11.1

Over 96% of the total number of farms in Romania (3.9 million farms) operated agricultural areas in 2010, of which 71.5% operated arable land (2.8 million farms). About 79% of the farms that operated arable land (2.2 million farms) have applied one or more methods of soil conservation: 34 % applied winter crops, 4% applied protective cultures, 15% applied crop residues and 82% have applied bare soil method. Total arable land under soil conservation methods was 6.5 million hectares, representing 73.8% of total arable land of the country (8.3 million ha). 53% of total arable land under soil conservation methods was operated by holdings sized more than 100 ha, 14% by holdings sized between 2-5 ha, 9% by holdings sized 1-2 ha, 7% by holdings up to 1 ha, while the rest of 17% by holdings sized in classes between 5-100 ha. The structure of the total arable land under conservation methods, according to the methods of conservation applied was: 47.2% under bare soil, 44.9% under winter crops, 6.6% under residues crops and 1.4% under intermediate crops. The application of soil conservation methods differ depending on size classes of arable land area The areas under winter crops increase with the increase of the size classes of the holdings, while the

[7] http://ec.europa.eu/eurostat/statistics-explained/index.php/Agri-environmental_indicator_-_manure_storage

areas under bare soil, covering more than 70% in holdings sized less than 0.5 ha, decrease to 40-50% in holdings bigger than 10 ha. Intermediate crops amounts up to at most 3% in all size classes, while soils covered with plant residues amount 9-12% in holdings sized up to 10 ha, 6-8% in holdings sized between 10-100 ha and 4% in holdings larger than 100 ha (Figure 1).

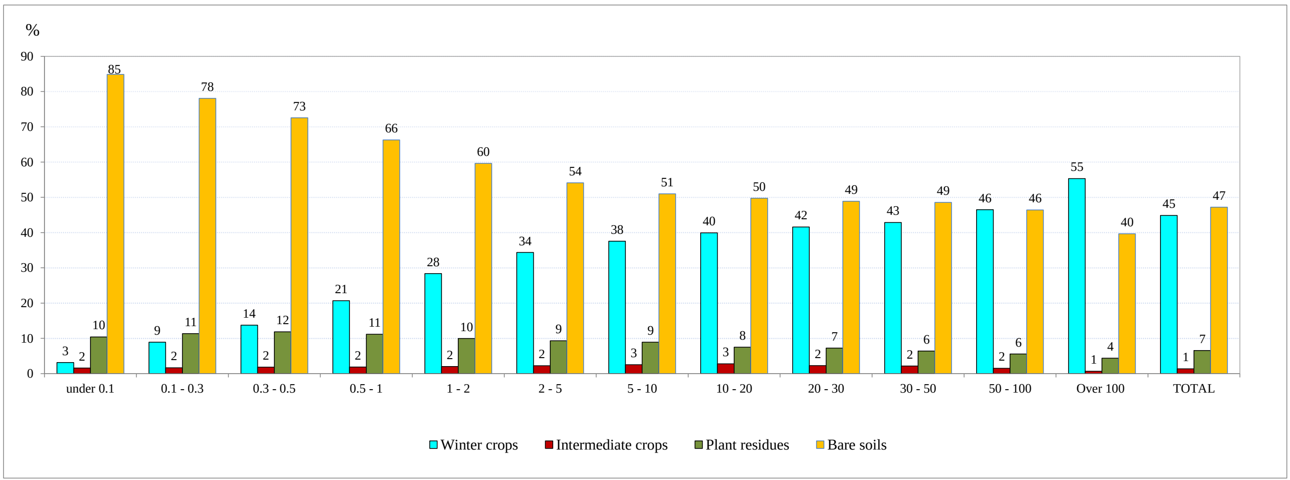

Figure 1: *Structure of arable land area on which were applied soil conservation methods, after the method of soil conservation applied, by size classes of arable land area*

3.2 Tillage practices - AEI 11.2

About 94% of the total number of farms with arable land (2.8 million farms) have practiced one or more tillage methods: 89% have practiced conventional tillage on 6.9 million hectares (83% of the total arable land), 2% farms have practiced conservation tillage on 193 thousand hectares (2% of the total arable land) and 13% farms practiced zero tillage on 584 thou hectares (7% of the total arable land). About 8% of the total area of arable land area (652 thou ha) was not tilled (without cultivation) (Figure 2).

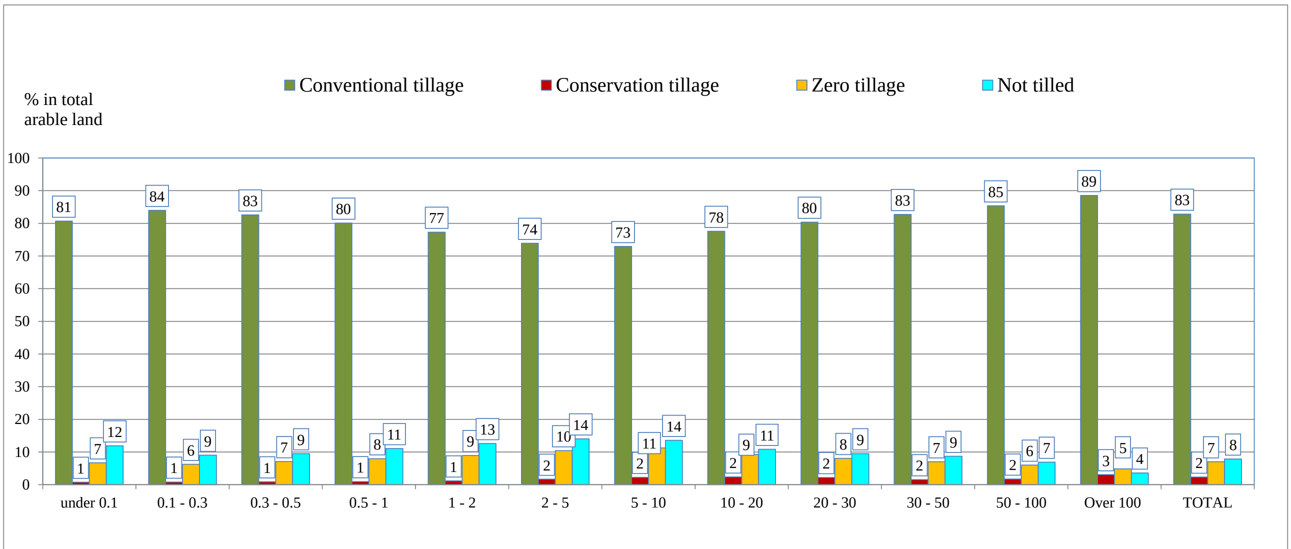

Figure 2: *Structure of arable land area on which were applied tillage practices, after the tillage method applied, by size classes of arable land area*

Over 80% of farms under each size class of arable land practiced conventional tillage, covering a total area of 6.9 million ha (83% of total arable land). Conventional tillage was practiced on 89% of total arable land operated by holdings larger than 100 ha, and on 73-85% on arable land operated under each size class of arable land area.

3.3 Manure storage - AEI 11.3

Romania is among the countries with a low potential for manure storage compared to other EU Member States. Thus, out of the total holdings with livestock (2.8 million holdings), only 15% have solid manure storage facilities. Out of the total holdings with storage facilities for solid manure, only 3% have storage facilities covered. Out of the total holdings with storage facilities for liquid manure, about 28% have storage facilities covered. Out of the total holdings with storage facilities for semi-liquid manure in basins, about 15% have storage facilities covered, while from total holdings with storage facilities for semi-liquid manure in reservoir 7% have storage facilities covered (Figure 3).

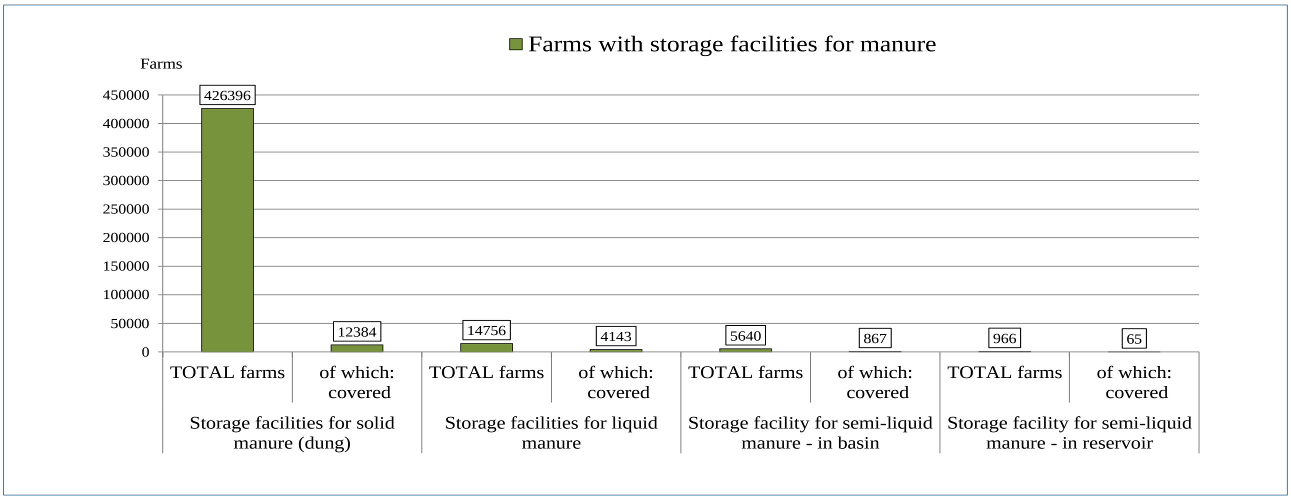

Figure 3: *Agricultural holdings with manure storage facilities, by type of manure storage*

Understanding farm management system is essential in order to implement the concepts of sustainable resource management. A relevant indicator giving a good insight in understanding the managerial approach at farm level is the *Share (number) of farm managers having practical experience, basic training, and full agricultural training* (one of the supporting indicators used for measuring AEI 3[8] related to the domain Responses in the DPSIR model). For Romania, this AEI indicates that from the total 3.9 million Romanian farmers[9] 0.4% completed full agricultural training, 2.1% had basic training in agriculture and 97.5% had only practical experience, ranking Romania on the last place among EU-28 in relation to the shares of farm managers with only practical experience.

4. Conclusions and recommendations

Winter covered soils are most effective against surface runoff and soil erosion, as well as nitrogen leaching during winter. This is why the extent to which winter crops protect against leaching and

[8] Farmers' training level and use of environmental farm advisory services
[9] Full scope Farm Structure Survey 2010

runoff is correlated with the presence of winter crops. AEI 11.1 can be further improved by including information about topography (Vinther Finn P. at al, 2011). A territorial approach rather than a national approach is essential to capture the diversity in farming systems and the environment.

Reduced tillage may in the short term lead to increased use of herbicides in order to compensate for the reduced mechanical weed control, but also can contribute to carbon sequestration in soil and thereby may alter the emissions of greenhouse gases, especially CO2 and N2O. The differentiation between reduced and conventional tillage is rather difficult, and clear definitions of reduced, minimal and conventional tillage would be needed. Reduced/minimal tillage may relate to both reduced frequency of tillage and to reduced soil depth of tillage (Vinther Finn P. at al, 2011).

SAPM, main data source for the AEI related to farm management practices, was carried out so far only in 2010. Collecting the data required for calculating these indicators by a statistically representative survey once every 2-3 years, together with FSS, would be useful for analysis the trend of these indicators, having in view that cropping systems and manure storage systems do not change significantly from year to year. This necessitates greater policy relevance and increased quality and timeliness of basic data sets, as well as a closer link between environmental data and existing economic and social information systems. It also necessitates more work to complement the indicators with information reflecting sub-national differences (Linster M. at al., 2001).

The set of AEIs have much in common with policy requirements, and even those that are not required directly for policy are useful for monitoring the outcomes of policy implementation. AEIs provide much of the needed coordination for data collection at an EU level to meet the needs of the key agri-environmental policies. Nevertheless, the results of monitoring and evaluation of sustainable development concepts based on AEIs must take into account that making decisions about the use of natural resources at their disposal, belongs directly to agricultural producers. Therefore, the successful implementation of any of the conclusions drawn from monitoring the indicators for the sustainable management of soil resources will depend on their acceptance by farmers.

ABSTRACT

Globally, organic farming continues to grow and, in many countries, has reached wide acceptance amongst farmers, consumers, market actors, policymakers, and the public. According to the latest available data (per 31.12.2014), 43.7 million hectares are under organic agricultural management, and this constitutes almost one percent of the global agricultural land; the global market is estimated to be 80 billion USD (Willer & Lernoud 2016). These data, which are mostly based on national data sources, are annually compiled by FiBL, which has been collecting and publishing data on organic agriculture worldwide since 2000. They are widely used and quoted by governments drawing up action plans for organic agriculture; researchers; market actors; market research companies, and the media.

However, with the collection of these data, there are challenges, including data gaps and incomplete data, issues related to definitions, classifications, data quality, and data access. Based on the work of the European research project OrganicDataNetwork, suggestions for the improvement of organic data at national level and in Europe have been made (Zanoli 2014). This paper highlights latest data and trends, illustrates current challenges and good examples, and makes recommendations related to data collection on organic agriculture based on the European experience.

Keywords: Organic agriculture, market data, data collection, data harmonisation

1. Introduction and background

Organic farming, which emerged in the first decades of the past century (Vogt 2000), continues to grow globally and has reached wide acceptance amongst farmers, consumers, market actors, policy makers and the public in many countries. Organic agriculture has garnered increasing official attention and support in the past few years, in particular since 2000. Among other reasons, governments support organic farming because it responds to consumer demand for high-quality food and environmentally friendly farming practices. The benefits of organic agriculture are documented in many peer-review scientific papers. Recent examples are publications on the positive effects on food quality (Branaski et al. 2014, Średnicka-Tober 2016 a,b), biodiversity and the environment (Schader et al. 2012), food security (Reganold & Wachter 2016), and climate change mitigation (Skinner et al. 2014), to name just a few. Organic agricultural land area and organic share of the total agricultural land is seen as an agri-environmental indicator by the OECD (2013), the European Environmental Agency (2015), and Eurostat (2015).

In many parts of the world, support is granted for organic agriculture in many ways; the most common is the establishment of organic regulations/laws, of which 87 exist today (Huber et al. 2016). Further support schemes include action plans e.g. in the European Union (European Commission 2014a) and many European countries (Sanders and Schmid 2014), institutional support for sector development, e.g. in Saudi Arabia (Hartmann and Bernet 2013), rural development support, e.g. in Brazil (Meireilles 2016), research support e.g. in Canada (Hammermeister 2016), support for export, e.g. Peru (Donahue et al. 2011), or an overall political commitment in Africa (African Union 2011). More information on the private-public collaboration in the field of organic agriculture is available from Bowen (2016).

However, a positive environment for organic sector development does not only require reliable policy support for farmers and food businesses but also a reliable information system (Stolze et al. 2016). Therefore, many governments have established collection systems for data on the organic sector. These are often linked to the establishment of regulations/laws about organic agriculture, such as the EU regulation on organic agriculture, which describes precisely what data should be provided (European Commission 2014b). Once such a regulation/law is established, there are rules about the registration of certifiers with a national authority, which opens up access to data from the certifiers. Public data collection systems mostly cover the organic area and operators and sometimes cover production and, rarely though, international trade data, but they mostly exclude data on the domestic market. There are some countries though, such as Denmark or Sweden, where the statistical offices (Statistics Denmark and SBC) collect retail sales data and, in the case of Denmark, also international trade data.

At the international level, the Research Institute of Organic Agriculture (FiBL) has been compiling and publishing data on organic agriculture since 2000 and continuously expanding the number of indicators on which data are collected. The data are published annually in a yearbook (Willer&Lernoud 2016) and online (FiBL 2016). Whereas in the beginnings of FiBL's data collection activities, only data on the organic area and the number of producers were collected, data collection has been expanded in the past few years, and today, data on all commodities/products and further indicators are collected, e.g., area, livestock numbers, retail sales, exports, and imports. Data collection is carried out in collaboration with many partners among a network of 200 data providers, including governments, private sector organisations, market research institutes, and certification bodies. The data is published together with the IFOAM – Organics International, the international umbrella of the organic sector. With the expansion of FiBL's global data collection, other activities have emerged, such as the collection of data on Voluntary Sustainability Standards (VSS), e.g., Fairtrade International, UTZ Certified, Rainforest Alliance/SAN, and others (Lernoud et al. 2016). Also, FiBL's organic crop data are of particular interest and can be used for a detailed analysis of certain commodities (Granatstein et al. 2015).

FAOSTAT, too, publishes global organic surface area/land use data online, partly based on the annual FAO land use survey, partly on data from FiBL (FAOSTAT 2016).

In Europe, Eurostat publishes data annually, covering a wide range of indicators such as area, livestock numbers, production, operator types including processor by NACE code (Eurostat 2016). These data are complemented by retail sales and trade data compiled by the FiBL and partners (Willer and Schaack 2016).

2. Organic agriculture world-wide – latest trends

According to the latest FiBL survey on certified organic agriculture worldwide (Willer&Lernoud 2016) as of the end of 2014, data on organic agriculture was available from 172 countries (up from 170 in 2013). There were 43.7 million hectares of organic agricultural land in 2014, including in-conversion areas. The regions with the largest areas of organic agricultural land are Oceania (17.3 million hectares, 40 percent of the world's organic agricultural land) and Europe (11.6 million hectares, 27 percent). Latin America has 6.8 million hectares (15 percent), followed by Asia (3.6 million hectares, 8 percent), North America (3.1 million hectares, 7 percent) and Africa (1.3 million hectares, 3 percent). The countries with the most organic agricultural land are Australia (17.2 million hectares), Argentina (3.1 million hectares), and the United States (2.2 million hectares). For 2014, almost 500'000 more hectares of organic agricultural land were reported than for 2013; since 1999, the organic farmland has quadrupled (See Table 1).

Currently, one percent of the agricultural land in the countries covered by the annual survey is organic. By region, the highest organic shares of the total agricultural land are in Oceania (4.1percent) and in Europe (2.4 percent). In the European Union, 5.7 percent of the farmland is organic. However, some countries attain far higher shares: Falkland Islands (36.3 percent), Liechtenstein (30.9 percent), Austria (19.4) percent. In eleven countries, more than ten percent of the agricultural land is organic.

Forty percent of the world's organic producers (at least 2.3 million) are in Asia, followed by Africa (26 percent) and Latin America (17 percent). The countries with the most producers are India (650'000), Uganda (190'552), and Mexico (169'703).

Global retail sales of organic food and drink reached 80 billion US dollars in 2014 according to Organic Monitor (Sahota 2016). North America and Europe generate most of the sales of organic products, comprising approximately 90 percent of organic food and drink sales. Many of the organic crops grown in other regions, especially Asia, Latin America, and Africa, are destined for exports. The global market for organic food and drink has expanded over fivefold between 1999 and 2014, and Organic Monitor projects growth to continue. According to Willer & Lernoud (2016) in 2014, the countries with the largest organic markets were the United States (27.1 billion euros), Germany (7.9 billion euros), and France (4.8 billion euros). The largest single market was the United States (approximately 43 percent of the global market), followed by the European Union (23.9 billion euros, 38 percent) and China (3.7 billion euros, 6 percent). The highest per-capita consumption with more than 100 euros was found in Switzerland, Luxembourg, and Denmark. The highest organic market shares were reached in Denmark (7.6 percent), Switzerland (7.1 percent), and Austria (6.5 percent in 2011).

However, some challenges are associated with the collection of organic data, which include data gaps and incomplete data, issues related to definitions, classification, and quality and data access. Even in the European Union, despite the efforts of private organic sector institutions and the fact that EU organic farming legislation requires the collection of relevant statistical information as a tool for market operators and policymakers, organic market data is not nearly as detailed and reliable as general agricultural and food industry statistics (Stolze et al. 2016). Therefore, it is necessary that data suppliers, and in particular governments, pay more attention to the collection and dissemination of data on organic agriculture.

Table 1: *Organic Agriculture Worldwide: Key indicators 2014*

	World	**Leading region**	**Leading countries**
Organic agricultural land	43.7 million hectares	Oceania (17.3 million ha)	Australia (17.2 million ha), Argentina (3.1 million ha), USA (2.2 million ha)
Share of total agricultural land	0.9%	Oceania: 4.1%	Falkland Islands (Malvinas) 36.3%; Liechtenstein (30.9%), Austria (19.4%)
Organic retail sales	62.8 billion Euros	North America (29.6 billion euros)	USA 27.1 billion euros, Germany 7.9 billion euros; France 4.8 billion euros
Organic per capita consumption	8.3 euros	North America 82 euros	Switzerland 221 euros, Luxembourg 164 euros, Denmark 162 euros

Challenges

From the experience of FiBL's long-standing data collection, there are a number of challenges related to organic data collection that need to be tackled. These include (see also Willer & Schaack 2014):

- Lack of data and incomplete data: In most countries, only very basic data such as data on certified organic farms, land areas and livestock numbers are reported; in fact, for many countries only the total organic area is available without any further details. Currently, reliable, detailed market data, such as data on domestic markets, international trade, and consumer prices do not exist or exist only as rough estimates in most countries.
- Lack of common classifications/aggregation rules across countries: Countries use different definitions, nomenclature, and classifications; only a few use international classifications (exceptions: Denmark uses the UN's Standard International Trade Classification SITC for its organic trade data; the Czech Republic uses EUROSTAT's CPA codes for its import data). Therefore, country-to-country data comparisons are very difficult. Another problem is that data is often aggregated, and only incomplete breakdowns by crop or product are available, which may make data of little use for some purposes. What makes things worse is that there is no harmonized

way of aggregating these data. In addition, aggregation may change from one year to another even in one country, so that times-series comparison becomes impossible.

- Lack of common definitions: A good example is that of livestock data. The commonly used indicator (e.g., Eurostat and FAOSTAT) is "number of heads," which is interpreted in different countries as the "average stock per year" or "animals slaughtered." These differences in definition make country-to-country comparisons of livestock impossible.
- Inconsistent data: The plausibility checks carried out annually by FiBL (such as year-on-year comparisons and comparison with the overall total) show many inconsistent data sets, as simple quality checks are often not performed by the data providers, even though these basic plausibility checks often allow inconsistencies to be identified.

3. Recommendations

The European OrganicDataNetwork project, funded under the 7th Framework programme for research and technological development in the European Union, has developed recommendations from the project results on principles of desirable organic market data development, production, and dissemination (Zanoli 2014). These have been elaborated in the OrMaCode, the ORganic market data MAnual and CODE of Practice (Zanoli et al. 2014) based on the European Statistical Code of Practice (Eurostat, 2011).

Recommendation 1: Extend the mandate for statistical data collection

There is still a major lack of data on organic agriculture in many countries. Therefore, it would be beneficial if more governments set up data collection systems for organic data or expanded the scope of existing data collection efforts by increasing the number of indicators collected, in particular, related to volume and value of production, retail sales, and imports and exports by product or product groups. In addition, the collection of price data should be considered. In order to ease this process, countries could follow the example of the European Union, which makes the collection of basic data mandatory in the organic regulation (European Commission 2014). In addition to the authorities in charge of organic data and the supervision of the control system, it would be beneficial if this mandate could be expanded to other bodies such as statistical offices, customs authorities and, where relevant, individual companies. Better data availability at a country level could then lead to better data availability at a global level, for data currently provided by FiBL for area, area by crop, operators, and market data (FiBL 2916) and by FAO for area and land use data, partly based on the data from FiBL (FAOSTAT 2016).

Recommendation 2: Develop better statistical processes to increase accuracy of data collection on the organic market

There is a clear need for data providers, be they governmental or private, that develop improved statistical processes to increase the accuracy of data about the organic market, specifically by paying more attention to coverage and adopting improved sampling procedures in the case of data that are not based on a census (in particular, retail sales). In cases where only expert estimates are available, these need to be checked against other sources, and overall, it would be good if the principles as laid down in the OrganicDataNetwork's (2014) OrmaCode would be applied.

Recommendation 3: Harmonise the statistical processes for data collection on the organic market to increase coherence and comparability

National statistical institutes and national authorities should harmonise statistical processes for data collection on the organic market to increase coherence and comparability, specifically by harmonising the national definitions, nomenclature, and classification of statistical outputs to international classifications and by harmonising aggregation rules. Following these rules would make international data sharing a lot easier, and it could be the task of international organisations to help national data collection efforts follow international standards.

Recommendation 4: Establish a system of routine quality checks

Data providers should establish a system of routine quality checks for organic market statistical data by balancing data accuracy versus timeliness in data publication and dissemination, by applying plausibility checks, and by comparing and cross-checking non-official statistical data from at least two independent sources to increase accuracy and consistency. Again, this needs to happen at a country level, but also, any transnational compilation of data at a global or regional level needs to apply quality checks.

Recommendation 5: Strengthen the institutional framework for statistical data collection on the organic market

Institutional support for statistical data collection on organic data should be strengthened, specifically by increased data collection efforts of FAOSTAT and national statistical offices, by establishing and funding permanent, long-term networks of data providers and users at the global, regional, and national levels, and by developing training initiatives to improve the quality of organic market data collection.

Outlook

The positive development of the organic sector, which has seen the continuous growth of the organic market and land under organic management, reflects the dynamic and innovative nature of organic food and farming in response to the expectations of policymakers and the demands of consumers for high-quality food production. On a global level, availability of data on organic agriculture has improved considerably in the past years, in particular for data on organic agricultural land. However, with the collection of these data, there are challenges, including data gaps and incomplete data, issues related to definitions, classifications, data quality, and data access. Therefore, data suppliers must pay more attention to data collection on organic agriculture in order to fill data gaps, harmonize data and improve data quality. Better support for data collection from governments and international institutions could help to improve the situation.

Acknowledgements

The authors gratefully acknowledge support for the data collection on organic agriculture worldwide from the Swiss State Secretariat for Economic Affairs (SECO), the International Trade Centre (ITC) and, in the framework of the OrganicDataNetwork project, the European Commission.

ABSTRACT

The most fundamental challenge faced by European agriculture in the early 21st century is how to increase production in order to respond to the significant growth in global food demand while preserving natural resources and the environment. Thus, the productivity and environment nexus of farms is particularly relevant, also in a policy perspective.

The central empirical question addressed by this paper is to assess whether, and by how much, productivity and environmental performance affect each other in the presence of farm heterogeneity. To examine these implications empirically, we have assembled a uniquely detailed dataset of Lombardy FADN farms observed over the period from 2008 to 2013 that merges FADN information on farm structure and economic performance, a productivity index and an environmental indicator, both properly reconstructed at farm level.

We firstly calculate a farm-level total factor productivity index and then estimate a farm-level greenhouse gases (GHG) emissions intensity indicator. The use of micro data to obtain farm-specific parameters is one of the novelty of the approach that can allow better capturing the actual heterogeneity of farms in production and environmental efficiency. We then investigate the nexus of this productivity index with emission intensity on a farm-by-farm basis.

Results are not only informative on the nexus between TFP and GHG emissions, but could be also used to gain insights in the direction of obtaining a unique indicator of the joint economic and environmental performances of farms: i.e. an Environmentally-Adjusted TFP.

Keywords: Total Factor Productivity, GHG emissions, FADN, farm-level indicator

1. Introduction

Increasing food production while preserving natural resources and the environment is the most fundamental challenge faced by European agriculture in the early 21st century. However, assessing to what extent EU agriculture is really moving along this innovative path of, at once, higher productivity and higher sustainability (i.e., better economic and environmental performances), remains a complex methodological challenge.

Productivity gains are typically measured as Total Factor Productivity (TFP) growth (OECD, 2001). However, TFP measures do not account for those inputs and outputs that represent non-marketable resources (i.e. for goods, or “bads”, for which private markets do not exist or are poorly functioning). This could lead to a systematic bias in productivity calculations and incorrect policy conclusions, mostly for the agricultural sector, which has a peculiar relationship with non-marketable goods (OECD, 2010). Some of these environmental effects produced by agricultural activities, like greenhouse gases (GHG) emissions, can be quite well captured and measured by appropriate environmental indicators that accompany the TFP in order to provide a multivariate representation of the joint economic and environmental performance of agriculture.

Whether, and by how much, productivity and environmental performance affect each other in the presence of farm heterogeneity is largely an empirical issue. The central question addressed by this paper is measuring such a nexus with micro data, which represents a novel approach to this topic so far and the main value added of the methodology proposed. In fact, both in TFP and GHG calculation, aggregation bias can highly affect estimates and, consequently, the relationship between economic and environmental performance, concealing micro performances.

The first step of the analysis is to elaborate a farm-level indicator of both economic and environmental performance and then to investigate the nexus between the two. A uniquely detailed dataset of Lombardy FADN farms observed over the period from 2008 to 2013 has been assembled merging FADN information on farm structure and economic performance, a TFP index and an Emission Intensity (EI) estimation, both properly reconstructed at farm level.

The structure of the paper is as follows. Section 2 illustrates the sample analysed and the methodology and data used to reconstruct TFP index and agricultural GHG emissions with micro data and presents the farm-level performances across the FADN balanced sample to highlight the main trend and differences across farm size and typology. Section 3 analyses the farm-level relationship between TFP and CF, then section 4 highlights some concluding remarks.

2. Farm-Level Performances

2.1 The FADN sample

The use of micro data is one of the novelty of the approach that can allow better capturing the actual heterogeneity of data and detecting and comparing both economic and environmental performances of single farms. To our knowledge, the nexus between productivity and sustainability in the agricultural sector, has not yet been explored by the literature using micro data, while the prevalent literature that focused on the micro level, analyses the wider economy and the nexus between trade and environmental efficiency (see among others Cui *et al*., 2016).

In our work the sample analysed to reconstruct the farm-level indicator, is the constant sample of FADN farms of one Italian region, Lombardy (362 farms), observed over the period 2008-2013. The choice of Lombardy is due the importance of the regional agricultural sector both in terms of production and in terms of GHG emissions.

It is worth reminding that the FADN sample is not fully representative of the whole national agriculture. The reference population from which the FADN sample is ideally drawn, is only representative of a sub-population of Italian farms, those farms that can be here refereed as professional or commercial farms (Sotte, 2006).

2.2 The farm-level TFP index

In calculating TFP, micro level data can better approximate a real productivity measure through the complete information provided by FADN (detailed input and output quantities and prices) that help the analysis of structural sources of productivity. However, trying to measure a multilateral indicator of productivity is challenging mostly if the calculation is referred to a panel dataset. In this research, relative productivity levels are derived at farm level for each year between 2008-2013 using the index number approach. Transitivity is achieved by chaining bilateral comparisons across a spanning tree as suggested by Hill (HIll, 2003). The spanning tree identified is the one that minimizes the sum of the Paasche-Laspeyres spreads between the nodes of the tree. Bilateral comparisons are made using the Fisher index number formula.

In the following table some summary statistics on the distribution of farm-level relative TFP levels are presented by farm specialization and economic size. The minimum, median and maximum value of farms' TFP relative levels are presented for each group. Production performances can be compared only within each group.

Table 1 *Summary statistics of TFP index by Specialization and by Economic Size.*

Specialization	**TFP min**	**TFP median**	**TFP max**
Dairy	0.035	0.554	4.693
Rice	0.062	0.455	3.967
Wine	0.023	0.205	1.339
Arable crops	0.022	0.204	2.993
Mixed crops and livestock	0.035	0.201	4.222
Cereals	0.009	0.175	1.42
Fruits	0.014	0.164	1.365
Garzing Livestock	0.015	0.154	1.707
Horticulture	0.002	0.136	4.32
Granivores	0.007	0.095	2.067
Economic Size			
Large	0.007	0.562	4.693
Medium	0.014	0.310	4.222
Small	0.002	0.124	1.25

Source: Authors' elaborations

Table 1 is useful to highlight the heterogeneity in the production performance of different categories of farms. In terms of specialization, the distribution of the farm-level TFP index is concentrated around a higher median for Dairy farms followed by Rice and Wine. Less clear is the production performance for farms specialized in Arable crops, Horticulture, Mixed crops and livestock and Grazing livestock. Their distribution of TFP levels are markedly dispersed around their median and present either low minimum TFP values and high maximum TFP values. In terms of Economic size, there seems to be a positive relation between size and production performance. Larger farms are those with a higher median value of TFP levels followed by medium-sized and small-sized ones.

However, the relation is not clear cut as there is a number of large and medium-sized farms with a low production performance.

2.3. The farm-level CF index

The environmental indicator analysed in this study are farm-level GHG, as a by-product (bad-output) of the production process. The choice of this environmental externality has been made for the relevance of the climate change mitigation objectives in the international (Gerber, 2013) and in EU political agenda, were climate policy sets important mitigation targets also for agriculture (European Commission, 2011) and the Common Agricultural Policy (CAP) gives instruments and incentives to reach these targets (European Council, 2014). In particular, at international level, agricultural GHG emissions are a relevant issue for they are largely determined by developing countries and the role these countries play in their mitigation has important implications in terms of development opportunities. Thus, relevant studies (Tubiello *et al*., 2015), have estimated agricultural GHG emissions at global level also to understand how targets on these emissions could affect different countries in the world. Both at European and global level, the main concern is how to curb agricultural GHG emissions without affecting productivity, i.e. without increasing costs or decreasing output. Studying GHG performances together with productivity ones, and deriving their joint performance can thus be more informative on this topic. To reconstruct a GHG farm balance, we have adapted the Intergovernmental Panel on Climate Change (IPCC) methodology (IPCC 2006) at the farm level, using activity data connected to the main agricultural activities (Coderoni and Bonati 2013). Methane (CH_4), nitrous oxide (N_2O) and carbon dioxide (CO_2) emissions are estimated from the following source categories: livestock production, crops, land use, fuel and fertilizers. These different farm-level GHG emissions are then summarised into a unique indicator using each GHG's Global Warming Potential (GWP). The conversion factors updated over time by the IPCC are used. Currently, Italy uses GWPs in accordance with IPCC Fourth Assessment Report, i.e. 25 for CH_4 and 298 for N_2O (ISPRA, 2015). GHG emissions expressed in CO_{2e} represent what we define the Carbon Footprint (See Baldoni *et al*. 2016 for a more detailed description of the methodology used). Table 2 shows which FADN data have been used to estimate the respective CF category and the corresponding emission source.

Table 2 *Summary of GHG emission sources considered and the respective FADN activity data used.*

Emission sources	CF category	FADN data
N_2O manure management	Cf livestock	Animal numbers
CH_4 manure management	Cf livestock	Animal numbers
CH_4 enteric fermentation	Cf livestock	Animal numbers, milk production, pasture, % birth, animal average weight
CH_4 rice cultivation	Cf crops	Rice area (UAA)
N_2O agricultural soils:	*Various*	
-Use of synthetic fertilisers	Cf fertilizers	N quantities or fertilisers exp.
-Animal manure	Cf crops	Manure reuse
-Histosols	Cf crops	Crop area (UAA)
-Crop residues	Cf crops	Crop area (UAA) or crop yield
-Atmospheric deposition	Cf fertilizers/ic crops	N quantities or fertilisers exp.and animal numbers
-Leaching and run-off	Cf fertilizers/ic crops	N quantities or fertilisers exp.and animal numbers
CO_2 Urea	Cf fertilizers	Urea quantities
CO_2 Energy	Cf fuel	Fuel expenditure or quantities
CO_2 Forest land	Cf land use	UAA
CO_2 Cropland	Cf land use	UAA
CO_2 Grasslands	Cf land use	UAA

Source: Authors' elaborations

The main value added of this study, respect to others with a similar approach (Coderoni and Esposti 2015) is estimation of a "farm-specific" emission factor, i.e. an emission factor that varies according to farm characteristics or management practices (i.e. more or less intensive management of livestock population). For data availability this has been possible only for emissions from enteric fermentation (that account for 45.6% of national emissions in 2013) for three animal categories - bovine, buffalos and sheep - that represent 95.2% of total emission from enteric fermentation (ISPRA 2015). Table 3 shows minimum and maximum values of EF calculated with the farm-specific methodology. Data show a high difference with respect to national specific or default values.

Table 3 *Minimum and maximum values of EF calculated with the farm-specific methodology for cattle and sheep for year 2008 and 2013. (Kg CH_4 head-1 year-1).*

		2008		2013	
Livestock category	**National (or default) values**	**Min**	**Max**	**Min**	**Max**
Cattle–male	47.53	1.95	90.41	1.95	72.3
Cattle–dairy	134.21	60.62	198.47	54.3	174.18
Cattle-female	47.53	1.95	69.62	1.95	43.69
Sheep (>1 year)	8	4.56	14.3	2.28	16.74
Sheep (<1 year)	8	1.6	10.05	1.6	17.68

Source: Authors' elaborations

To allow comparisons with the TFP, which is scale independent, the CF has been divided for the Standard Output (SO) at farm level, obtaining the Emission Intensity (EI) (or carbon intensity), i.e. the level of GHG emitted to produce each euro of SO. In fact, as noticed by Coderoni and Esposti (2014) the scale effect always makes the emission growing with the size of the farm (e.g. livestock farms who are on average very big in Lombardy sample, show the highest CF), but what is interesting to analyse here, is if there are scale effect in relative terms, i.e. if biggest farms are more or less efficient than others even when we control for their dimension. The analysis of the emerging evidence in table 4 only concerns some descriptive indicators about the evolution of the EI over time across farm typologies and sizes; this makes emerge some major heterogeneity in terms of emission performance. Size evidently matters: the larger the economic size (ES), and the physical one (UAA), the larger is EI. On trend, smallest farms have the sharper decline. Even looking at data for UAA small farms have a lower EI and sow a better performance over time. However, in this case, the correlation between EI and UAA is positive (and higher than the previous one), meaning that biggest farm have worst environmental performances. Among the agricultural specializations, rice specialist farms and rice and other cereals, have the higher impact on GHG emissions, which also increases over time. Rice cultivation is relevant in the Region (32 farms in the sample) and farm size is particularly high, with medium to big farms and 60 ha of average rice UAA. Activities associated to livestock, show high EI, confirming the evidence of absolute values, but they show also declining median variation. From table 1 and 4 there seems to be a relationship between the two performances. This, however, is very influenced by the size and farm specialization. Thus, it is worth asking whether the nexus between TFP and EI exists, and how it behaves, beyond this obvious dependence on size and product specialization.

Table 4 *2008-2013 evolution of the farm-level Emission Intensity across different farm typologies (Kg CO_{2e}/€).*

3. Farm-Level Nexus Between TFP and CF

As already mentioned, the micro level of analysis of both TFP and CF, could be very informative of synergies between productivity growth and GHG mitigation (the so called win-win mitigation strategies), that are not unusual in the agricultural sector. The farm-specific parameters calculated are meant to be a summary statistic representing various forms of heterogeneity in production and environmental efficiency. The first stage of analysis investigates how the productivity index correlate with emission intensity on a farm-by-farm basis. Table 5 shows the correlation coefficient between the farm-level total CF and TFP (calculated for each farm as if all the years were pooled into one period). Correlation is low and significative only for some farm typology. This results suggest the idea that nexus between CF and TFP could be hidden by the large heterogeneity of data.

Table 5 *Correlation between the farm-level total CF and TFP OP across different farm typologies.*

Specialization:	TFP-EI correlation coefficient	Number of obs.	
Granivores	0.236	123	***
Grazing livestock	0.227	172	***

Mixed crop and livestock	0.180	98	*

Total	0.201	2070	***

Source: Authors' elaborations

To put forward this concept, our empirical analysis focused on the estimation of the nexus of environmental and economic performance assuming that different level of carbon intensity can influence the TFP of the farm. In other words, the carbon intensity is perceived as an addition input of the production process. The relationship is estimated as follows by using a polynomial functional form (quadratic), including other relevant control variables and the interaction between EI and economic size:

$$\ln(TFP)_{it} = \alpha + \beta EI_{it} + \gamma {EI^2}_{it} + \sum_k \varphi_k d_{t,k} + \sum_m \delta_m s_{it,m} + \sum_m \theta_m s_{it,m} * EI_{it} + \sum_m \pi_m s_{it,m} * {EI^2}_{it} + \varepsilon_{it}$$

Where: TFP is the farm-level TFP, the EI is emission intensity, α is the constant term; *d* are time dummies; s are dummy variables that flag if farm i is of m type (i.e. small, medium or large) and ε is the stochastic error term (assumed i.i.d); *i* is the ith farm and *t* is the time dimension (2008-2013). Results are shown in table 7. The hypothesis of the existence of a nexus between EI and TFP performance seems to be confirmed by statistically significant parameters associated with EI and EI2. However, trying to define uniquely this nexus is not an easy task, for the presence of interactions between variable that make more difficult to delineate a relationship. However, two major evidences emerge: the nexus is different among firm sizes, in particular weaker (in absolute value) for smallest farms, and it also changes when EI interacts with farm size.

Table 6 *Results of the estimation of the relationship between the farm-level EIand TFP (stand. error in parenthesis).*

Source: Authors' elaborations

The nexus between the EI and TFP is not univocal. The relationship, in its in sample performance, not only is different for different farm sizes, but it also changes sign - if we sum all the influences of the different coefficients (see Baldoni *et al*., 2016) - drawing an inverted U shape, more evident for medium and large farms. This means that, in fact, there is a more sustainable way to produce and that, in particular, all the points in the left side of the turning point of the curve, represent a benchmark in terms of environmental sustainability than those that are in the right side. The hint that a same productivity performance can be obtained with different environmental performances is not new in the agricultural sector, were farm structures and management techniques are various and complex and there is no "one size fits all solution" to the mitigation of emissions. Findings of this study, if confirmed by larger sample analysis, give a quite complex picture: there is no dualism between productivity and sustainability, but more productive farms can also bring with them worst environmental performances. Foster productivity growth may thus not necessarily lead to greater sustainability. An efficient policy of agricultural GHG emissions mitigation should then stimulate the spread of best practices, reflecting the standards of the farms whose performances are environmentally more sustainable.

4. Some concluding remarks

This work aims to analyse the relationship between sustainability, in terms of GHG emissions and productivity at farm level. The micro level of analysis, which in fact is the main original content of the study, seems to be the most appropriate to analyse the nexus between productivity and sustainability. The farm-by-farm analysis can better capture the actual heterogeneity of data and connections between the evolution of TFP and EI, overcoming aggregation bias issues, which can conceal micro performances of specific territories, farm typologies or structures. Results firstly confirm the great heterogeneity of farm performance, strengthening of usefulness of the micro approach adopted. The nexus between the emission intensity and TFP not only seems to exists, but it is not univocal: it changes among farm sizes and within the same size, varying sign over certain threshold values. If this evidence would be confirmed for other regions, or at national scale, it would suggest that a more efficient way to pursue the relevant EU mitigation targets, would be to work on the dissemination of best practices at the sub-sectoral level. This works represents thus just an initial, though necessary, step in the direction of a joint indicator of both economic and environmental performance of agriculture at micro level. To this respect, results are encouraging. Starting from here, future researches are expected to put forward appropriate theoretical concepts, models and econometric approaches to estimate and Environmentally-Adjusted TFP at micro level.

MEASURING THE IMPACT OF GLOBAL WARMING AND EXTREME WEATHER EVENTS ON AGRICULTURE

Session Organizer
G. Dono | Università degli Studi della Tuscia | Viterbo | Italy
A. Ferruzza | Istat | Rome | Italy

ABSTRACT

Over the last decades scientists have extensively studied the greenhouse (GHG's) effects,which holds that the accumulation of carbon dioxide (CO_2) and other greenhouse gases emissions,due to human production and consumption activities, are the main causes of both global warming andsignificant climate changes (CC) such as extreme weather and out of season events (floods and droughts). CC impacts and vulnerabilities affects both human and natural systems, with heavy consequences in manycountries.In the long list of potential problems from global warming, it has been widely recognized that the risksto world agriculturestand out as among the most important.

CC can affects agriculture in direct and indirect ways as itdirectly depends on temperatures variation, shifting precipitation patterns, extreme weather events and water resources availability. Shifting in climate conditions bring tochanges in agricultural zones and crop and livestock production activities in many regions. Extreme weather events can threaten the development of the crops and value and quality of yields. Moreover, CC can affect both the demand and the supply for water in agriculture through variations in rainfall patterns, surface water and groundwater, snow and glaciers in many areas.

Non-climatic drivers can also affect water supply and demand as population growth and increasing urbanization.Globally the overall impact of global warming is a reduction of agriculture productivity in the long run. Climate change is already underway and is already influencing the productive potential of agricultural systemsin every countries.

Numerous studies underline that a heavy concentration of losses will be found in the developing countries and in particular in the poorest countries associated, in some cases, with the rising sea levels. On the one hand they have a less capacity to adapt to CC effects than do their wealthier neighbors and on the other side they are in warmer parts of the globe, in some of which temperature are already close to thresholds value for crops. As a result, CC will probably also increase the risk of food securityfor some vulnerable groups of population. Moreover, agricultural sector has become one of the main driving forces to climate changes through anthropogenic GHG's emissions and land use changes (conversion of non-agricultural land into agricultural one, deforestation, rural exodus).

Strategies and actions to mitigate and adapt to CC impacts are neededin particular driven by either developed countriesthat mainlyhave contributed in the past and big developing countries heavily contributing to the GHG'S emissionsin the last decade. Also promoting an environmental sustainable agriculture represent a central issue, as thissector strongly contributes toCO_2 concentration increasing.In this context, the role of official statistics is crucial to gauge climate changes and related impacts, meteorological variables, water availability and use, crops typologies and yields, irrigation systems and land use. This wide information represent the basis to define policy targetsand to monitor their achievement at different spatial scale and to integrate adequate measures into international and national policies and strategies. Rural development policies are already devoting significant financial resources to intervene, both for mitigation and adaptation to climate change. Therefore, it is necessary to provide adequate information on the evolution of the climatic conditions, for adequately supporting the planning and the actions of farmers and local institutions which apply these measures.

ABSTRACT

This study aims to understand and quantify the link between climate and agriculture in Cameroon on one hand; and to analyze how the expectations of farmers on climate change affect investment and production decisions, and the process of adjusting factors of production, on the other hand. The data used come from Food and Agricultural Organisation, Surveys and Agricultural Statistics Division of Cameroon Ministry of Agriculture and Rural Development and the third Cameroonian survey on household. To achieve the first objective, we estimate the Ricardian model by the Ordinary Least Square method. While the second objective is achieved by estimating a dynamic stochastic model by the nonlinear three-stage least square method. Firstly, regarding the marginal effect, we found that an increasing for 1mm of precipitations leads to a decreasing for FCFA 2200.20 of farm income per hectare. While an increasing for 1°C of temperature leads to an increasing for FCFA 2322 of farm income per hectare. As for the elasticity of farm incomes, the results show that an increasing of 1% in temperature leads to higher farm revenues by 32.4 % while an increasing of 1% in precipitation leads to lower farm revenues by 12.9 %. Finally, under uncertainty and market price change, Cameroonian agricultural farmers take about two and a half years to fully adjust the desired level of their crops, about 24 years for capital, one and half year for labour and about nine months for fertilizer to their optimal level . So, in Cameroon's agricultural sector, crops adjust most rapidly than capital toward their respective optimal levels. So, under climate change, farmers gradually adjust production and inputs. These dynamic adjustments are due to adaptation measures implemented by farmers under uncertainty.

Résumé

Cette étude vise donc à comprendre et quantifier le lien entre le climat et l'agriculture au Cameroun d'une part; et à analyser la façon dont les anticipations des agriculteurs sur le changement climatique affectent les décisions d'investissement et de production ainsi que le processus d'ajustement des facteurs de production, d'autre part. Les données utilisées proviennent de la Food and Agricultural Organization, de la Division des études et statistiques agricoles du Ministère de l'agriculture et du développement rural et de la Troisième Enquête Camerounaise auprès de Ménages. Pour atteindre le premier objectif, nous estimons le modèle Ricardien par la méthode des Moindres Carrés Ordinaires. Tandis que le second objectif est atteint grâce à l'estimation d'un modèle stochastique dynamique par la méthode des Triples Moindres Carrés non linéaires. S'agissant de l'effet marginal, les résultats montrent premièrement que l'augmentation de *1mm de précipitations conduit à une augmentation de 2322FCFA du revenu agricole par hectare. Tandis qu'une augmentation de 1°C de la température conduit à une baisse de 2200.20FCFA du revenu agricole par hectare. Quant à l'élasticité des revenus agricoles, les résultats montrent qu'un accroissement de 1% de la température conduit à une augmentation de 32, 4% du revenu agricole alors qu'une augmentation de 1% des précipitations entraîne une baisse de 12,9% du revenu agricole. Enfin, face à l'incertitude et le changement des prix du marché, les ménages agricoles camerounais prennent environ deux ans et demi pour ajuster complètement le niveau de leurs récoltes, environ 24 ans pour ajuster le capital, un an et demi pour ajuster travail et environ neuf mois pour ajuster les engrais souhaité à leur optimal niveau . Ainsi, dans le secteur agricole au Cameroun, les récoltes s'ajustent plus rapidement que le capital vers leur niveau optimal respectif. Donc, face à l'incertitude climatique, les ménages agricoles ajustent graduellement leurs inputs ainsi que leurs productions. Ces ajustements dynamiques sont dus aux mesures d'adaptation mises en œuvre par les agriculteurs face à l'incertitude.*

Key words : Agriculture, Climate Change, Uncertainty.

1. INTRODUCTION

Cameroon, attic of Central Africa sub-region, is divided into five agro-ecological zones namely monomodal forest zone, bimodal forest zone, highland area, area of the high savannas and Sudano-Sahelian zone. The share of the agricultural sector in the Cameroonian economy is important. Indeed, this sector employs almost 60 % of the active population and contributes about 20% to gross domestic product (NIS, 2013). Exports of agricultural products represent 40% of total non-oil exports. However, in Cameroon, in recent years, climate changes cause instability in rainfall leading to disruption of the agricultural calendar and a substantial decline in agricultural productivity. Thus in the north of the country in the Sahel region, these climate variabilities cause desiccation of rivers, west drought surface water; and rising sea coast with flooding. This explains why IFPRI (2009) estimates that population in the developing world, already vulnerable and exposed to food insecurity, are likely to be most seriously affected.

High temperatures and current fluctuations in precipitation, combined with population growth, are a real and permanent threat to food security through their impact on agriculture in Cameroon. Indeed, rising in temperature causes lower yields of desirable crops and the proliferation of bad harvests in the short run on the one hand, and a substantial decline in agricultural production in long run on the other hand. With this in mind, resilience to climate variability and climate change becomes imperative in order to limit their socioeconomic impacts in the sub-region and particularly in Cameroon. Moreover, Molua (2009) shows a positive relationship between adaptation measures and increasing agricultural yields. For the author, adaptation is an operational strategy to deal with climate change. According to this study , 60% of surveyed Southwest farmers adjusted their farming practices to climate variability, and about 40 % of farmers have used for agricultural strategies aiming to conserve water and soil.

Our study aims answer the following research questions: are there a direct link between climate change and agricultural productivity in Cameroon? And how do farmers' expectations on climate change affect investment and production decisions and the process of inputs adjustment in Cameroon?

This study has two objectives. Firstly, it aims to assess the impact of climate change on agriculture in Cameroon. Secondly, it aims to analyze how famers' expectations on climate change affect investment and production decisions; and process of adjusting factors of production.

Ricardian approach, initiated by Nordhaws and Shaw (1994) and developed by Mendelsohn et al. (1994) is used to estimate the impact of climate variability on the production or agricultural yield in Cameroon. It is based on observation of David Ricardo that value of land would reflect its profitability in a perfectly competitive market. This method, linking regional differences in climate to value difference of land, permits to compare sensitivity to climate change in different regions (Ouedraogo, 2006). Furthermore, in order to analyze investment behavior of farmers under uncertainty and adjustment costs induced by climate variability, we build a stochastic model based on dynamic duality developed by Epstein (1981) and then developed by Vasavada Chambers (1986), Howard and Shumway (1988), and Agbola and Harrison (2005). The development of this model through the integration of expectations in the dynamic duality theory was recently done by Pietola and Myers (2000) and Krysiak (2006). Sansi and Schumway (2014) used this approach to analyze the structure adjustment of inputs and output in the US agricultural sector.

The uniqueness of this study is based on two main arguments. First, there are no studies in Cameroon, to our knowledge, on the modeling of the dynamic output supply and input demand in the cameroonian agricultural sector. In addition, our study is a contribution to the formulation of an expanded theoretical framework as well as the application of econometric models derived from the dynamic duality apporach under uncertainty. The remaining of the paper is organized as follows. Section 2 presents a review of dynamic input demand models. Section 3 presents the econometric estimation methods, while Section 4 discusses the data. The results are presented, analyzed and discussed in Section 5. Finally, Section 6 concludes.

2. Overview of the link between climate and agriculture in Cameroon

Cameroon is located in Central Africa and stretches from the Gulf of Guinea to Lake Chad. Cameroon has 475 650 km^2 of area with a long coastlines of 402km. The country is bounded on the north region by Chad lake, on the South by Congo, Gabon and Atlantic Ocean, on the east by Chad and Central African Republic and on the west region by Nigeria.
The Sudano-Sahelian zone covers North and Far North with 10 million hectares in which 0.56 million are cultured (IRAD, 2008). Regarding climate, it is characterized by a single mode type of rainfall varying between 400 and 1200 mm per year. The Temperatures vary between 28°C and 45 ° C. Given this climate the main agricultural products are cotton, sorghum, millet, rice, maize, groundnuts and cowpeas.

The Area of high Guinean savannas, for its part, covers entire region of Adamawa, a part of central region namely northern zone of Mbam and an Eastern region zone particularly Lome-et-Djerem. It has 138,000 km^2 of area; this means about 29% of total area of Cameroon. Climate is characterized by average annual rainfall which is around 1500 mm for about 150 days. Because of altitude, temperature on the other hand is moderate between 20 and 26 ° C. These climatic conditions certainly determine the quality of the soil in this area and therefore agricultural products which are primarily produced for human and animal living at the expense of trade activities. Thus, corn is the main crop followed by millet, sorghum, groundnut and yam.

The Highlands of western zone covers western and North West region with 3.1 million hectares of area. Type of climate "camerounien altitude" is structured in two seasons: a dry season from mid-November to mid-March and a rainy season extends from mid-March to mid-November. As for temperatures, they are low in average of 19 ° C and abundant rainfall ranging between 1500 and 2000 mm per year. Thus all kinds of crops (food and export) are practiced namely groundnut, banana, robusta and arabica coffee, cocoa, vegetables, corn and tea.

The Unimodal humid forest zone covers littoral and southwest regions and a coastal edge of the southern region. This zone covers 4.5millions hectares of area in which 282,000 are cultivated. The land includes the volcanic slopes of Mount Cameroon and the original rocky sediments along the coast. Under Cameroonian climate type, very wet and very hot, the rains vary on average between 2500 and 4000mm except Debunscha locality which is considered as one of the rainiest zone in the world. Indeed, in this locality, 11000 mm of rain fall per year according to a monomodal rainfall regime with a long dry season. As for the temperatures, they vary between 22°C and 29 ° C. Food crops for exports such as coffee, cocoa, tea, bananas, palm oil, etc, are also produced in this zone.

The Humid forest zone with a bimodal rainfall. It covers Cameroonian south plateau between 500m and 1500m of altitude, Central and Eastern region. Climate is Guinean, hot and humid, with 25°C of temperatures of and 1500-2000mm/year of rainfall. In this area, there are grown cocoa, robusta coffee, vegetables, various fruit trees, plantains, sugar cane, corn, tobacco and tubers.

3. Litterature review

The literature review focuses on the application of the Ricardian model and stochastic dynamic dual models. The approach used to assess the link between climate and agriculture is Ricardo approach.

3.1. Ricardian approach: review of applied models

The Assessment of impacts of climate change on agriculture began in the 1980s (Da Silva, 2009). Thus, through the Ricardian model, Molua (2002) examines impact of climate change on agricultural land in eleven African countries: Burkina Faso, Cameroon, Egypt, Ethiopia, Ghana, Niger, Senegal, South Africa, Zambia and Zimbabwe . Results of this study show that decline in rainfall and rising temperatures lead to a significant drop in farm net incomes in these countries. Furthermore, results show that farms in arid areas are particularly sensitive to climate. Global warming affects positively farms irrigated because they are in relatively cold regions of Africa. Mariara and Karanja (2006) analyze impact of climate change on agricultural net income of 816 are of Kenyan households. Authors identify three models. The first model takes into account impact of climate variables only, the second includes the hydrologic variables and soil and the third assesses impact of household characteristics. Using variables as net farm income, wage rates, rainfall, temperature and soil moisture indices, results show the effectiveness of impact of climate change on agriculture in this country. Indeed, hydrological variables significantly impact farm net income. On the other hand, even if rainfall has higher elasticity than those of temperatures, marginal effects of the former are smaller than those of the latter.

Kurukulasuriya and Mendelsohn (2008) use Ricardian approach to study impact of climate change on agricultural income of farmers following 9064 randomly selected regions of the eleven African countries. Authors also identify three models. The first takes into account all land under cultivation, the second not only integrates irrigated land and the last one integrates rainfed farms. Results show that effect of climate variables varies by model. Increasing in temperature has a significantly negative effect on net farm income of farmers operating on land depends on rainfall.

By cons, this increasing temperatures positively impacte net agricultural farmers' income of irrigated land. This study shows that irrigated agricultural lands are less vulnerable to climate variability. Furthermore, drylands are more sensitive to climate than irrigated land. Elasticity of temperature in arid land is 1.9, while this value is 0.6 for irrigated land.

Using the same Ricardian approach, Ouedraogo (2012) assesses impact of climate change on net farm income for 1530 Burkinabe farmers. The model includes variables such as climatic, edaphic, hydrological and socio-economic. Results show that there is a nonlinear relationship between net farm income and climate variables such as temperature and precipitations. Thus, marginal impact of temperature on net farm income is US $ -19.9 per hectare while marginal impact of precipitations on the same variable is US $ 2.7 per hectare. This shows that rising temperatures helps to reduce income of farmers while rainfall increases income in Burkina Faso.

From 184 randomly selected villages, consisting of 384 households over 8 regions namely Dioubel, Fatick, Kaolack, Kolda, Louga, Saint Louis, Tambacounda and Thies; Ahmadou (2014) analyzes impact of climate change on agricultural production, kilo-calorie consumption and lean period. Results show that climate change has significant effects that amplify vulnerability of Senegalese farmers. Indeed, rainfall has a positive impact on agricultural production and temperatures both in dry season and rainy season have a negative impact on agricultural production. When fixed effects of villages are taken into account, negative impacts of temperature on production decrease significantly. Moreover, temperatures have a negative effect on consumption of kilo-calories while impact of rainfall on calories consumed depends on whether its term is linear or quadratic. In the first case, impact of rainfall level has a positive impact on the consumption of kilo-calories while in the second case this effect is negative. This rainfall has a negative impact on weld time.

3.2. Stochastic dynamic duality approach: review of applied models

The Adjustment costs of factor demand that arise in response to market shocks have been widely sudied and documented in the litterature. For example, works of Lucas(1967),Caballero(1994), Hammermesh and Pfan(1996), Hall(2004), Lambert and Gong(2010). But, the fact that climate change may cause adjustment costs has received very little attention(Sansi and Schumway, 2014). However, adjusment costs that arise form environmental shock can not be ignored since they are very important in investment, production and factor adjustment process. For instance, decrease in pricpitation raise demand for water which in turn raises the demand for more efficient irrigation systems. To build new irrigation infrastructure takes time and effort, and therefore causes adjsutments costs. Kelly and al.(2005) examines adjustment costs in the context of profit loss in the process when a firm with incomplete knowlegde learns about the distribution of climate change over time. However, authors did not consider the case of quasi-fixed or strictly fixed factors. They assume that all factors of production are fully variable, ignoring the fact that adjustment of inputs cannot be done instantaneously and can make it difficult in short run any change in their amount. Knowledge and information have a very important role in the magnitude of adjustment costs to climate change. Indeed, if the farmer knows or anticipates future climate conditions, induced adjustment costs will be low or zero.

Since the second objectives of this study is to examine how adjustment costs affect input and output response both to price shocks and to stochastic climate change in the cameroonian agricultural sector, we make use of dynamic dual approach which is based on results of McLaren and Cooper (1980) and formalized by Epstein (1981). Application of this model is not recent. First applications are made in the work of Epstein and Denny (1983), Taylor and Monson (1985); and Vasavada and Chambers (1986) in the US agricultural sector. The second one includes the work of

Bernstein and Nadiri (1988), Howard and Shumway (1998) and Agbola (2005). The development of this approach has been made by Pietola and Myers(2000), Krysiak(2006).

Dynamic duality approach consist in transforming intertemporal value function of the firm in term of Hamilton-Jacobi-Bellman equation. This equation represents the present or discounted value of profits (or costs). The problem is therefore to maximize or minimize depending on whether we have profits or costs function. Solution obtained by hotelling lemma, is a dynamic equations describing optimal path of investment demand of quasi-fixed inputs and supply of the firm.

Pietola and Myers (1998) use dynamic duality approach under uncertainty in order to develop and assess on Finnish pork industry data, a generalized model of firm investment. In this study, effects of uncertainty on investment are estimated by making use of dummy variables. Results show that the greater the uncertainty on the prices of machinery and equipment increases, the less investment is important in this sector. Furthermore, employment decision is not sensitive to increased uncertainty. Sansi and Shumway (2014) derive and estimate a stochastic dynamic duality in order to examine adjustment structure of two types of output and three categories of inputs in the US agricultural sector under climate uncertainty. Results of this study show that, given uncertainty induced by changes in market prices and climate change, farmers gradually adjusting the two types of output and three inputs considered. For instance, crops adjust mostly toward equilibrium levels and capital adjusts most slowly.

4. Econometric Estimation Methods

According to Guerrien and Vergara (1985), the first task of econometrics is to put empirical *pulpits* around the theoretical framework. In this case, the theoretical model and their functional form have to be specified. In this section, we first specify the functional form of the the ricardian model and the firm value function as well as econometric form of input demand equations. Then hypothesis tests are performed as well as the estimation of the derived models.

4.1. Functional form of the ricardian model.

The formulation of the Ricardian model is obtained as follows:

$$RA = \beta_0 + \beta_1 C + \beta_2 C^2 + \beta_3 S + \beta_4 E + \beta_5 SA + \beta_6 TM + \delta_1 M + \delta_2 IR + \delta_3 ER + \varepsilon \quad . \qquad (1)$$

C et C^2 represent the linear and quadratic terms of climate variable. We introduce the nonlinear term in order into account for the nonlinear effect of the relationship between net income and Climate (Ouedraogo, 2012). S represents the soil variable , M market access, E is the flow of water, SA is agricultural land, TM is the household size, IR irrigation and ε error term. The irrigation and market access are dummy variables whose parameters are equal to one if the individual has used this practice and 0 otherwise.

Introduction of variables such as agricultural area, household size and irrigation allows to take into account the adjustments made directly by farmers and their effects on their income.

4.2. Theoretical Model and functional form of firm value

We build an intertemporal optimization problem in order to model the adjustment path of the inputs and outputs almost fixed in time. We assume that the firm purchases its inputs in a competitive market and its expectations on climate and market prices are rational. This means that farmers hardly make forecasting errors. In addition, investment and production decisions of farmers take into account the uncertainty induced by climate change following a stochastic process. To account for this uncertainty, we introduce the climatic elements such as temperature and precipitation in the production function of the farmer. In each period, the farmer's decisions depend on their expectations on climate and market prices.

Farmers use variable factors and quasi-fixed factors. They know current prices of all inputs and outputs, but they only formulate expectations about future developments of these prices and climate conditions. However, farmers must decide on production levels to be attained, the amount of inputs to be used and the level of investment in quasi- fixed factors to be achieve without ignoring adjustment costs.

We assume also that at each base period and for a price given by the market, agricultural firm determines its optimal policy by maximizing the present value of its expected future profits. Furthermore, we assume that this firm does not face the constraint opportunities when developing its production program. Since the choice of the stock of quasi-fixed factors today affects the adjustment costs of the future, the problem becomes dynamic. Therefore, the firm must solve the problem according infinite horizon:

$$J(K_0,p_0,w_0,r,C_0)=\max_{L\geq 0,I\geq 0,C\geq 0}\int_0^{\infty} e^{-rT}(1-\tau)\left[F(L,K,I,C)-{}^{t}wL-{}^{t}pK\right]dt \quad (3).$$

s/c

$$\dot{K}=I-\delta K \quad (4)$$

$$\dot{C}=\delta(C)+\rho\varepsilon \quad (5)$$

$$K_i(0)=K_0\geq 0, C(0)=C_0, (K,p,w)\in\Theta, \forall t\in\left[0;\infty\right[$$

$K_i(0)$ is a vector of quasi- fixed factors held by firm i at the initial period $t_0=0$

$\dot{K}_i(t)$ net investment in quasi-fixed factors, $w\in\Omega^2$ et $p\in\Omega^2$ are respectively vector prices of variable factors and quasi-fixed factors. C is climate vector that consists of temperature and precipitation indices. Its evolves stochastically and exogenously following Brownian motion with drift which is characterized by the transition equation (5). $\delta(C)$ denotes a non-random vector of drift parameters ; ρ is a vector with $\rho^t\rho=\sum$, ε is identically and independently distributed(iid) normal vector with , $E(\varepsilon)=0, \mathrm{var}(\varepsilon)=dT, E(\varepsilon_i\varepsilon_j)=0$, $i\neq j$. Θ open bounded set and domain definition of value function J, $r\geq 0$ is discount rate. It is equal to 5.5%.

Solution of the problem (2) is done by using dynamic programming, third approach of dynamic optimization problems. This approach, developed by Bellman (1957), has been successful in its application to problems in discrete and continuous time.

To derive demand functions of investment and employment, we use the dynamic duality approach. This method was initiated and developed for the first time in the theoretical work of Epstein (1981). This new duality provides a broad class of functional forms of application of inputs, which can be tested and applied to the theory of adjustment costs. The primal problem in our approach is the Hamilton-Jacobi-Bellman equation and the dual is the inverse of this equation:

$$rJ(T,K)=\max_{I}\begin{bmatrix} g(T_0,K_0,I)+{}^t wL+{}^t pK+J_K(T_0,K_0)\dot{K} \\ +J_C\delta(C)+0,5vec(J_{CC})^t vec(\Sigma) \end{bmatrix} \tag{6}$$

The above is Hamilthon -Jacobi -Bellman equation and is the primal problem. It is established as a necessary condition of equilibrium of a dynamic optimization program with a continuous time under constraint[1]. Indeed, Hamilton -Jacobi equation is a necessary and sufficient condition to maintain firm value at its maximum level in each period. It also allows transforming dynamic problem (3) in an easily handled form. This equation is a static form of the problem (3) and implies that firm value can be defined as the sum of the maximum current profit and the present value of marginal benefit resulting from the optimal adjustment in net investment. According to Epstein (1981, op.cit), firm's technology function can be determined and represents optimal behaviour firm supply as follows:

$$F(L,K,I)=\min_{(p,w)\in\Theta}\begin{bmatrix} rJ(K_0,p_0,w_0,r,C_0,T_0)+{}^t wL+{}^t pK \\ -J_K(K,p,w)(I-\delta K)- \\ J_C\delta(C)+0,5vec(J_{CC})^t vec(\Sigma) \end{bmatrix} \tag{7}$$

$$\left(L,K,I,C\right)\in\Phi$$

[1] Hamilton -Jacobi – Bellman equation is different from the Euler equation, also called Euler-Lagrange equation. This equation is the necessary condition of equilibrium in a dynamic optimization program in continuous time without constraint.

Suppose that J is a diffeomorphisme. That means this function is bijective, différentiable on Θ an its inverse on Φ, for all (K_0, p, w, C_0).

According to envelope theorem which consist of differentiating the above equation with respect to prices w and p, and rearranging, we obtain the following system equation which represent dynamic quasi-fixed inputs and output; and variable inputs.

$$\dot{K}^* = {}^tJ^{-1}_{Kw}(r^tJ_p + K) - J_C\delta(C) + 0{,}5vec(J_{CC})^t vec(\Sigma) \tag{8}$$

$$L^* = -rJ_w + {}^tJ_{Kw}\dot{K} - J_C\delta(C) + 0{,}5vec(J_{CC})^t vec(\Sigma) \tag{9}$$

The first equation describes the dynamics of quasi- fixed factors. While the second equation expresses the optimal path of variable factors.

According to Vasavada and Chambers(1982), and Sansi(2014), functional form for the Hamilton-Jacobi-Bellman equation form of value function that allows for linear homogeneity in prices and concavity in quasi-fixed inputs is a modified generalized Leontief:

$$J(K_0, p_0, w_0, r, C_0, T_0) = \left[pw\right]AK + {}^tpB^{-1}K + \left[{}^tp\,{}^tw\right]HC + \left[{}^tp\,{}^tw\right]Ivec(C^tC) + \left[{}^tp^{1/2}\,{}^tw^{1/2}\right]C\begin{bmatrix} p^{1/2} \\ w^{1/2} \end{bmatrix} + \left[{}^tp\,{}^tw\right]DY \tag{10}$$

This function allows taking into account the quasi- fixity of inputs and output. Then the specified form of equation (8) is:

$$\dot{K}^* = (rI - A)K + AH(rC - \delta(C)) + AI(rvec(C^tC) - vec_C(C^tC)\delta(C) - 0{,}5vec(\Sigma)) + rA\left[diag(K^{1/2})\right]MK^{1/2} \tag{11}$$

Approximating $\dot{K}$ discretly as $\dot{K} = K_t - K_{t-1}$, we have the final functional form of equation (10) as:

$$K_{iT} = (I + M_a)K_{it-1} + AH(rC - \delta(C)) + AI(rvec(C^tC - vec_C(C^tC)\delta(C) - 0{,}5vec(\Sigma)) + rA\left[diag(K^{1/2})\right]MK^{1/2} \tag{12}$$

Econometric specification of demand equations is then done by adding error terms for each one of the system equation. The error term measures the difference between actual observed values of the dependent variable and the values that should have been observed if the functional relationship was strictly accurate. Specification of equations (12) is then made by adding the error terms for each of the system equations. These terms reflect also errors and optimization technology shocks

Consequently, system of quasi-fixed factors demand can be written in the following form:

$$\begin{aligned} K_{iT} &= (I + M_a)K_{it-1} + AH(rC - \delta(C)) \\ &+ AI(rvec(C^tC - vec_C(C^tC)\delta(C) - 0{,}5vec(\Sigma)) \\ &+ rA\left[diag(K^{1/2})\right]MK^{1/2} + \varepsilon_{iT} \end{aligned} \quad (13)$$

5 . Sources and data definition

In this framework, data definition consist to neutralize price effect in the variables, and to normalize factors with respect to output price.

5.1. Data sources and identification of agricultural production units

The data used in this study come from Food and Agricultural Organisation (FAOSurveys and Agricultural Statistics Division (SASD) of Cameroon Ministry of Agriculture and Rural Development (MINADER) and the Cameroon National Institute of Statistics (NIS). Climate data including temperature and precipitation indices are collected from observation posts régionaless of the ten regions of Cameroon namely Abong-mbang, Ambam, Batouri, Ebolowa, Garoua, Lobe, Maroua, Menoua, Nkambe, Ngaoundere, Nkolbisson, Nkongsamba, Tibati and Yagooua. This is data were completed by those of World Bank (2015) and especially Climate Change Knowledge Portal. Moreover, since investment is intermittent at the firm level, we use data aggregated at the national agricultural sector. This aggregation of data is justified by the fact that the model we have derivative is a convex adjustment model. This aggregation can also be justified by reasons statistic: achieve significant results.

To assess the impact of climate change on agricultural income, we estimate Ricardo model on a sample of 2132 households identified in the Cameroonian Survey on households or *Enquête camerounaise auprès des ménages*(ECAM3, 2007), available at the National Institute of Statistics (NIS). It is important to recall that NIS is undertaking the fourth Cameroonian survey on household

(ECAM 4), but results of this survey are not yet available. So, we then use data on agricultural household provided by ECAM 3. It should also be important to note that ECAM 3 was carried out in six of the ten existing regions namely Centre, Littoral, Far North, West, Southwest and Northwest region. The reason is that in these areas, most of households practice agriculture. Then, to analyze the dynamics of adjustment of inputs and outputs, we make use of data aggregated at national level provided by FAO for the period 1961-2013 STAT.

5.2. Data Definition

Variables used in this study are defined as follows:

a- The Physical capital stock which includes machinery, equipment and land.

b- The Labour. It is used taking into account degree of qualification of workers. Thus, this factor contains two categories, namely the number of workers (family labour) and the number of qualified employees. The first category perfectly fit into the variable factors, while the latter category is stored in the so-called *quasi-fixed* factors.

c- The total value of the energy. For energy, we mean fuel, electricity and water. The value is obtained by aggregating data in order to obtain the level of annual energy consumption in the agricultural sector.

d- The total value of inputs: fertilizer

The price of workforce or hourly rate of pay is relative to the number of hours worked on average

f- Price of capital.

g – The Farm net income. It is the difference between production and associated production costs (seed costs, inputs, pesticides, storage, equipment and agricultural equipment, etc.)

h-The Temperatures and annual precipitation. They are computed as the sum of monthly precipitation and temperatures. Moreover, since according to the Intergovernmental Panel on Climate Change (2007) observed changes in temperature and rainfall at the regional level are often correlated. To take into account this correlation, we use a VAR model. Im-Pesaran-Shin test (IPS) shows that the VAR model (2) better explains this temporal correlation.

We also added two dummy variables including irrigation and measures against erosion. These two variables are useful in estimating Ricardo model because they allow to capture adaptation measures undertaken by farmers under climate change. Irrigation permits to see what is the effect of the measures taken during the drought. while the second variable informs about effect of adaptation measure during rainy periods.

6. Presentation and analysis of results

The Results in this section relate to the estimation of the Ricardian model and interdependence and quasi-fixity hypothesis tests. Ricardian model informs about climate impacts on incomes of farm households. While interdependence and quasi-fixity tests inform about dynamics of production adjustment and quasi-fixed inputs to their respective optimum levels. Regression is done in two stages. In a first step, we introduce socioeconomic and climatic variables except irrigation and measures against erosion in Model 1 called model without adaptation. In the second step, especially in model with adaptation we introduce practice of irrigation and measures against erosion (both dichotomous variables) in order to assess impact of these adaptive measures on incomes of farm households. Parameters are estimated by ordinary least squares method (LSQ). Results obtained are shown in **Table 1** below.

6.1. Estimation results of Ricardian model

Table1 – Estimation results of the ricardian models

Variables	Modèle 1		Modèle 2	
	Coef.	t	Coef.	t
Climatic variables				
Temperature	-710.340**	6.08	-615.10*	4.96

The explanatory power of the two models is excellent, according to values of correlation ratio. Correlation ratio for the first model indicates that farm income fluctuations are explained at 39.82 % by different climatic and socioeconomic variables while this ratio is 42.56% for the second model. This implies that quality of equation adjustment to dependant variable is also good. Fisher-Snedecor test shows, moreover, that the two models are globally significant. As for Student test, it shows that quadratic terms of temperature and precipitation are significant at 5% level and 1% respectively. Consequently relationship between climate and farm income is nonlinear.

The Signs of parameters relating to socio-economic characteristics are those theoretically expected except agricultural area. Indeed, we found that soil quality, market access, practice of irrigation and household size positively affects net farm income. This means that the more quality of soil is good and farmers have market access, the more net farm household income is high. The Positive influence of irrigation on farm net income is explained by the fact, during dry season, irrigation allows farmers to adapt their activity to climate variations. Practice of irrigation is an important need in Central Africa in general and Cameroon in particular since country's agriculture is mainly rain-fed agriculture.

For cons, effect of agricultural area on net income is negative. This can be explained by practice of extensive farming by in order to compensate low productivity of agricultural land. In the short run, this practice increases agricultural production without improving productivity of agricultural land. In the long run, this practice lowers crop yields due to insufficient resources to maintain activity on these large areas. As Ouedraogo (2012), we assessed sensitivity of farm incomes with respect to climatic variables. Thus, **Table 2** shows that an increasing of 1% in temperature leads to higher farm revenues by 32.4 % while an increasing of 1% in precipitation leads to lower farm revenues by 12.9 %.

Table 2: Elasticity of farm incomes.

	Elasticity	**R^2**	**F-statistic**	**t-statistic**	**DW**
Temperature	0.324	0.68	631.23	3.99	2.01
Precipitations	-0.129	0.56	57.59	13.03	1.55

Source : By us from MINAGRI, ECAM 3 and FAOSTAT data

Table 3: Marginal effect of climate variables on farm incomes.

	Marginal effect	**R^2**	**F-statistic**	**t-statistic**	**DW**
Temperature	-2200.2	0.68	631.23	1.99	2.01
precipitations	2322	0 .56	57.59	13.03	1.55

Source: By us from MINAGRI, ECAM 3 and FAOSTAT data

Looking at the marginal effects of climate change on agricultural income, Table 3 shows that increasing 1mm rainfall leads to an increase in net farm income of 2322 FCFA per hectare. While an increase of 1°C leads to decrease of 2200.20 FCFA per hectare.

6.2. Results on Dynamics of adjustments under uncertainty.

In this sub- section, we present and analyze results on dynamic adjustment of inputs and agricultural production in Cameroonian agricultural sector based on the coefficients of adjustment matrix $M_a = rI_4 - A$. Estimation results relate to 67 parameters in **Table 5** in appendix.

This second part of our study is to examine dynamics of adjustment in the agricultural sector in Cameroon. This objective is achieved performing quasi-fixity and interdependence tests. The first test is performed on agricultural production, labour, fertilizer and productive capital (approximated by machinery and equipment). The second test concerns independence of adjustments between these variables. In this study, these tests are used to assess if there is relationship between two variables, even when those variables are qualitative. It is whether, at the agricultural firm level, production adjustment affects inputs adjustment and vis-versa. Independence test, for example allows controlling of interdependence between production adjustment and amount of used quasi-fixed inputs on one hand; and interdependence between quasi-fixed inputs on the other hand. According to Monson and Taylor (1985), independent adjustment rate means that each quasi-fixed input adjusts to their long-run equilibrium level regardless of the other quasi-fixed inputs. According to Howard and Shumway (1988), independence reflects the fact that in the adjustment matrix, crossed adjustment coefficients are equal to zero.

$a_{ij} = a_{ji} = 0$, avec $i \neq j$. So, a quasi- fixed variable is adjusted to long-run equilibrium level independently of each other. For example, at a certain period, firm can hire new workers without needing to vary level of physical capital (amount of equipment and machinery) or it may decide to vary level of physical capital without needing to hire new workers.Null hypothesis is the lack of interdependence and therefore independence between adjustments. According to Warjiyo and Huffman (1995), univariate partial adjustment model is then appropriate to estimate adjustment coefficients. Consequently, change in relative price of input has no effect, even indirectly on the amount of other input. Alternative hypothesis reflects interdependence between adjustments of the various quasi-fixed factors: level change in amount of an input requires change in the amount of other input and vice-versa. In this case, flexible accelerator multivariate adjustment pattern appears to be a better representation of adjustment behaviour of quasi-fixed inputs by agricultural firms, instead of univariate partial adjustment model. The following table gives results of chi-square independence test.

Instantaneity implies that in the adjustment matrix, the own and crossed adjustment coefficients are equal to 1 and 0 respectively:

$\begin{cases} a_{ii}=1 \\ a_{ij}=a_{ji}=0 \end{cases}$. These restrictions reflect the fact that production and quasi- fixed inputs adjust instantaneously to their optimum level of long-run and are considered to be variable inputs in short and long-run. Therefore, the current amount of inputs $K(t)$ is always at the desired level or long-term equilibrium $\overline{K}$, variation in the amount of inputs $\dot{K}(t)$ is zero for all t and the adjustment matrix is an identity matrix of order 4. In this case, any adjustment of production, fertilizer, capital, labour is done smoothly and without costs. In other words, agricultural firm adjusts these variables in one period.

Quasi-fixity test is performed as follows:

$\begin{cases} H_0 : a_{ii} = 1, a_{ij} = 0 \\ H_1 : a_{ii} \prec 1, a_{ij} \neq 0 \end{cases}$. a_{ij} et a_{ji} are different from zero.

Null hypothesis reflects the fact that adjustments are instantaneous. Hence, firms adjust immediately and without costs in one period their level of output and production capacity to their optimum level. Thus, in the absence of adjustment costs, firms, facing change in relative prices adjust their output and theirs inputs freely without suffering production or revenue losses. As for alternative hypothesis, it represents the fact that changes in levels of quasi- fixed inputs are progressive: adjustment of amount of quasi-fixed inputs to their optimal level is done in several periods. Therefore, inputs are gradually adjusted to their l long run equilibrium level. In adjustment matrix, crossed and own adjustment coefficients are not only equal to zero but also strictly less than unity. They are then, in the short run , modeled as quasi-fixed inputs.
The Results of quasi- fixity test are shown in the following table:

Table 4. Tests of interdependence and instantaneity.

Hypothesis Tested	**Wald Test**	***df***	***p*-value**
Independent and instantaneous adjustment	32876.29	18	0.0000
Independent adjustment	112.03	14	0.0000
Quasi- fixity	301.10	18	0.0000
Independent and instantaneous adjustment *for*			
Crops	37.25	5	0.0000
Capital	967.39	5	0.0021
Labour	16.54	5	0.0301
Fertilizer	22.20	5	0.0100

Source: By us from MINAGRI, ECAM 3 and FAOSTAT data and with SAS software

The Wald test we use is particularly interesting in the sense that it is possible to perform simultaneously interdependence test and instantaneous adjustments test. So, according to the results, assumptions of independence and instantaneous adjustments are rejected since adjustment matrix M_a is different from unit matrix I_4. This confirms existence of adjustment costs in the process of adaptation and resilience to climate change and in market prices changes by farmers. Furthermore, independent adjustment test shows that production adjustment leads in capital adjustment, labour and fertilizer and vis-versa. Indeed, in Cameroon, farm households practise extensive agriculture in order to increase agricultural production affected by climate change. This practice also requires an increase in production capacity in terms of capital, labour and fertilizer. The results show that these adjustments to climate change and to changes in market prices do not happen instantly. Thus, at 10% level, quasi-fixity hypothesis is accepted for production, capital, fertilizer and labour. The fact that agricultural production is gradually adjusted can be explained by the limited adaptability of plant species. Capital which includes machinery, equipment and land, may be less flexible during certain periods (Sansi and Schumway, 2014). Since fertilizers are purchased, amount and also calendar of use are adjusted gradually. Results in the above table also show that workforce which includes paid self-employment and labour, do adjusts instantly.

The Adjustment matrix which provides information about speed of adjustment of quasi-fixed variables shows that all coefficients of this matrix are significantly different from -1 at 5% level for production, labour, and fertilizer and at 10 % for capital. This implies that in the short run and under climate change and market prices changes, production, capital, labour and fertilizer are actually quasi-fixed variables and their adjustment is not made in an annual period, but in several years. Own adjustment rate of production -0.4 implies that harvests adjust at 40% to their desired level every year in response to price shocks and climate change. While capital adjustment rate -0.0104 implies that this input is adjusted at 1.04% towards its equilibrium level in a year. In addition, labour adjustment rate -0.6666 means that workforce is adjusted at 66.66% annually. Finally, adjustment rate of fertilizers -0.9834 reflects the fact that this variable is set at 98.34% annually. It can be said that under climate change and prices shocks, Cameroonian farm households take about two and a half to adjust production at its optimum level (or desired level), about 24 years to fully adjust capital, one and a half to adjust workforce and about nine months to adjust fertilizers, each of them at their optimum level. These results show that in the Cameroonian agricultural sector, farmers are renewing more slowly their level of capital which includes machinery, equipment and agricultural land.

7. Conclusion

The first objective of this study is to understand and quantify the link between climate and agriculture in Cameroon. The second one is to examine how expectations of farmers on climate change affect investment and production decisions and inputs adjustment process. The first objective is achieved by applying two Ricardian models namely model **without adaptation** and **model with adaptation**. In the model without adaptation, irrigation and measures against erosion are not taken into account while in the model with adaptation, these measures are introduced in order to capture theirs effects on farm incomes. We found that soil quality, market access, irrigation and household size positively affect net farm income. This means that the higher the quality of soil is good, farmers have access to markets, the more the farm incomes are improved. With regard to irrigation, it permits to adapt to climate change, especially during dry seasons, since Cameroon's agriculture is mainly rain-fed agriculture. We also found that effect of agricultural area on farm income is negative. Then, estimates show that income of farm households are significantly sensitive to climate variations. Thus, a 1% increase in temperature leads to higher farm revenues by 32.4% while a 1% increase in rainfall causes a drop in farm income by 12.9%. As for climate marginal effects on incomes of farm households, we found that an increase in 1mm of rainfall led to an increase in net farm income per hectare of FCFA 2322. While an increase in 1°C of temperature leads to a decrease of FCFA 2200.20 per hectare. Finally, estimates of dynamic stochastic model show that, under uncertainty induced by climate change and in market prices changes, farmers gradually adjust production and inputs. These dynamic adjustments are justified by adaptation costs of measures implemented by farmers under uncertainty. Thus, in this uncertain environment, farmers take about two and a half years to fully adjust desired level of their crops, about 24 years to adjust capital to its desired level, one and a half to adjust work and about nine months to adjust fertilizer.

However, beyond all these results, although model allows to highlight adjustment costs induced by climate change and market prices change, it does not allow decomposition of these two effects. So in this study, changes in climate and relative price occur simultaneously.

This study contributes more to the validity of dynamic inputs demand models derived from dynamic duality approach in an uncertain environment, developed by Pietola and Myers (2000) and Krysiak (2006). In the same vein, this study shows that it is possible to model supply and demand for several quasi-fixed inputs and outputs through transformation of the value function of the firm in Hamilton-Jacobi-Bellman equations. Looking at the political contributions, interest of understanding and anticipating impacts of climate change on agriculture is very important for policy makers. It permits to implement appropriate measures to mitigate the socio-economic consequences.

ABSTRACT

Climate change is possibly the greatest environmental challenge facing the world this century. The impact of climate change is a reality and it cuts across all climate - sensitive sectors including the Agriculture sector. It well documented by several scientists, Intergovernmental Panel on Climate Change and other experts that climate change threatens sustainable economic development and the totality of human existence. This study was conducted in Nkangala District, Mpumalanga province. Mpumalanga province remains the largest production region for forestry and the majority of the people living in Mpumalanga are farmers and they have contributed immensely to promote food security. However, due to the impacts and threaten by climate variability and change which resulted into shortage of food production and changes in the rainfall pattern. It was noted that there is a need for climate change awareness across the agriculture sector including farmers. Random sampling technique was used to select two hundred and fifty one farmers to be interviewed. The questionnaire was administrated to farmers and included matters relating to climate change awareness and agronomic practices including maize production. Data was captured and analysed using software package for social science (SPSS version 20). Descriptive analysis was used to describe data and Multivariate regression analysis was conducted to demonstrate the relationship and association of variables. It was noted that the majority of farmers in this province need capacity building and also climate change awareness initiatives which would assist these farmers to build the adaptive capacity, increase resilience and reduce vulnerability.

Keywords: Climate Change awareness, Nkangala District Mpumalanga Province South Africa, Small Scale maize farmers.

1. Introduction

According to (Hughton, D. 2002) climate change is possibly the greatest environmental challenge facing the world today. The impact of climate change varies globally; however, the problem and the challenges of climate change are becoming more threatening to sustainable economic development and the totality of human existence (Adejuwon, S.A, 2004). Small-scale farmers suffer the most because of their dependence on rain-fed agriculture, limited financial capacity, low adaptive capacity, high dependence on natural resources, inability to detect the occurrence of extreme hydrological and meteorological events due to low technology adoption, limited infrastructure, illiteracy, lack of skills, level of awareness and lack of capacity to diversify (Kurukulasuriya, P. and R. Mendelssohn, 2006a). Maize constitutes about 70 percent of grain production and covers about 60 percent of the cropping area in South Africa. It is a summer crop, mostly grown in semi - arid regions of the country, and is highly susceptible to changes in precipitation and temperature [Durand, W. 2006 & Benhin, J.K.A, 2006). In addition, maize is the main staple food in Southern Africa, and maize production in the country constitutes about 50 percent of the output within the Southern African Development Community (SADC) region (Durand, W. 2006). Consequently, maize is one of the key drivers of food inflation in South Africa BFAP (Bureau for Food and Agricultural Policy, 2007). A considerable number of studies have been done to investigate the impact of climate change on yields of grain crops such as maize under controlled experiments (Du Toit *et al;* 2002 & Durand, W. 2006). There is very little awareness on climate change in the developing countries (IPCC, 1996: Climate Change 1995). The overall objective of the paper is (i) to create awareness through which farmers can understand the impact and the threats that climate change pose within the agriculture sector. (ii) Build adaptive capacity and reduce vulnerability facing small scale farmers in Mpumalanga Province. This will enable small scale maize farmers in Mpumalanga province to have basic understanding about the impact of climate change in their areas.

2. Materials and Methods

This paper used quantitative design as a well detailed structured questionnaire written in English language as part of the data collection methods. The questionnaires consist of a logical flow of closed ended questions which address issues related to climate change, agricultural production, yields etc. Data was collected through face to face interviews with the farmers and also the help of the extension officer where 251 questionnaires were administered in the study area. The study was conducted in Emakhazeni local municipality within the Nkangala district municipality in the Mpumalanga province of South Africa. Stratified sampling technique was used to select two hundred and fifty one farmers to be interviewed. Data was captured and analysed using software package for social science (SPSS version 20). Descriptive analysis was used to describe data and Univariate regression analysis was conducted to demonstrate the relationship and association of variables. The following econometric model was used to determine association of variables:

Wi = _ + _Xi + _i (1)

Wi is the dependent variable value for person i (2)

Xi is the independent variable value for person i (3)

_ and _ are parameter values (4)

_i is the random error term (5)

The parameter _ is called the intercept or the value of W when X = 0 (6)

The parameter _ is called the slope or the change in W when X increases by one (7)

3. Results and Discussion

As shown in Table 1, there is association among the following variables: gender, age, occupation, education, source of income, information on climate change, extension service, importance of information on climate and quantity of harvest. This is supported by the fact that their estimate values are more than 1 at 95% confidence interval.

Gender (Female) had significant impact on the level of climate change awareness. According to Table 1, the odds of climate change awareness are 1.00 percent higher for female households than male households. It is widely recognised that climate change does not affect people equally (UNEP, 2011). It was reported that women and men perceive and experience climate change in diverse ways because of their distinct socially constructed gender roles, responsibilities, status and identities, which result in varied coping strategies and responses (Luseno *et al;* 2003 & , FAO, 2010). The situation observed in Mpumalanga province is not different from a research conducted in Limpopo province by (Maponya, P. and S. Mpandeli, 2012) that women play a vital role in supporting households and communities, thus, they are more aware and adapt to climate change through experience gained in agricultural production and the fact that the majority of these women spend most of their time in the field ploughing, removing weeds, monitoring the crops, harvesting etc. Often, women are more vulnerable to climate change than men.

Age is another significant variable which is associated to climate change awareness. According to Table 1 the odds of climate change awareness are 1.00 percent higher across all age categories. This is not surprising because climate change awareness is made across all age categories even in the schools and out of the school through the use of fliers, posters and many medium. According to (Bayard *et al;* 2005) age is positively related to some climate change adaptation measures that are related to agricultural activities. According to (Okoye, 1998) found that age is positively related to the awareness and adoption of conservation measures. The result of this research agrees with the findings of (Yusuf, 2005) that most farmers are within their active years and can make positive contribution to agricultural production, thus farmers' age had a significant impact on the awareness of climate change.

According to Table 1 the odds of climate change awareness are 1.10 percent higher across all occupations. The study shows that occupations of the respondents have significant impact on the level of climate change awareness. This could be from the fact that some farmers take farming as a full time and some farmers take farming as part time activity but in each case, they all come across awareness either through indigenous knowledge or at their various place of work through adverts. According to (Adebayo Tukur, 2003) occupation has a significant association with awareness of climate change. The more they carry out farming activities, the more the awareness and adoption to climate change.

According to Table 1 the odds of climate change awareness are 1.01 percent higher across all educational levels. Many research studies have shown that education increases ones's ability to receive, decode, and understand information relevant to perception and making innovative decisions (Wozniak, 1984). However, the result from the study area showed that education increases the probability of the level of climate change awareness. According to (Noor, 1981) and (Omolola,

2005) are of the view that education facilitates farmers' understanding and use of improved crop technologies. According to (Anley & Haile-Gabrile, 2007) improving education and employment is the key to stimulate local participation in various adaptation measures and natural resource management initiatives.

According to Table 1 the odds of climate change awareness are 1.00 percent higher across for households who rely on maize as source of income than households who don't rely on maize as source of income. From the study, farmers who rely on maize as a source of income have no other job or extra source of income, than farming activities, thus, they are involve and concern about their environment in relation to their faming activities because they need to provide for the household thereby tends to be more aware of the climate change as an environmental factor responsible for production, unlike farmers who have other source of income apart from farming.

According to Table 1 the odds of climate change awareness are 1.53 percent for households with climate change information. This shows that climate change information is significantly associated with awareness level of climate change. This is not surprising because a study reported by (Luseno *et al;* 2003) said the more the farmers had access to extension services and information about climate change, the more they adapt to climate change. From this study, the amount on climate change information at farmers' disposal determines the level of awareness of climate change. According to (Pender *et al;* 2004), it is hypothesized that farmers who have significant extension contacts have better chances to be aware of changing climatic conditions and as well as adaptation measures in response to climatic changes.

Access to extension services is another significant variable which is associated to climate change awareness. According to Table 1 the odds of climate change awareness are 1.50 percent for households with access to extension services. The study shows that access to extension services significantly affects awareness to climate change. Extension services provide an important source of information on climate change as well as agricultural production and management practices. Farmers who have significant extension contacts have better chances to be aware of changing climatic conditions and also of the various management practices that they can use to adapt to changes in climatic conditions. The role of extension service is to provide information to extension clients in order to allow them to use available resources by increasing technological options and organizational skills that in turn allow them to take greater advantage of production and market opportunities (GoK, Government of the Republic of Kenya 2001). According to (Nhemachena, 2008, & Apata *et al;* 2009 & Deressa *et al;* 2009 & Bryan *et al;* 2009) they have indicated that access to extension services had a strong positive influence on adapting to climate change and awareness.

According to Table 1 the odds of climate change awareness are 1.12 percent for households who recognise the importance of climate change information. According to (Hassan and Nhemachena, 2008) farmers that perceive change in climatic conditions and farmers who have access to climate change information have higher chances of taking adaptive measures in response to observable changes. Importance of climate change information brings about awareness on climate change and enhances farmer's knowledge on adaptation to climate change.

According to Table 1 the odds of climate change awareness are 1.01 percent for households who received good quantity of harvest. Good quantity of harvest is another significant variable which is associated to climate change awareness. Though the relationship between seasonal climate variables can be quite complex, we expected that farm revenues would have a significant relationship with climate change awareness (Kurukulasuriya and Mendelssohn, 2006a).

4. Summary and Conclusion

Due to prevailing problems associated with changes in weather patterns such as high temperatures, changes in rainfall patterns and effect of greenhouse gases (GHGs), which has resulted in low crop production, food insecurity, low income for farmers, there is a need to investigate whether small scale maize farmers are aware of climate change. So this study will enable small scale maize farmers and households in Mpumalanga province to understand the meaning of climate change, by creating awareness through which households and farmers can cope with climate change. This will improve climate change adaptation and thus increasing maize production as well as income for households and farmers.

Table 1: Univariate regression analysis of potential determinants of climate change awareness and maize production

Variable	Total	(%)	OR [95%CI]
Females	52	20.7	1.00[0.508 – 2.711] 1
Age	251	100	0.99 [0.440 – 2.567] 1

ABSTRACT

The Mediterranean region has always shown a marked inter-annual variability in seasonal weather, creating uncertainty in decisional processes of cultivation and livestock breeding. This should not be neglected when assessing the impact of climate change (CC), which modifies the atmospheric variability and generates new uncertainty conditions, and is particularly relevant when modelling the adaptive responses of farmers to the CC itself. Our analysis examines precisely this aspect by reconstructing the effects of inter-annual climate variability in a diversified agricultural district that represents a wide range of rain and irrigated agricultural systems in the Mediterranean. We generated the atmospheric variability conditions of ten years representative of present climate (2000-2010) and as many of near future (2020-2030) by processing the results of a Regional Atmospheric Modelling System. Then, we implemented calibrated crop and livestock models to estimate the corresponding productive responses in the form of probability distribution functions (PDFs) under the two climatic conditions. We assumed these PDFs able to represent the expectations of farmers in a discrete stochastic programming model that reproduced the economic behaviour of the main farm types operating in the study area under uncertainty conditions. The comparison of the results in the two scenarios provided an assessment of the impact of CC, also taking into account the possibility of adjustment allowed by present technologies and price regimes. Major differences in the economic response emerged among farm typologies and sub-zones of the study area. As discussed in a previous paper, a crucial element of differentiation is water availability, since only irrigated C3 crops can take advantage from the fertilization effect of increasing future atmospheric CO_2 concentration. Instead, the reduction of spring rainfall associated to the higher temperatures depresses the rainfed crop production. A dualism emerges between the smaller impact on crop production in the irrigated plain sub-zone, equipped with collective water networks and abundant irrigation resources, and the major negative impact in the hilly area, where these facilities and resources are absent. Yet, increasing summer temperatures also negatively affected milk production and quality, and cattle mortality of intensive dairy farming. In this latter paper, after summarizing those impacts, we focus on some repercussions of the CC on the supply of agricultural products. Interesting aspects emerge about the link between CC and food security in the context of an advanced agriculture in the Mediterranean.

Keywords: CC adaptation, Mediterranean-farming systems, integrated assessment, modelling approaches

1. Introduction

The meteorological conditions of a climatic zone often presents a significant inter-annual variability: this is true even in periods in which people perceive the climate as in a stable condition. Many studies mention and explain the determinants and expressions of climate variability in the various sections of the Mediterranean area (Navarra and Tubiana, 2013). The atmospheric circulation in the Atlantic Ocean determines the variability of rainfall in the autumn period (Altava-Ortiz et al., 2011). Heat waves are a frequent feature of the Mediterranean summer (Gaetani et al., 2012). In addition, several anomalous warm summers have occurred in the Mediterranean and in southern Europe over the last 60 years, with hot events of different intensities and lengths (Segnalini et al., 2011).

Climate variability influences crop production and livestock as extensively treated in the scientific literature. The relationships between variability in the climatic conditions and livestock production have been investigated with specific mathematical and statistical models (Vitali et al., 2009; Bernabucci et al., 2014). Agronomical models have provided a rich characterization of optimal growth to represent the response of crops production under different climatic conditions (Liu and Tao, 2013; Dono et al., 2013a, 2013b, 2014). Various studies have used these models to assess the impact of CC by comparing crop yield or the requirement of inputs under conditions of current and future climate (Eckertsen et al., 2001; Semenov and Shewry, 2011; Rötter et al., 2012; Olesen et al., 2011; Palosuo et al., 2011; Reidsma et al., 2010; Iglesias et al., 2009). In addition, there is a growing recognition that the aggregate results can hide large amounts of variability, and is important to evaluate the effects of Climate Change (CC), and the possible adaptation strategies, to the level of farming systems, or agricultural households (Claessens et al., 2012). In this regard, it is important to considering that farmers base their annual planning on expectations about crop and livestock production that depend on inherent variability of climate and will prove correct, or less, only several months later. Therefore, when assessing the impact of CC on agriculture, and possible adaptation strategies, it must be considered how they can alter their production choices also responding to the changes in the climate variability.

A recent paper presented the main characteristics and results of an integrated study on the effects of climate variability on crop and livestock production, and farm management of a diversified Mediterranean agricultural district (Dono et al., 2016). The analysis assessed the productive and economic impact of CC at farm typology level, including the effect of changing the variability of atmospheric conditions. The study area is located in the Oristano province in the central-west Sardinia (Italy), and it is one of the Regional Pilot case studies conducted under the research activity of the FACCE MACSUR Knowledge hub[1]. This agricultural district extends for 54,000 hectares (Ha) and presents a variety of farming systems covering a wide range of conditions under both irrigated and rainfed Mediterranean conditions. Therefore, many issues generated by the interaction of CC seasonal impacts on different cropping and livestock systems were deeply explored and analysed. Data from the sixth Census of Agriculture, 2010, and records from the FADN and the local Water Users Association (WUA) show that irrigation is practiced on 36,000 Ha of that territory. The main crops of this sub-area are wheat, corn and forage, and cow's milk is the key product. In addition, vegetables are common, as also rice, citrus, olive trees and vineyards. Additional 18,000 Ha are instead rain-fed and used for pasture and rye grass, for sheep milk production, woods and set-aside. This latter sub-zone uses farm wells to irrigate very limited areas.

[1] http://macsur.eu/index.php/regional-case-studies

The problems due to the change of agro-climatic conditions in this area were analysed by integrating climatological, agronomic and livestock models, whose outputs, once treated with statistical methods, were included in an economic model that simulates the farm choices under present and then future climate context. Our hypothesis is that the represented farming systems were also relevant to many other areas of the Mediterranean, and the results obtained can provide a relevant support for the development of contextualized effective and strategic adaptive responses far beyond the analysed local context, in the transition to future climate. This also justifies the short-term time horizon chosen for the analysis, which addresses the changes in climate variability that can be immediately relevant for the development of strategic adaptation policies in the context of rural development.

Dono et al. (2016) provides a detailed description of the analysis; following a summary of its main steps and the description of some further results that we report in this paper, and regard the biomass production of the main agricultural activities. This aspect seems relevant in the context of food security given the changes in crop yields and in milk production generated by the CC.

2. Materials and method

A Regional Atmospheric Modelling System (RAMS) nested into an atmosphere-ocean model based on ECHAM 5.4, generated the current and future climate scenarios of the Oristano area (Scoccimarro et al., 2011). We defined these scenarios with reference to a decade, and not compared to one year, just to induce the model RAMS to consider the variability inherent in the climate, and generate a wide spectrum of conditions that may arise. Therefore, the greenhouse gas scenario A1B of 2000–2010 denotes the current climate; the scenario A1B of 2020–2030 denotes the future climate. A post-processing procedure based on observed data and reconstructed sea surface temperature reduced the errors due to poor geo-morphological description (mountains, land cover) from numerical models. The outcomes of RAMS for the current and future climates were furtherly processed with the weather generator WXGEN to obtaining data for 150 stochastic years under each of the two scenarios. These data defined the entire range of inter-annual climate variability in that territory under the two climates. Comparing the two scenarios emerges that the footprint of CC is the increase of the summer daily temperature, maximum, but mostly minimum. Temperature increases slightly during the spring, and markedly in fall–winter. Rain variability increases, coupled to a reduced annual average.

The EPIC (Environmental Policy Integrated Climate) model was used to estimate the impact of temperature, rainfall and atmospheric CO_2 in the two scenarios on yields of irrigated (silage maize, ryegrass, alfalfa) and rain-fed (grasslands, hay crop) crops (Balkovic et al., 2013). The model calibration utilized crop, soil and climate data from field experiments, and interviews to farmers. The impacts of the two climates on cattle breeding were evaluated using equations derived from the literature on the relationship between the index of temperature and humidity (THI), mortality (Vitali et al., 2009), milk yields and its somatic cell content (Bertocchi et al., 2014). These relationships were estimated with linear regression analyses in two phases in Italian areas where the Holstein Friesian is bred similarly to the study area.

Those results were processed with maximum likelihood methods to estimate the probability distribution functions (PDF) of the yields, current and future, of pastures and grasslands in the rainfed zone, and of irrigation needs, and relative yields, of maize, ryegrass and alfalfa in the irrigated zone. The irrigation needs of the other crops were estimated based on their present values and the percentage change in *net evapotranspiration* of the future climate with respect to the present. The range of each PDF was divided into 3 *states*, with 25% probability for low and high states, and 50% for intermediate, which constitute the vector of probability (P) of each uncertain variable. The representative value of the variables in the three *states* is the average of their values in the synthetic years falling in each *state*.

Those values were used to represent farmers' expectations on the course of weather in the incoming season in a model of discrete stochastic programming (DSP) that simulates their annual planning under uncertainty on atmospheric conditions (Hardaker et al., 2004). According to this modelling scheme, farmers plan their choices considering the probabilities of the various *states of nature* that may arise in the course of the season, and the possibility to correct the decisions taken if unexpected *states* should occur. Applying corrective actions minimizes the impact of those conditions, even if at a cost (the cost of uncertainty) that causes sub-optimal results. DSP has been used to represent the economic impact of many agricultural uncertainties: availability of irrigation water (Calatrava and Garrido, 2005), productive results of technologies (Coulibaly et al., 2011), on weather risks (Mosnier et al., 2009), change in climate variability (Dono and Mazzapicchio, 2010).

Our DSP model represents the territorial agricultural supply based on 13 farm types (Dono et al., 2016). The climatically driven variability accounted for in this study relates to summer water needs of crops, spring yields of pasture and hay from grasslands, autumnal yields of pastures and of grazed grasslands. The corrective actions regard the pumping of irrigation water from wells in case of higher temperatures and water requirements of the crops, and the buying of feed in case of lower yields of fodder. The mathematical representation of the model is compactly defined as follows:

$$\max_{X_1, XR_{n_s}} z = GI\,X_1 - \sum_{n=2}^{N}\sum_{s=1}^{S} P_s\,Cr\,XR_{n_s} + Pm\,Qm \qquad (1)$$

subject to:

$$A\,X_1 \leq B \qquad (2)$$

$$A_s\,X_1 \leq B + \sum_{n=2}^{N} XR_{n_s} \qquad \forall s \qquad (3)$$

$$N\,Y_s\,X_1 + \sum_{n=2}^{N} XR_{n_s} \geq R \qquad \forall s \qquad (4)$$

$$X_1 \geq 0 \text{ and } XR_{n_s} \geq 0 \qquad \forall s \qquad (5)$$

n is the number of stages of the decision making and s are the *states of nature* that uncertain variables can assume; X_1 is land, whose allocation occurs in the first stage; XR_{n_s} are corrective actions performed in the subsequent states (n= 2,..,N) on the actual occurrence of one of the *states*. These actions modify the available additional resources, at a cost (Cr). Equation (1) is the objective function (z) that sums different components: gross margins (GI) of the activities chosen in the first stage (X_1); costs (Cr) of the corrective actions XR_{n_s}. In this last case, the values of the uncertain activities in the *states of nature* are weighted with their probabilities (P_s), and summed over the N stages. Finally, the objective function sums the revenues of milk, based on the price (Pm) and the total quantity (Qm) obtained under present climate and future[2]. Constraints (2) refer to land and

[2] The model sections dedicated to the allocation of land do not account for the effects of climate on the revenues of cow milk, which are considered in the objective function, as for crops to sale (rice, wheat and barley). The effects of climate

labour resources: A is the matrix of technical constraints and B is the quantity of available resources. Constraints (3) refer to the water resource and show that uncertainty affects A_s, i.e. watering needs of irrigated crops, and that choices involve corrective actions, XR_{n_s}, in stages (n) for each states (s). Constraints (4) refer to animal feeding: N are the unitary contributions of nutritional elements, R are the nutritional needs of livestock categories. The uncertainty affects Y_s, i.e. yields of forage crops, and that choices involve corrective actions, XR_{n_s}, in stages (n) for each states (s).

We calibrated the model to the reference year 2010 with the PMP approach of Rohm and Dabbert (2003) that models the choice between technically similar crops, whose mutual substitution elasticity is greater than that relating to other crops[3]. The calibration involved land allocation among crops decided in the first stage.

3. Results of the DSP model

The values of the three *states of nature*, and the respective probabilities were included in the DSP model that generated the productive and economic results under the two scenarios. Table 1 reports the results on the *biomass production* of the main crops in the present scenario, and their percentage changes in the future for the total study area and its two subzones. The table also shows the impact on cow milk production.

Table 1: biomass production under present and future climatic scenarios [percentage changes of future over current (%Δ)]: total area, zone irrigated by the *WUA* and *rainfed* zone.

on costs of milk production are considered in sections on production and the purchase of fodder, for which, inter alia, are also provided corrective actions in case of adverse conditions. Similar corrective actions concern the sheep sector. In this case, however, the summer production of milk is irrelevant; therefore, the model neglects climate impacts.

[3] For more details, see Cortignani and Dono (2015).

Cereal production grows significantly across the study area; the largest increases are in rice and corn production that, due to irrigation, may benefit from the fertilization effect of the increase in atmospheric CO_2 concentration. Instead, the production of fodder reduces, with sharp falls mainly in the non-irrigated sub-area, where the decrease of the spring rains causes a drop in the yields of hay crops. On the contrary, water availability allows an appreciable increase of the productivity of the Italian ryegrass in the irrigated sub-area, thereby increasing the production of that crop in the beef and dairy farms, and in the sheep farms that manage some farmland in that sub-region. Also, the production of corn silage increases, due to the notable expansion of the late hybrid at shorter circle, which compensates the considerable drop of the variety that is currently widely cultivated. Minor changes affect vegetable crops: the appreciable contraction of early potatoes also depends on the choices of the dairy farms to expanding the acreage of the irrigated late hybrid of silage maize and of Italian ryegrass. The last lines of the table show the reduction in bovine milk: this is only due to the decrease in the unitary production, given that the simulation keeps fixed the number of bred cows. A relatively small reduction of the annual production emerges; the drop is instead quite impressive in the summer months.

These production variations contribute to generating the changes in net income (NI) in the two sub-areas that the table 2 identifies for various groups of farm types and their aggregates. Data show that the negative impacts in the irrigated sub-zone affect almost exclusively the dairy cattle farms that suffer a -5.3% average drop of NI. The decrease of revenues is mainly due to the reduction of cow's milk production; however, this is partly offset by the decrease in the purchase of livestock feed due to the expected increase in farm fodder yields. Other types in this sub-zone benefited by increases of NI, due to the increased cereal yields from the CO_2 fertilization effect. In the rice-growing farms, the effect on the rice crop yield is notable, and the same applies to their NI.

Table 2: net income (NI) per group of representative farms in the present and future climate (000 €); percentage changes of future NI over present (% Δ NI)

	Present NI	Future NI	% Δ NI
Rice	4,317	4,718	9.3
Trees and arable crops	3,874	3,874	0.0
Dairy farms	33,180	31,433	-5.3
Mixed crops	23,500	23,459	-0.2
Irrigated zone	66,102	64,721	-2.1
Greenhouses	1,231	1,236	0.4
Mixed crops	3,733	3,730	-0.1
Sheep	7,903	7,230	-8.5
Rain-fed zone	11,636	10,961	-5.8
Total area	77,738	75,681	-2.6

Source: our elaborations and analyses on (Dono et al., 2016)

A larger reduction occurs for the NI of the rainfed area, due to an increase in variable costs that is more than proportional to the increase in revenues caused by higher grain yields and sales of arable crops. In particular, there are significant consequences of the reduction in the fodder production from grasslands and hay-crops: sheep farms had to notably increase purchases of feed and hay, which greatly compressed NI of these types and of the entire zone.

4. Discussion

The results showed that in the next 2020-30 decade the CC can generate different types of alterations of atmospheric conditions that are all relevant for the annual planning of agricultural activities under Mediterranean conditions. Those changes can be beneficial to some farm activities but unfavourable for others, thus leading to winners and losers under the same area and climatic pressures. Even within the same farm type, CC can generate impacts of different sign and intensity among different agricultural activities. For example, the decrease of spring hay yields offsets the increase in yield of grass meadows and pastures of sheep farms. Similarly, the decrease in milk production due to heat stress elides the potentially positive effects on income generated by the increase in irrigated fodder yields of dairy farms. However, magnitude and sign of the productive and economic impacts depend on the resource endowment of farms in the specific context, and the way access to them is regulated. For example, in rainfed areas the increased probability of high temperatures and low rainfall in the spring, has a negative impact on the fodder production and, therefore, increases the costs for purchasing fodder. On the contrary, the current, non-limiting availability of water resources in the WUA sub-zone, allows irrigated farms to escape the negative effects of spring drought on fodder production, and to take full advantage of the potential yield increase of C3 crop species due to the expected increased concentration of atmospheric CO_2. This results into higher yields, consistently with the results of other studies in Europe (Schönhart et al., 2014), and lower cost for fodder supply. This advantage at least partially compensates for other negative economic impacts of CC in dairy farms, due to the reduction of production and quality of milk in the summer months and increased mortality of livestock. This confirms the close relationship between the capability of adaptation to CC and farms' resource endowment, as evidenced by Antle et al. (2004) for northern USA farming systems. Similarly, Reidsma et al. (2010) conclude that the heterogeneity of the income impacts of the CC on EU agriculture, at both regional and farm levels, and the adaptation capacity largely depends on the characteristics of the farms (size, intensity and kind of land use) in the same region. We found this evidence particularly true for the Mediterranean context.

Our results show that in some cases available technologies provide considerable opportunities for adaptation, as already found in other studies (Shrestha et al, 2013). For example, the availability of a wide range of silage maize hybrids with different degree of earliness can contribute to mitigate the impact of higher temperatures prolonging the duration of the crop production cycle, and thus maintaining substantially unchanged the current crop yield level. The criteria used to manage the resources influence this flexibility. The peculiar water payment system "hectare-culture" (i.e. the cost of water depends on the type of crop and not the actual use water) implies that only the variation in the irrigated area, and not also in the amount of water used, affects the cost of using the resource (and the payments to WUA) (Dono and Giraldo, 2012).

On some important aspects these results only give helpful hints, but no clear indications. In fact, the structure of the model we used, which is a local agricultural supply model, does not allow defining the productive implications due to CC on market prices, along the food chain, as well as the relationships with buyers of agricultural products and suppliers of agricultural raw materials. For instance, the 8.4% reduction in the production of milk in the summer months may generate problems in the cheese-making, which also suffers because of a reduction in the quality of milk[4]. This is important for the study area because the summer sales of fresh dairy products are financially very relevant to the cooperative cheesemaking company that uses the totality of the milk produced in the area, and is the leading producer of these foods in Sardinia. The problem will have wider repercussions if the decline in milk summer production will be generalized to the north of the Mediterranean area: this might affect the summer production of many cheeses with protected

[4] Another impact of the CC reported in Dono et al. (2016)

designation of origin in those territories. Conversely, a generalized increase in the supply of cereals from other, more important, areas of production may reduce market prices, reducing the positive effects indicated by our model for the farms involved in those productions. Similarly, the reduction in the production of some fodder and the increase of their demand may increase prices, as well as the demand for land rented for their production, with further negative effects on the budget of livestock farms.

5. Conclusions

The interdisciplinary modelling approach adopted for this study allowed an integrated assessment of the expected impacts of CC over a wide range of farming systems under Mediterranean conditions. This approach assessed the sensitivity to CC by identifying the crucial phases of the cropping systems, and by framing the agricultural management issues from the farmers' perspective. Under rainfed conditions, the expected increase in summer temperatures might only slightly affect farming systems that are already designed considering a summer drought condition. This is the case of the sheep farming in rainfed conditions, which is often already managed for minimizing the requirements of feed of the flocks in the summer. Instead, other changes, sometimes neglected, might be particularly relevant. This is the case of the increased temperatures and reduced rainfall in spring, which reduce the hay-crop yields, hence increasing the vulnerability of rainfed livestock farming systems.

The need to focus on specific aspects of CC that are most worth to consider as they may reveal gaps in the adaptive capacity of the different farming systems, is an important conclusion of this study.

In contrast, a limitation of this study is the absence of connection with the CC effects on market balance, and on the productive relationships between agriculture and other segments of the supply chain of agricultural production. The local supply model used for this analysis assumes, in fact, that the prices of inputs and outputs remain unchanged, and this hypothesis can be restrictive if we assume that the model can represent the CC agricultural effects in a wider area. Of course, for some industries, even a large area such as the Mediterranean has little influence on the market balances; for others, changes in local agricultural productivity and supply may however influence prices. At this time within the MACSUR project, we are just trying to consider the set of these market effects, integrating the results of local models like this with the results of the CAPRI model (www.capri-model.org), which can simulate the change of market balances and the more general climate impacts.

Overall, however, the outcomes of this study suggest that the challenges posed by CC in the near future require more than just a more efficient management of resources at local scales. Effective adaptation pathways may emerge from a strategic long-term contextualized visionary perspective of the future of agriculture, emerging from the integration of scientific and lay knowledge (Nguyen et al, 2014). This is particularly important in the vulnerable areas of the world such as the Mediterranean basin.

ABSTRACT

The accelerating pace of Climate Change (CC) is having significant consequences on Italian agriculture in terms of impacts and adaptation options. Weather heavily affects crop production trends, yields and quality variability with impacts that can vary by region. Measuring and enhancing the relationship between Agriculture and CC is complex. To develop the analysis of CC effects on agriculture in a comprehensive way, an urgent need of CC related statistics (CCRS) has been recommended by international institutions (UNECE, IPCC, Eurostat, OECD) in recent years. National Statistical Offices are called for actions aimed to improve the usefulness of existing statistics and to develop new statistics, filling information gaps. To appropriately address official statistics to the measurement of CC impacts on agriculture new methodologies need to be adopted, enhancing multidisciplinary approach and expertise, linking datasets across domains, reviewing existing classification systems, geo-referencing data, developing partnerships among different producers. This work mainly aims i) to present current official statistics production in Italy, highlighting data gaps in CC analysis; ii) to describe operating actions needed to better measure CC impacts on agriculture; iii) to integrate results provided by the Istat surveys on agricultural and meteo-climatic phenomena. Statistical innovations are addressed to enhance the availability of new relevant data, necessary for the analysis of CC impacts on agriculture at the national and local scale. In this study the relationship among meteorological factors, crop yields, water resources used in agriculture compared to water used in other sectors have been presented. Our work highlights the need to strengthen collection and use of several data sources by integrating data from surveys with administrative data. To this aim, the cooperation and the awareness of all agencies and institutions operating in the National Statistical System are essential to exploit the existing information assets and to develop new statistics coherent and consistent with the statistical international framework.

Keywords: Climate Change, Impacts and Adaptations, Official Statistics, Agriculture and Water statistics.

1. Introduction

After Paris agreement and other international initiatives, the demand for high quality statistics related to CC keeps growing. CC is a global multidimensional phenomenon that affects almost every aspect of human life and interactions between human and natural systems. National Statistical System (NSS) and National Statistical Offices (NSO) are called to enhance their contribution in the production of official statistics related to climate change to best satisfy user needs.

In 2014, the Conference of European Statisticians (CES) published a set of Recommendations on Climate Change-Related Statistics[1] (CCRS) to help ensure that information needs are effectively met. The work is an important step towards taking data needs related to CC more fully into account in NSSs, improving the contribution and involvement of official statistics in measuring CCRS. The CES recommendations define CCRS as "environmental, social, economic data that measure the human causes of CC, the impacts of CC on human and natural systems, the efforts of humans to avoid the consequences as well as their efforts to adapt to the consequences". They are organized into five conceptual areas: drivers, emissions, impacts, mitigation and adaptation.

The primary drivers of CC are anthropogenic emissions of greenhouse gases (GHG) from production and use of fossil fuels, agricultural and forestry practices and manufacturing processes. The efforts to mitigate CC are aimed at changing production and consumption patterns. To the extent that mitigation fails, the ensuing impacts and human efforts to adapt to CC will be heavily felt by the economy and society. It's clear that CCRS involve a wide range of interlinked statistical domains.

In this contest, agriculture plays a dual critical role, on one side as a cause of CC as producer of GHG emissions, on the other agriculture is threatened by CC impacts, by the increasing demand rising from population; by the increasing pressure of natural resources; by extreme events and disasters impacts. Improving sustainable agricultural productivity has become a global challenge.

The UN's new Sustainable Development Goals (SDG)[2] include a series of targets related to CC and agriculture. Goal 2 of SDG addresses to "End hunger, achieve food security and improved nutrition and promote sustainable agriculture". In particular the target 2.4 declaims: "By 2030, ensure sustainable food production systems and implement resilient agricultural practices that increase productivity and production, that help maintain ecosystems, that strengthen capacity for adaptation to climate change, extreme weather, drought, flooding and other disasters and that progressively improve land and soil quality". Goal 13 addresses to "Take urgent action to combat climate change and its impacts". In particular the target 13.1: "Strengthen resilience and adaptive capacity to climate-related hazards and natural disasters in all countries". Climate-related hazards and natural disasters can threat agriculture. They can be caused by CC, as extreme weather events such as floods, landslide, extreme temperatures, cyclones and other natural consequences that provoke environmental degradation (desertification, salinization, acidification, insect infestation) or they can be caused by other natural or man-made hazards, that provoke direct or indirect damages (pollution, contaminations, etc).

In 2015, an UNECE Task Force (TF) on Measuring Extreme Events and Disasters[3] has been defined to clarify the role of official statistics in providing data related to extreme events and disasters and to identify practical steps how NSOs, in coordination with national agencies responsible for disaster management, can support disaster management and risk reduction. The work takes into account the relevant issues raised in the context of SDGs and Sendai Framework[4]

[4] https://sustainabledevelopment.un.org/frameworks/sendaiframework

for Disaster Risk Reduction 2015-2030. A first objective of the TF is the international harmonization of terminology in connection with the Open-ended Intergovernmental Expert Working Group on Indicators and Terminology Relating to Disaster Risk Reduction[5].

The demand for high quality statistics to measure and describe all this interlinked dimensions is evidently expanded. Global and local analysis are needed, as well as statistics at national and sub regional level. There's a huge amount of data already available from several producers (inside and outside NSS) that suffer lack of standardization and quality standard. The role of official statistics in this contest is to guarantee the production of statistics meeting user's needs and to ensure high quality levels standards, in order to obtain relevant, consistent and comparable statistics and indicators. Referenced frameworks among the several national and international initiatives have the advantage of structuring the over whelming amount of information produced providing standardization of definitions, methods, classifications and ensuring homogeneity and comparability. UNSD-FDES[6], 2013 and its methodological 2014-2016 developments, is based on a multi-purpose conceptual and statistical approach, defining standardized concepts, definitions and methodologies. The System of Environmental Economic Accounting 2012 – Central Framework (SEEA-CF[7]) provides the first international statistical standard for environmental-economic accounting.

The work of the UNECE task force highlights how NSOs already produce data potentially relevant to CC, but that have been collected and produced with other purposes. This data should become usable for CC analysis. To do so, NSOs are recommended to facilitate access to data that already exists; improve geo-spatial analysis; improve linking between socio-economic and environmental data. Furthermore NSOs should develop new statistics based on a review of key data needs.

The aim of this work is to describe the current production of data potentially useful for measuring CC impacts ad adaptation options in agriculture, through a review of the main data sources available in Italian national institute of statistics (Istat). Then, the work will present a critical analysis of the data gaps in which the NSOs should improve the efforts, in order to fill the statistical information required.

2. Climate Change and Agriculture

CC variability has effects on socio-economic and natural environment. Agriculture and water resources are expected to be the most sensitive. Global warming and changes in rainfall and temperature patterns affect water resources availability and crop water requirements. As CC will alter water cycle, the pressure on water resources will increase. Being water resources one of the major inputs for a sustainable agricultural development, CC may have adverse impacts on crop production systems. Increasing pressures impose a sustainable use of irrigation water supported by specific policy actions. In particular, measuring the relationship between water resources used for irrigation and meteo-climatic and hydrological variables is crucial.

In this context, official statistics may provide a solid basis to know quantitative aspects referring to multi-dimensional phenomena related to the analysis of CC impacts on agriculture such as: weather conditions variability, out of season events, water resources availability, trend of different crops yields, quality of agricultural products, water resources required by crops, pressure exerted on irrigation water by crop and by area, abandonment of less-favored farming areas.

[5] http://www.preventionweb.net/drr-framework/open-ended-working-group/
[6] http://unstats.un.org/unsd/environment/fdes.htm
[7] http://unstats.un.org/unsd/envaccounting/seea.asp

To develop empirical CC impacts analysis, data adequately spatialized, provided at a high degree of disaggregation and on yearly basis, are needed. In a context characterized by uncertainty inherent in climate variability, the role of policy is crucial in managing the water resources efficiently across space and time to prevent agricultural yield fluctuations causing welfare loss. For this purpose, policy makers need standardized tools to define optimal policies and measures for a sustainable agricultural development and water resources management and to monitor objective achievement.

In Italy, country located in the heart of Mediterranean basin, CC is in place in the last decades (as confirmed by meteo-climatic and hydrological official statistics) and affects either water resources demand and many crop products through decreasing yields and quality and livestock management. On the basis of Istat statistics, the data collected by meteorological stations located in the region capital municipalities have recorded a "warming" during the last fifteen years, because in the period 2001-2014, the average annual temperature was equal to 15.1°C, with an increase of about 1°C with respect to the long-term average for the 30-year period 1971-2000[8]. In the same period the meteorological stations located in the Italian regional capital municipalities registered a change in rainfall pattern, because the average annual precipitation was equal to 740.8 mm, with a reduction of about 1.1% compared to 1971-2000 mean value.

Negative impacts of CC are more common than positive ones in our country where irrigated agriculture is the major water user accounting for more than 47 % of total use.

Italian agricultural production is characterized by a wide range of high quality products, typical Mediterranean crops and IGP-DOP products. Many agricultural products need suitable microclimatic conditions otherwise decreasing yields and quality mainly due to changes in rainfalls and in minimum temperatures patterns. Not only quantity and quality of such crops, but also the choice of species and varieties that will be possible to grow and the location of the production, can be seriously compromised by CC effects. The increasing likelihood and severity of extreme weather events will considerably increase the risk of crop failure in Italy. Italian crop production system faces and will cope deep changes of weather conditions and water resources availability, intensifying problems of water scarcity and irrigation requirements especially in the South of Italy and increasing drought risk and heat stress. Moreover, CC effects could lead to inefficiency in the agricultural production also linked to the sector structure including many small firms, with a low capability to adapt themselves to a new situation.

As CC affects many dimensions, official statistics on different thematic issues need to be integrated and harmonized to provide a solid and consistent basis for empirical analysis on CC impacts. A poor integration between regulations relating to specific subject areas of environmental and agricultural statistics have been carried out in recent years. The role of official statistics is to produce and disseminate statistical information needed for any type of study for modelling, making scenarios and elaborating adaptation policies, related to all relevant dimensions, such as: crop yields, water availability and use, irrigated areas, areas under organic farming, use of fertilizer, seeds and pesticides, temperatures and precipitation patterns, extreme weather events (heat waves, drought, floods , storms, fire forest, etc.).

As a substantial delay with respect to the information needs emerges, strengthening production of CCRS, hydrological and meteo-climatic statistics, agricultural and water statistics is essential to ameliorate the analysis of CC impacts on water resources and agriculture in order to provide official data, useful also to policy decisions. By evaluating the adaptive capacity of the Italian agricultural system to deal with external influences, implementing optimal CC mitigation-adaptation strategies by policy makers is needed.

[8] http://www.istat.it/it/archivio/giornata+mondiale+acqua

Considering official statistics currently issued on these dimensions, short or medium run CC effects empirical analysis are bounded by the availability of some variables at an adequate level of disaggregation and of long time series for all the variables considered, as it would be appropriate for modelling. Official statistics show several data gaps and some points of weakness summarized in the following points:

- *volumes of irrigation water* would be crucial in the analysis (as input in the production function) to evaluate CC effects on crop production. The scarce availability of official statistics on irrigation water has forced to use over the years the variable *irrigated areas* as proxy. For the first time, statistics on irrigation water in Italy were issued by VI Agricultural Census 2010. Strengthening the production of official statistics on irrigation water means improving the analysis on the demand of water resources and water use efficiency in presence of CC;
- *meteo-climatic variables* are a measure of CC, the need emerges updating on regularly basis time series of *all meteo-climatic and hydrological statistics* both for recent years and at a high degree of spatialization, thus being suitable to study the connections between climate and agriculture at local scale too;
- *agricultural statistics* need to be strengthened also homogenizing the scale (temporal and spatial) and the disaggregation level at which data are provided to develop analyses on CC effects on agriculture at the national and local level. For example, it would be necessary to strengthen statistics on harvested production disaggregated by type of crops, inputs used disaggregated by crop meteo-climatic statistics spatialized and suitable updated for a medium-term CC effects analysis;
- *data on mitigation policies* undertaken by Italy, in accordance with EU Policy related with CC would be useful in the analysis.

To this aim, in recent years, some methodological innovations have been developed and introduced in the national structural sampling survey on agriculture (*Farm structure Survey*) and new domains have been detected in the 2013 and 2016 edition such as: volumes of irrigation water by crop, technique of irrigation, water resources used by source of abstraction of, organic farming production, use of plant protection, use of energy products for current production, production of energy from renewable sources.

Goals to achieve are represented by strengthening administrative archives, integration of different data sources, enhancing the production of statistics and new data crucial in this type of analysis, expanding temporal and spatial scale and disaggregation level at which data are provided, update all meteo-climatic statistics suitably spatialized.

3. Climate change, agriculture and water statistics in Istat

Warmer temperatures, changes in precipitation levels and patterns, extreme weather events are already impacting all human and economic activities. Agriculture, in particular, is extremely dependent on weather and climate events in order to produce the food necessary to sustain human life. CC is here and now. CC is expected to negatively condition both crop and livestock production in most part of the world, although some regions may actually take advantages from the changing conditions. The natural ecosystems are responding to change. So, for example, some fruits grow faster, others slower, changing so the normal length of their life cycle. The biological (phenological) responses to CC are very often unpredictable and their management becomes then increasingly difficult.

Overall, productivity levels may changes as CC consequences, for example increase of actual evapotranspiration and crop water requirements, decrease of water availability and quality. Substantial reductions in the impact that CC could generate on global agricultural production, and therefore food security, could be obtained thanks to a better understanding of the dynamics of the phenomenon.

Quantifiable indicators of the environmental sustainability of agriculture are a fundamental tool for monitoring current conditions, identifying trends, setting goals, evaluating progress and comparing performances among different regions and countries. This set of indicators is useful for policymakers, farmers, businesses, and civil society to better understand the state of the art.

The current statistical production, based on both official and non-official sources, even if already consistent, does not always allow at the moment the construction of timely, solid, comparable agri-environmental indicators that can respond to the needs of those who monitor CC in all its declinations and its essential relationships with the agriculture. There is doubtless a lack of integration of the various regulations, also at European level, relating to the different subject areas of the environment and agricultural statistics. The presence of missing data, the difficulty of integrating different data sources, the lack of long time series, make it extremely difficult to produce a connecting framework between the CC and Agriculture statistics.

Although many efforts have been initiated for a better performance of the official statistical production, the challenge is to continue to evolve the core suite of official statistics. Internally and externally, NSOs have to explore increased linkage of datasets, creating value from data, with the aim to give the society a plausible and consistent point of view, and more importantly, as the counterfactual for scenario analysis.

Agriculture and Water statistics will be deepened in the following paragraphs.

Considering the important role that agriculture has always played in the Italian economy, Istat regularly collects, checks, analyses and disseminates statistical data on agriculture. Istat production covers a wide range of subjects and several surveys are organized by the Institute in this matter, to comply with European regulations and to satisfy needs expressed at the national and local level.

Even if the information collected are periodically enriched, following the emerging information demand, the current production is not always prepared to adequately meet the requirements coming from the CC analysis needed.

In the next we will identify, analyse and profile the landscape of existing data sources, indicators, and datasets relevant to verify the environmental sustainability of agriculture.

The list of the main Istat activities, with features that could be used in an integrated approach directed at climate change and agriculture perspective in Italy, includes:

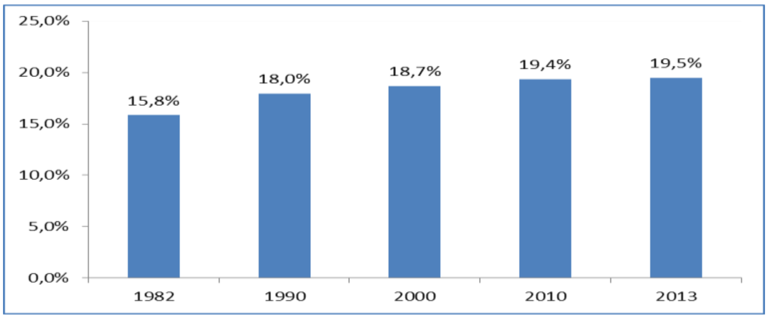
- **Agriculture Census[9],** periodically conducted in an European framework, provides in Italy since 1961, and every ten years, a statistical portrait of agricultural and livestock system at national, regional and local level. The data emerging from the Census have impact on the development of national and Community agricultural policies. The Census also absolve the disclosure obligations established by the Regulations on structural agricultural statistics, with the aim to homogenize the data collection and to disseminate comparable indicators. Census information useful for a CC lecture refer to crops, area cultivated, irrigable and irrigated area, organic farm, livestock, number of working days, volume of water of irrigation use (only for the 2010 edition).
- **Estimate of crops, flower and pot plant production and area,** that is a survey that allows currently to estimate cultivated area, harvested production, yields.
- **Farm structure survey[10]**, a sampling survey that every three years allows to identify the main transformations of the agricultural world and that disseminates data on irrigated

[9] http://www.istat.it/it/archivio/138962

[10] http://www.istat.it/it/archivio/167401

area, number of working day, irrigation by crop and system, production of energy from renewable sources, water supply sources, use of energy products for current production, organic farming, techniques of application of livestock effluents.

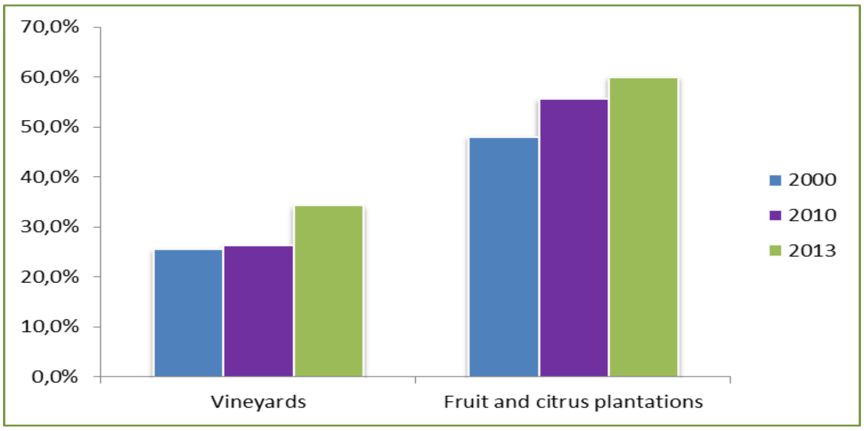
- **Survey on the fertilizers supply for agricultural use (chemical fertilizers, soil conditioners and improvers)**, that allows to observe the fertilizers supply distribution and the nutrients in fertilizers.



Source: Istat - Agriculture Census

Figure 1: *Share of irrigated area on the total utilized agricultural area (percentage values)*

Figure 1 shows about the share of total utilized agricultural area that has been irrigated in the period 1982-2013, more than thirty years. This indicator assumes always more importance due to the strong variation of water availability, that in some period of the year determines a condition of water scarcity.



Source: Istat - Agriculture Census (2000, 2010), Farm structure survey (2013)

Figure 2: *Share of irrigated area for some typical crops (percentage values)*

Figure 2 shows the share of irrigated area for some crops particularly representative of the Italian agriculture and typical of the Mediterranean area: vineyards, fruit and citrus plantations. In the period 2000-2013 the presence of the irrigation practice has increased for both crops especially during the warmest season.

Water is the main element through which CC influences the ecosystem and subsequently the livelihood and well-being of societies. Higher temperatures and changes in extreme weather conditions affect the availability and distribution of rainfall, snowmelt, river flows, groundwater and further damage water quality.

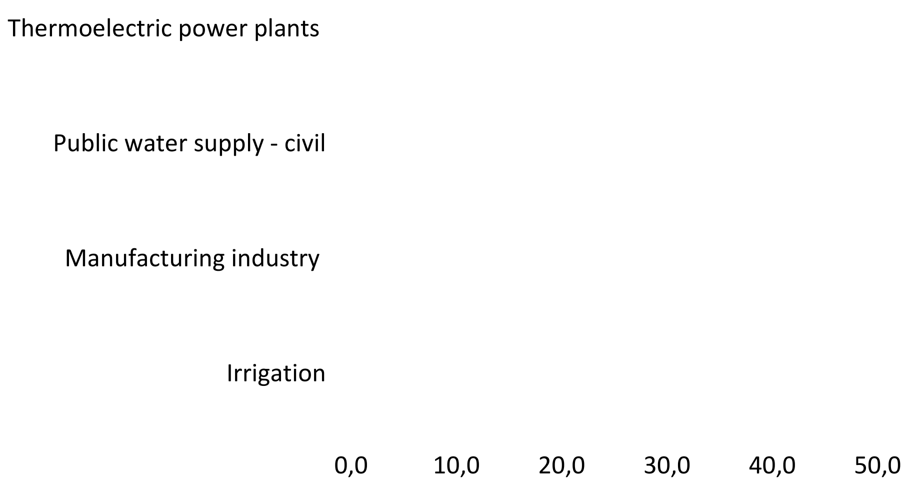
Water statistics represent, then, a fundamental card in the construction of our mosaic, playing a pivotal role in the adaptation process to CC.

In Italy there is a lack of uniform estimates on the amount of water abstracted, supplied, discharged and treated for different uses. Available data suffer from a large fragmentation of information, data heterogeneity and lack of standardization. To improve national knowledge on Water Statistics, several activities have been carried out following the guidelines of the EU relating to the Water Framework Directive (WFD, 2000/60/EC) and Eurostat initiatives on Water Statistics and Water Accounts.

The main activities carried out by Istat are:

- **Meteo-climatic and hydrological survey**: implementation of a geographical data-warehouse with meteorological, agro-meteorological and hydrological daily values measured since 1951. The thermo-pluviometric monitoring network has about 6,200 stations and the hydrometric one about 950 stations.
- **Urban water census:** since 1951 Istat has been periodically collected information on water resources for domestic use through a specific census. Data collected are referred to water abstraction and transmission, public water supply network, public sewerage and urban wastewater treatment plants.
- **Use of water resources**: estimation of water used in manufacturing industry, production and distribution of electricity, agriculture.

The integration of data coming from these sources allows to compare the use of water by sector: irrigation water, public water supply, manufacturing industry, thermoelectric power plants cooling (for process and cooling of inland water, without sea water). At the national level, in the crop year 2009-2010 the total volume of irrigation water amounted to about 11.6 billion of cubic meters. In 2012, water supplied by the public water supply system amounted to 5.2 billion of cubic meters; the total volume of water used as input by Italian manufacturing industry amounted to 5.5 billion of cubic meters; the volume of inland water used for cooling and process of thermoelectric power plants amounted to 2.2 billion of cubic meters (Figure 3). Summing the four values, the estimation of water used for the sectors included in the equation is equal to 24.5 billions of cubic meters. But this value does not represent the entire volume of water used, as for example the estimation of water used for livestock.



Sources: Istat - Meteo-climatic and hydrological survey, Urban water census, Use of water resources

Figure 3: *Water used by sector. Year 2012, crop year 2009-2010* (billion of cubic meters)

Water use represents the demand of water from the "environment to economy", where renewable freshwater resources statistics are fundamental to evaluate the stocks of water availability[11]. The Istat Meteo-climatic and hydrological survey has disseminated information at national, regional and river basin level, from 1971 to 2010; this has allowed the estimation of the indicators needed for the assessment of water balance.

Source: Istat, Meteo-climatic and Hydrological *survey*

Data availability on an annual basis provides a first assessment; but to fully understand the vulnerability of the resource, the temporal and spatial variability is essential. Precipitation and temperatures (minimum, average, maximum) on a monthly basis, allow an evaluation of the yearly oscillations (Table 2). Furthermore, specific climate extremes indexes[12] such us the number of frost,

[11] 2014 Eurostat Regional Environmental Questionnaire (REQ 2014)
[12] http://etccdi.pacificclimate.org/

summer or icing days, the number of tropical nights or the precipitation intensity index, could highlight changes in climate that can affect agriculture. Climate extremes indexes have been processed currently only for the thermo-pluviometric stations of region capital municipalities, while the analysis should be extended to the rural areas for the purposes of agriculture.

4. Conclusions

This work highlights how there is still a strong need of multidisciplinary statistical information for the study and analysis of interactions of all dimensions of CC impacts, to conceive adaptation strategies and to evaluate their effectiveness. Several international initiatives promote to enhance the production of high quality consistent, robust, relevant and international comparable statistics. The role of official statistics in the contest of NSS is recognized as crucial.

Existing statistics should become more usable for the analysis, investing in building and implementing harmonized methods and definitions, adequately transforming the overwhelming amount of statistical data available from several sources into comparable statistics; new statistics should be developed ensuring a coherent system at national and international level, suitable to meet the statistical information demand. NSOs have an important role in this contest; improving knowledge and awareness on emerging themes, providing internationally agreed guidelines and frameworks.

NSOs should strengthen their efforts to meet information needs. Proceeding step by step NSOs should make a review of their relevant data available adopting an integrated approach, considering all their sources of data both from surveys and registers. This relevant data should be organized in an combined mode. Istat already produces relevant data for the analysis of CC impacts and adaptation option in agriculture. Data are produced by the agricultural Census and by several surveys belonging to different statistical domains. It needs, immediately, an enlarged view of information, which no longer considers the various aspects individually, but that integrates information collected for different purposes. A global and integrated perspective is essential to approach multidimensional phenomena such as CC impacts and adaptation in agriculture. The most relevant areas refer to agricultural, hydrological, meteo-climatic statistics, but additional statistical domains could be relevant to explain all dimensions of the phenomenon. Besides the global and national scale, regional scale and georeferenced data are essential for the comprehension of the dynamics of the phenomena. Upstream planning of data collection, a review of the surveys, an exploration of the content of administrative archives, a joint activity between the various institutions that in various ways will have an active part in the construction and implementation of a CC Strategy, are certainly necessary activities so that - in the long run - the statistical offer could be considered robust, with an high social value.

BIG DATA FOR AGRICULTURAL STATISTICS

Session Organizer
P. Hackl | Vienna University of Economics and Business | Vienna | Austria

ABSTRACT

Growing information needs and the tendency to reduce the response burden to businesses and households stimulate the search for alternative data sources which may supplement traditional sources like surveys, censuses, and administrative sources. During the last ten years, big data became the subject of quite a number of projects which experiment with substituting traditional data. This statement is probably understood although no clear and commonly accepted definition of the notion big data has been established so far. In the context of the session "Big data for agricultural statistics", reports on the use of data from the following data sources are welcome and of interest:

- e-commerce, e.g., portals of retailers, service providers, price comparison services
- commercial transactions, e.g., credit card transactions, scanners in supermarkets
- sensors, e.g., satellite imaging, environmental sensors, road sensors
- tracking devices, e.g., tracking data from mobile telephones, GPS
- administrative sources, e.g., insurance records, bank records, medical records
- tracks of human behaviour, e.g., online searches, online page viewing

The presentations may report on projects where the derivation of agricultural statistics is based on or supported by data from one of the mentioned data sources. Of interest are also presentations which report on innovative methods that allow for results which cannot be derived from traditional data.

The presentations should inform as much as possible on the following points:

- he used statistical method,
- the quality of the alternative data,
- the representativeness and
- other quality-aspects of the resulting statistics.

Having the general theme of the ICAS-7 in mind, statistics which allow the monitoring of sustainable development goals are especially welcome.

ABSTRACT

In the recent years, it is observed that the scientist, planners, executives across the globe are using data collected from traditional record keeping by government agencies, data collected using sensors and satellite imagery technologies and combining it with predictive weather modelling. It is being done to help farmers to make better decisions with respect to optimal time of sowing/planting of the crops, optima time for application of pesticides, insecticides, and fertilizers starting with sowing, and time for harvesting crops in general and especially in a given region of the country at a given point in time. The technologies such as data warehouse/ big data are also being implemented to improve the quality of data since data provided by different arms of the government such as organizations of central government and state government varies a lot on many parameters and create problem in making right decisions. This is being done as part of digitization India program of central government. Keeping in view, the importance of quality and accuracy of data for planners, researchers, political leadership and farmers in particular, this paper presents various aspects of the data warehouse/ big data technology application in agriculture in the context of India. These aspects are (i) Identification of major domain of implementation of data warehouse/ big data technology in agriculture in India, (ii) identification of present status of application of data warehouse /big data technology and harvesting the benefits of the technology in India, (iii) identification and quantification of the benefits of the data warehouse/ big data technology application in increasing agriculture production or reducing losses to farmers (iv) identification of most popular data warehouse / big data technologies to be implemented in India (v) identification of targeted components of crop life cycle for data warehouse/ big data technology in agriculture in India, and (vi) impact of usage of technology and role of technologies such as data warehouse /big data in eradicating hunger or poverty from earth by way of helping farmers in increasing production and in maintaining ecosystem of the crops. The analysis being carried out by keeping in view irrigated and rain fed areas under cultivation in India and also changing climatic conditions which are impacting agriculture production in India.

Introduction

India's total area is 3.287 million km². The area under agriculture was 60.6% during 2013-14. Agriculture sector (Agriculture proper & Live stock, Forestry & logging, Fishing and related activities) accounted for 17.8%[1] of the GDP (gross domestic product) in 2013-14. It was more that 51% during 1950-51. The total production of agriculture sector was US$ 366.92 billion. Indian share in world agriculture output is 7.68%. About 50% of the workforce is employed in agriculture in India. Though the contribution of agriculture to GDP is steadily declining but still agriculture is demographically the broadest economic sector and plays a significant role in the overall socio-economic fabric of India. As per FAO 2010 reports, India was the world's largest producer of many fresh fruits and vegetables, milk, major spices, select fibrous crops such as jute, staples such as millets and castor oil seed. India is the second largest producer of wheat and rice.

Food security of India depends mainly on production of cereals crops. However, it needs to increase production of fruits, vegetables, pulses, and milk to meet the demands of growing population with rising income. India's priority areas in the context of agriculture are (i) higher productivity with optimal usage of water and other resources, (ii) poverty alleviation and management of natural resources, (iii) sustaining the cultivated land for future productivity and environment, (iv) reducing the waste of food grains and other agriculture produce, and (v) keeping the balance of prices of agriculture produces between producer and consumers, and many more.

The key to success depend on availability of quality data. The quality data can be captured / created, stored in times series manner, and analysed with technologies such as data warehouse, big data, data analytics, and reporting tools. To mention here as an example, Big data in agriculture refers to the Electronic Farm Records (EFR) which includes soil temperatures maps and data, precipitation maps and data, electrical conductivity maps and data, moisture content data, air permeability maps and data, nutrient contents and pH level data, past cultivation records, past losses, insurance and yield related information. It also includes social media data including tweets, blogs, new feeds, agriculture research reports and research articles in agriculture and other related journal. The technology will also help in mining the big data and discover the associations, understand patterns and past & future trends to improve the agricultural systems, accurate estimation of large number of input and output parameters, increase crop productivity in relation to changing input parameters, and reduction in input costs by accurate diagnoses and analysis of large numbers of factors effecting it.

Keeping in view the importance of quality data as suggested by Addison (2015), the present research paper is an attempt to (i) identify major domain of implementation of data warehouse/ big data technology in agriculture in India, (ii) identify present status of application of data warehouse /big data technology and harvesting the benefits of the technology in India, (iii) identification and quantification of the benefits of the data warehouse/ big data technology application in increasing agriculture production or reducing losses to farmers (iv) identification of most popular data warehouse / big data technologies to be implemented in India (v) identification of targeted components of crop life cycle for data warehouse/ big data technology in agriculture in India, and (vi) impact of usage of technology such as data warehouse /big data in eradicating hunger or poverty from earth by way of helping farmers in increasing production and in maintaining ecosystem of the crops.

[1] http://data.worldbank.org/indicator/NV.AGR.TOTL.ZS

The analysis being carried out by keeping in view irrigated and rain fed areas under cultivation in India and also changing climatic conditions which are impacting agriculture production in India.

Research Methodology

The present study can be termed as exploratory cum descriptive in nature. Research article is based on secondary as well as primary data. Secondary data is about application of data warehouse and big data technologies in agriculture and primary data collected from 20 villages of Aligarh District of State of Uttar Pradesh through group discussion method from farmers. This data was mainly about usage of machinery by the farmers, challenges of supply chain of agriculture produce, government initiatives, and their awareness about data collection by different agencies with respect to soil fertility, applications of fertilizers & pesticides and other inputs, existing practices adopted by farmers etc. The data is analyzed mainly in the form of frequency distribution.

Result & Discussion

Identification major segment of data warehouse/big data technologies in agriculture in India (1).

Big data / data warehouses technologies along with mobile technologies can be used in sourcing large set of data of agriculture sector activities, processing of this data, and generating valuable information for farmers, consumers, and government agencies from large set data. To be specific, Big data farming (or precision farming) is going to help farmers by offering to farmers (i) highly accurate weather forecasts and real time field data to optimize the resources & to reduce losses to farmers specifically in rainfed regions, (ii) real-time optimization of farming machinery, irrigation schedules, and other inputs, (iii) cloud-hosted cost effective information resources for farmers, (iv) automated irrigation and other farm practices recommendations, (v) monitoring the attack of insects, pest & diseases on crop with changing climatic conditions, (vi) monitoring of prices of agriculture produce before sowing and after harvesting, (vii) management of inventories of public distribution and its large & complex supply chains, (viii) monitoring of temperature, humidity, oxygen levels, and other needed parameters of food storage containers and shipment containers to maintain quality of agriculture produce before it is consumed, (ix) collection and analysis of post harvest field data for suggesting the activities with respect to maintaining the fertility of soil and making agriculture environmental friendly.

Identification of present status of application of data warehouse /big data technology and harvesting the benefits of the technology in India (2).

Four set of technologies are implemented in an organization to harvest the real benefit of information technologies. These are (i) technologies to source data/capture data/automate business processes, (ii) technologies to transport data from one place to another, i.e., from source to destination (Sylvester (2013)) (iii) technologies to integrate and store data, and (iv) technologies to analyse and report the data / information to consumer of information. Due to large size of the country as well number of organizations, implementation of all four set of technologies is not yet completed in India. In addition, implementation of technologies is easy in government owned organization but difficult in a segment which is not so organized. For example, meteorological department is collecting, analysing, and reporting information to users about meteorological parameters in general but not in relation to the cultivation of a particular crop in a particular region and its impact. Secondly, basic data of 105, 64,74, 292 citizens (80+% of population) is captured as part of Unique Identification Authority of India (UIDAI) project using data warehouse technology *(*https://portal.**uidai**.gov.in/). Thirdly, major procurement and distribution agencies such as Food Corporation of India and others are computerised for monitoring the inventory of food stocks on day to day basis (http://fci.gov.in/). There is a need to integrate various data bases in order to derive values to farmers out of this data.

Identification and quantification of the benefits of the data warehouse/ big data technology application in increasing agriculture production or reducing losses to farmers (3)

Many studies are conducted for identification and quantification of benefits of data warehouse / big data technologies. Madgavkar and Krishnamurthy (2014) estimated that technology based applications in agriculture in India will have US$ 45-80 billion impact annually as given in table 1. These estimates are not comprehensive.

Table 1: Impact of Technology based application on Indian agriculture (US$ Billion)

Sized Applications	Economic impact	Potential reach	Potential productivity or value gains
Hybrid and GM crops	1-4	10% of total of 92 million tones of farm produce under GM crops	5-10% productivity improvement
Precision Farming	8-30	20% of total arable land under precision agriculture	15-60% yield improvement 2ill help 22 million farmers.
Real-time market information	10-15	90 million farmers (60% of total) using real-time market information	3% productivity increase, 2.5% increase in price realization, input cost reduced by 3%.
Reduced leakage and Waste	27-32	$19 billion leakage in (PDS), $28 billion of non-PDS food waste	Up to 90% reduction in PDS leakage. 50% lower wastage in distribution of other produce.

Yield is a function of genetical characteristics of crops, environmental conditions & farm practices. The input variables are not independent. One need to develop predictive/ prescriptive models to optimize yield for a specific environment by optimizing farm practices for genetically different crops. This is possible only by conducted experiments, collecting and analysing data of these experiments. This will need in turn data warehouse/ big data technologies to store and analyse large set of data. It will result into many useful finding to boost agriculture at low cost. To mention, farmers in India usually burn residues of the rice crop after harvest in winter and of wheat in March-April. However, it is observed in adopted villages under Consultative Group for International Agricultural Research (CGIAR) project on Climate Change, Agriculture and Food Security (CCAFS) that zero tillage along with residue management and diversification of crops reduce the fertilizer requirement by a fifth after three years. Experimental data revealed that a tonne of rice and wheat residues, about 40% of which is carbon, contain 5-8 kg of nitrogen, 1-2 kg of phosphorus and 11-13 kg of potassium.
Further empirical studies confirmed an increase in yield by 10-15% with zero tillage and line sowing of wheat. Zero tillage reduces diesel cost by 80-85% (Seetharaman (2016)). This is not propagated in other part of the country due to non-availability of data in electronic form.

Identification of most popular data warehouse / big data technologies to be implemented in India (4)

Big data started with precision farming. Further, it can store data on fertilizer consumption (from production in factories and imports if any), planting (data are collated from different sources), crop protection (data are collated from different sources), harvesting and yield of crops (large number of crop cutting experiments & imaginary data). In addition data of 3rd parties on weather, data from satellite / aerial imagery (large amount of granular data is collected), data of soil fertility (not much data is collected), topographic data (large amount data is available with many companies), research & development data (data from academics & industry), land records and fertility data (data are collated from different sources), and data of machinery and equipments of manufacturers, data of commodity markets (local, regional and global), weather data can be integrated with big data technologies. Scope of these technologies is unlimited but major initiatives are needed (i) in storing data of all farm produces, (ii) data of live stock & fisheries etc, (iii) data of complete supply chain of farm produce, (iii) marketing and procurement, distribution policies and systems. It will help in reducing losses. Once it is achieved in a comprehensive way more initiatives should be taken to input side of supply chain.

To achieve these objectives government scientific organizations have taken initiatives in identifying utility and segments of agriculture sector for implementing these technologies. To mention, (i) Council of Scientific & Industrial Research (CSIR) has approached scientific community to work on research projects to prepare roadmap for big data technologies in India (http://www.dst.gov.in/big-data-initiative-1), (ii) National Agricultural Bioinformatics Grid (NABG) project at Indian Agricultural Statistics Research Institute (IASRI) launched in 2010, (iii) Advanced Supercomputing Hub for OMICS Knowledge in Agriculture – ASHOKA established during 2014. Peisker and Dalai (2015) suggested a frame work for agriculture sector once connectivity with households, villages, elected village level institutions, government departments is established. They reported that present sources of data are (i) kisan SMS portalsystem, (ii) Community information Center, (iii) AGMARKNET (http://agmarknet.dac.gov.in), (iv) e-choupal, (v) agriwatch.com. These sources may be further integrated and augmented. Channe et al (2015) proposed an approach based on five key technologies: Internet of Things, Sensors, Cloud Computing, Mobile Computing and Big-Data Analysis.

Precision Farming Development Centres (PFDCs) been established in India to promote "Precision Farming & Plasticulture Applications for high-tech horticulture" and located in State Agricultural Universities (SAUs); ICAR Institutes such as IARI, New Delhi; CIAE, Bhopal & CISH, Lucknow and IIT, Kharagpur. These centers have been operating as hub-centers of plasticulture and precision farming in respective states. National Committee on Plasticulture Applications in Horticulture (NCPAH) during the year 2008-09 established five new Precision Farming Development Centres located at Bhopal, Imphal, Leh, Ludhiana & Ranchi under the centrally sponsored scheme Micro Irrigation (http://www.ncpahindia.com/pfdc-mandate).

Identification of targeted components of crop life cycle for data warehouse/ big data technology in agriculture in India (5)

Data warehouse/ big data technology is needed during the complete life cycle of the crop but capturing data on all factors impacting yield is not possible with existing resources available with developed economies and specifically in India. With the existing data on rainfall, seed, farm practices, fertilizer, pesticides, insecticides production & imports, these technologies can target data on inputs and its analysis to extend full advantage of moisture content of soil as well as life in days of the crop. Second, life cycle to be targeted for data collection and analysis is post harvest period. Initial cycle will help in reducing cost of cultivation and post harvest will reduce losses of supply chain.

Impact of usage of technology such as data warehouse /big data in eradicating hunger or poverty (6)

This section presents problems of supply chain of agricultural produce and other related problems and the technologies used by farmers not necessarily data warehouse and big data technologies. These findings are based on primary data collected from Aligrah District (Northern part of India) mainly on three themes. The findings on these themes are listed in the following:

(i) Usage of farm machinery: Indian farmers have started using machinery at their fields. The popular ones are tractors, walking tractors, combine, laser levellers, and other farm farm equipment to open furrows in the ground, shredding, spraying and fertilizing the soil. In many cases machinery is replaced by services provided by farmers from State of Punjab. In the recent years due to increase in cost of diesel, almost all farmers have applied laser levellers and auto start switches for water pump sets. They are also using tractors, combine but not much is employed for data collection. Data collection is either manual or through imaginaries.

(ii) Supply chain of Agri-produce and challenges: Indian agriculture supply chain is spread in large geographical area. The agriculture produce are grown in specific geographical areas and sold by farmers either to government agencies, whole seller or retailers in other parts of the country. Road transport is major mechanism to transport agriculture produce for shorter distance and rail for longer distance. The agriculture markets are not yet developed in smaller towns, & district headquarters. Major movements are between large markets.

Based on analysis of data collected form 20 villages from Aligarh district (State of Uttar Pradesh) it was inferred that (i) every farmer brings its produce specifically grains, fruits & vegetables, milk etc to the centers listed in fig 1 (Khair, Atrauli, Khurja, Iglas, Manai, and Aligarh) with no advance information about demand-supply and price variations. Another group of consumers (farmers & non-farmers) come to these centers to buy the same produce from these towns at a high cost due to market taxes, and transportation costs etc at other time (ii) all storage facilities are located in these towns which in turn increases transportation costs and also loss of work at home, (iii) in many cases the farmers bring their produce to nearby state of Delhi which operates a larger markets and small traders buy the same produce from Delhi markets & do retailing in the small towns which are much nearer to producer farmers. It results in to higher transportation cost to traders & farmers, (iv) most cases return to the farmers are not linked to quality of the produce in many cases, as they cannot pack or certify their produce as organic and inorganic (v) farmers are guided by resources available, and advise of local traders or peers with respect to usage of fertilizers or pesticides rather than scientific methods, (vi) their knowledge about residual effect is very low, (vii) crop rotation is limited to wheat & paddy and in other segments potato & paddy, (viii) all farmers burn residues of wheat, sugarcane, paddy, maize with no interference from experts, (ix) farmers are not much aware of data collection activities by any agencies for the purpose of new research initiatives, and (ix) invest lots of resources in tillage which is not needed specifically in paddy.

Fig 1: Map of Aligarh District (Uttar Pradesh)

(iii) Making government initiatives more effective & beneficial to farmers.

Indian government protects the farmers by fixing minimum support price for major crops every year. Government agencies (Food Corporation of India, State corporations etc.) procure major food grains directly from farmers every year as part of its food security program to provide major food grain to the weaker sections of the societies though public distribution systems. Government has implemented information technology based systems for capturing data of the activities of these organizations but integration of data among these agencies is still needed. As mentioned, earlier all data of benefits of government schemes is linked to Aadhaar card (UIAI) and also to the bank account of farmers. It has reduced leakage of government monetary help to the farmers.

Concluding Remark:

It is beyond doubt that application of data warehouse / big data technologies will help all members of eco-systems. Quality data is vital for growth of agriculture in India. Government has taken many initiatives for capturing data and making use of it. The success is achieved in relation to collection and analysis of (i) weather data, (ii) forecasting area under different crops & yield using remote sensing application, data of crop cutting experiments, and data collected by state irrigation departments etc, (iii) data of procurement of food grains & vegetables, storage centers, public distribution systems etc, (iv) data generated academic/research institutions, (v) information about shelf life of the produce and many more segments of eco-system.

What is needed? Integration of all these data sets using data warehouse and big data technology for the purpose of analysis to make concept such as precision farming realty. Most of data used in research is generated from big agricultural universities and institutions farms where resources are available in developing new varieties etc but this is not the case with farmers. Experiment must incorporate some constraints to see the potential of new varieties or new practices. This will be possible in a country like India with private sector development in developing such technologies, public and private collaboration in implementation, and government support and investment as in case of some other sectors (World Economic Forum (2012)).

ABSTRACT

The US Department of Agriculture's National Agricultural Statistics Service (NASS) has the responsibility of quantifying the nation's agricultural production. Historically it has focused on large, production agriculture. With increased interest and activity in the urban areas, NASS has begun exploring how to better quantify urban agriculture. This segment of agriculture is particularly challenging to enumerate because the agricultural holdings tend to be small, widely dispersed, and more transient than the predominantly large farms in rural areas. In collaboration with the Multi-Agency Collaboration Environment (MACE), a new approach to list building was explored in a pilot study conducted in the City of Baltimore, Maryland. Using a big data approach, areas of potential agricultural activity were identified by gathering information (state and local permits, facebook and twitter feeds, interest groups, *etc.*) via the web. A sample was drawn from the list, and an in-person survey was conducted to assess whether or not the identified areas were producing agriculture. Here the lessons learned from the study and next steps are discussed.

Keywords: urban agriculture, list building, web scraping

1. Introduction

Urban agriculture has been of increasing interest at the local, state, and national levels. Some cities, such as Detroit, Michigan, have goals of increasing their food resiliency by growing a large portion of the fruits and vegetables used by their citizens within the city limits (Colasanti, *et al*. 2010). Cities have also promoted urban agriculture to ensure that the vacant lots, abandoned buildings, and other under-utilized land are used productively (Goldsmith 2014, Santo, *et al.* 2016). Urban agriculture takes a variety of forms including backyard gardens, school or community gardens, urban farms, greenhouses, hoop houses, converted warehouses, and vertical gardens. At the local level, policies favourable to urban agriculture have been developed, access to land has been facilitated, and sometimes funding can be obtained to initiate agricultural activity. Federal funding programs for urban agriculture, such as The New Farmers and People's Garden Initiatives, have been established. The US Department of Agriculture (USDA) has developed a website with a wealth of information, including more funding opportunities, for urban farmers (USDA 2016). Organizations focused on urban agriculture have also been developed. These efforts have naturally led policy makers at the local and national levels to ask whether or not the programs are effective in increasing urban agriculture.

Although USDA's National Agricultural Statistics Service (NASS) has always included urban farms in its counts of farms and farm production, the estimates have not been as precise as those for other sectors of the agricultural economy. Because urban agriculture is responsible for a small portion of the total farm production, NASS has not devoted the resources—and has not had the resources—needed to provide better estimates. Policy makers at all levels are increasingly interested in the efficacy of programs designed to increase urban agriculture. Thus, the Under Secretary for USDA's Research, Education and Economics asked NASS to explore ways to better quantify the extent and food production of urban agriculture.

Urban farms tend to be smaller, more diverse, more transient, and more widely dispersed than the more traditional farms in rural areas of the U.S. This makes these farms challenging to identify and thus to quantify. The NASS list frame is thought to have substantial under-coverage of urban farms. During the 2012 Census of Agriculture, capture-recapture methods were employed to adjust for under-coverage, non-response, and misclassification, using the NASS Census mailing list and a sample from the NASS area frame, as the two independent samples (Young, *et al.* 2012). For a survey of urban agriculture, a sample from the NASS list frame, which is a list of all known confirmed or potential farms in the US, could serve as one sample in a capture-recapture analysis. However, it is cost prohibitive to obtain sufficient numbers of urban farms in a sample drawn from the NASS area frame because these farms tend to be dispersed (not concentrated) within the urban areas. Thus, NASS began to explore alternative ways to build a list of urban farms that would be independent of the NASS list frame, provide good coverage, and be relatively inexpensive, as a foundation for a second sample.

Taylor and Lovell (2014) identified potential areas of urban agricultural activity in Chicago, Illinois, from high-resolution aerial images in Google Earth in conjunction with ArcGIS. First, lists from several non-governmental organizations were combined to identify 1236 potential community gardens in Chicago. The sites were visited in 2010, and 12.9% were found to be food gardens with the others being ornamental garden/parks, a streetscaping projects, or no garden. The confirmed food and non-food gardens were analysed to develop a visual classification approach to classifying urban agriculture. Then the Google Earth images of Chicago were analysed visually, and 4493 potential areas of agricultural activity that were not included in the 1236 areas on the lists were identified. In a follow-up survey of 194 of the sites, 166 (89.6%) were found to have agriculture on them.

Although the methods used by Taylor and Lovell (2014) were effective for identifying urban agricultural sites, the approach was labor intensive, and it would be cost prohibitive when scaled to the national level. Thus, NASS began to consider ways in which to automate the approach. The results of that effort are presented in this paper. In Section 2, the target population for a national urban agricultural study is defined. A pilot study of a new approach to identifying urban agriculture in the City of Baltimore, with considerations for national implementation, is described in Section 3. The final section reviews the lessons learned and future directions.

2. Urban Agriculture

Historically, urban agriculture has not been reported separately; it has been combined with all other types of agriculture. To report on it separately, urban agriculture had to be defined so that an operation can be unambiguously identified as either being or not being urban agriculture. After consulting with the USDA's Economic Research Service, agriculture within the urbanized areas, as defined by the US Census Bureau, was defined to be within the target population (see Figure 1).

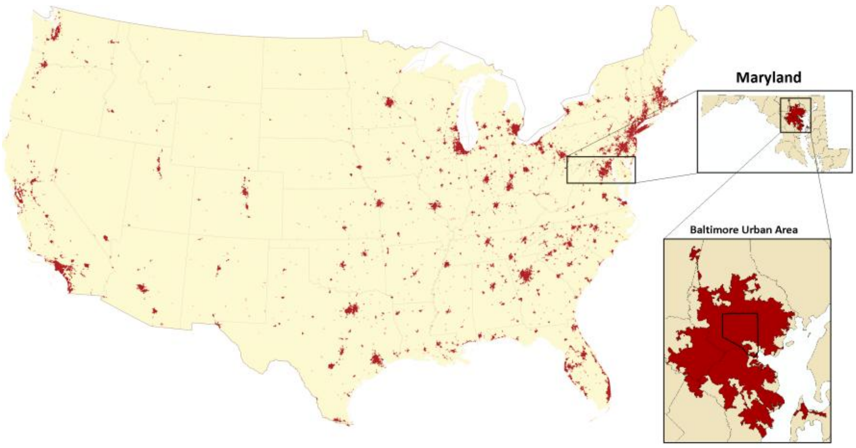

Figure 1: *Urbanized areas within the US (left), area of pilot study within US (upper right), and Baltimore City boundaries contrasted with Baltimore urbanized area (lower right)*

Then consideration turned to what should be included as agriculture within these urbanized areas. In the US, the definition of a farm is any operation that produces and sells or has the potential to sell $1000 or more of agricultural products in a year. Thus, an individual with a large backyard garden who sells the excess produce at a farmers market is a farmer if the produce sells for at least $1000 over the course of a year.

Community gardens are a common form of agriculture occurring in urbanized areas. For these types of operations, NASS has traditionally considered each plot as an operation, which either qualifies as a farm and is counted or found to not qualify as a farm and is not counted. Often none of the plots produces enough to qualify as a farm even though the total production of the community garden could well be enough to be classified as a farm. This could contribute to the perception that NASS is not fully reporting agricultural activity in urban areas. Thus, for the purposes of the pilot study, all agriculture was considered, but the entities meeting the definition of a farm were to be reported separately from those that did not qualify as a farm, such as ones that produced food only for home consumption.

What types of urban agriculture were within the target population? Community and school gardens were included as well as animal production, such as bees and chickens. In many urban areas, abandoned warehouses have been converted for agricultural production, which were part of the target population. Greenhouses on the top of buildings, production in hoop houses, and aquaponics were also determined to be within the scope of urban agriculture.

What types of entities were not included in the target population of urban agriculture? Gardens on the top of buildings for enjoyment and not for production were excluded. Plants grown in window boxes or in pots on the porch were excluded. Also, mobile gardens, such as those on the top of a bus or in the bed of a pickup, were not in the target population.

3. City of Baltimore Pilot Study

A pilot study was conducted in the city of Baltimore. Recent city urban agricultural initiatives include the Baltimore Office of Sustainability's Land Leasing Initiative, the Urban Agriculture Tax Credit, and the Urban Agriculture Training Program (Baltimore Office of Sustainability 2016). With a plethora of vacant buildings and vacant lots, Baltimore City is focused on redevelopment strategies for the city's land use policies and on greening initiatives, such as urban agriculture. Based on available funds, the study area did not include the full urbanized area of Baltimore but was restricted to the City of Baltimore (see Figure 1).

To build a list of agricultural areas within Baltimore, NASS collaborated with the Multi-Agency Collaboration Environment (MACE). MACE is a consortium of Government agencies and contractors that solves complex data problems. In collaboration with the Air Force Research Laboratory, they explored the use of text and image analytics to create a list of urban farms within the City of Baltimore.

Traditional imagery analysis techniques were found to not be useful for automatically identifying the small areas of agriculture common in urban farms. The satellite imagery available had a 0.5-m resolution. An example of that imagery is provided on the left side of Figure 2. On the right is a 15-cm aerial imagery of the same area. (The green dots are at the same point in space on each.) The human eye is more effective than algorithms in detecting items within imagery. The agricultural activity evident in the 15-cm imagery is not visible in the 0.5 satellite imagery. Thus, satellite imagery was found to not be useful for this purpose. With the aerial imagery, the presence of agriculture is evident, and automatic identification is potentially possible. However, the aerial imagery was prohibitively expensive for NASS, so NASS was unable to take advantage of either satellite or aerial imagery. Therefore, the MACE list was based on the web-scraping techniques associated with the text analytics.

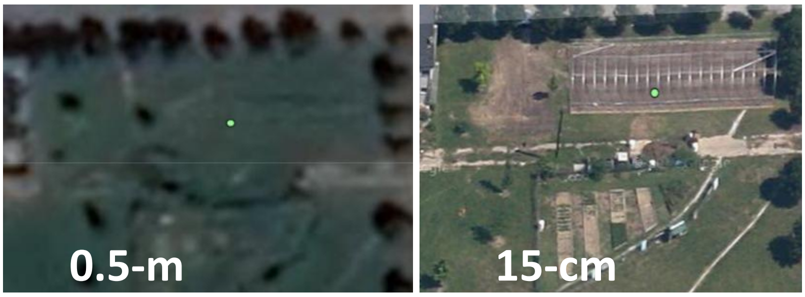

Figure 2: *Comparison of visibility of agricultural area using 0.5-m satellite imagery (left) compared to 15-cm aerial imagery (right). The green dots are at the same point in space.*

MACE identified 505 areas of potential agriculture. The City of Baltimore had a 2013 list of areas of agricultural activity that was not available for the development of either the NASS list frame or the MACE list. Of the 159 non-school garden areas on the list, one was on the NASS list frame, and 89 were on the MACE list. The NASS list frame has only farms and potential farms while the MACE list is broader, including agricultural activity of any size. This could explain some of the difference. However, Baltimore's list included 13 urban farms; one of those was on the NASS list frame; the MACE list included all 13 farms.

To further evaluate the MACE list, an in-person survey was conducted to assess whether or not the identified areas had agricultural activity. A random sample of 266 of the potential areas were selected. For the community gardens, efforts were made to sample the plots within the community garden. Only 12 of the plot surveys were completed in six community gardens. It was extremely difficult to identify the plot operators for an interview; finding the manager or coordinator of the community garden was much easier. It became clear that interviewing the operators of the individual plots would be cost prohibitive. Of the 266 sites, 71% (188) of the interviews were completed. In 21% (73) of the cases, the operator could not be found, and there was a 2% (5) non-response rate.

If the operator could not be contacted, the interviewer was asked to make an effort to observe whether or not agriculture was present. In 5% of the cases, the presence or absence of agriculture could not be ascertained from either an interview or observation. For about half (52%) of the sites, agriculture was present. During the 2012 census, half of the operations on the list frame were identified as farms; the other half were non-farms. Of course, some of those on the MACE list identified as having agricultural activity were not farms.

From the 188 completed interviews, 108 unique operations were identified with agricultural activity. Backyard or home gardens (34), school gardens (29), and community gardens (20) were the most common types of operations. Urban farms, vacant lot gardens, roof top gardens, aquaponics, hydroponics, and a commercial enterprise were also present.

People grew a variety of produce on urban agricultural sites, with fruits and vegetables being most common, but a sizeable proportion raised or kept farm animals and produced animal products. As one would expect, the areas dedicated to agriculture tended to be small, with about 2/3 having an area of less than 1000 square feet.

3. Results and Discussion

Several lessons were learned from the pilot study. Only areas of at least 36 square feet were considered during the pilot study because it was anticipated that satellite imagery would be used to identify agricultural sites in urban areas. Since satellite imagery did not prove to be useful at the 0.5-m resolution available, the minimum area requirement has been dropped for future work.

Although people could generally report the total area available for agricultural activity, they had difficulty specifying the land devoted to each purpose, such as tomatoes, peppers, bees, *etc*. Many were unable to quantify the amount of agricultural products produced, either in terms of weight or in value. This was particularly true for those who sold no produce. Thus, if the full range of agricultural activity is to be reported, it would be best to separately quantify those agricultural operations that qualify as a farm and those that do not. In addition, the questionnaire should undergo extensive testing and perhaps revision so that the respondents can provide more accurate data.

Community gardens are challenging. Whereas few, if any, plots qualify as a farm, the total output of the community garden may qualify as a farm. Although each individual plot may be correctly classified as a non-farm for all community gardens within an area, it may be perceived that the contribution of community gardens is under-estimated. Reporting the activity for the community gardens instead of the plots within the gardens would result in another set of challenges. In particular, reporting the demographics of those engaged in urban agriculture would be difficult. The manager of the community garden may not have the demographic details of the plot operators, such as age, sex, race, and ethnicity of the individual plot operators.

Although the list building approach has good potential for providing the foundation for improved estimates of urban agriculture, funding will not be available for an enhanced urban agriculture effort during the 2017 Census of Agriculture.

The web scraping approach to list building is being used for the NASS 2015 Local Foods Marketing Study, and local foods producers tend to live in or near urban areas. The MACE list is used to draw a second sample in a capture-recapture framework with the first sample coming from the NASS list frame. The data from the local foods study will provide good insights into the viability of this approach to list building.

A pilot study in the state of Washington is being conducted to explore the use of web scraping to build a list of small farms. Three NASS staff are working with MACE personnel for this project in an effort to build capacity for web scraping within NASS. In general, identifying all types of small farms continues to be a challenge. For the 2012 US Census of Agriculture, capture-recapture was used to adjust for coverage, non-response, and misclassification. Two independent samples were the Census mail list and the June area frame. Could web scraping be the foundation for a third sample? Finally, some challenging methodological issues need to be addressed if this listing building approach is to be used, along with a capture-recapture approach. For example, it is likely that the probability of capture varies with list.

With constant pressure to provide statistics on emerging sectors of agriculture in short time frames, it is important to identify new, cost-effective approaches to addressing the questions of interest to policy makers and other stakeholders. Web scraping, technology, and secondary data sources for this purpose may be tools that are used increasingly.

ABSTRACT

National Statistics Offices (NSO) are including new information sources, as Big Data, specifically Earth Observation (EO) data into their production processes, in order to improve official statistics for different subjects. Under this approach, DANE, the NSO of Colombia, carried out a pilot project to complement the information on land cover for the agricultural statistical framework of Colombia in three municipalities of the Atlántico department and their multi-temporal analysis. Processing was carried out with available Landsat satellite images for the years 2005, 2010 and 2014 usingErdas, InterIMAGE and ArcGIS software. As a result, the variable land cover was imputed for the 20% of the agricultural statistical framework units without information. It is concluded that, in order to get more disaggregated coverages, further research must be done including higher resolution images and multi-temporal analysis in periods shorter than one year.

Keywords: Satellite images, land cover, object-basedimage analysis, data imputation.

1. Introduction

43 years after the realization of the last agricultural census in Colombia, and with the aim to know the present situation of agriculture and livestock in the country, during 2013 and 2014 DANE carried out the third National Agricultural Census (CNA for its acronym in Spanish).During the country-wide field collection process more than 113 million hectares were covered, in the 1101 municipalities distributed across the 32 departments that integrate the country.It is important to highlight that besides the administrative division of the territory, 181Afro-descendant communities' lands, 773 indigenous territories and 56 national natural parks were included in the census operational design.

Nevertheless, census coverage was under 70% in some municipalities because of:

- Inability tocontact producers orsuitable informants.
- Uninhabited properties.
- Inaccessibilitydue to geographical and public order conditions
- Rejection to census enumerators.

Following these shortcomings and for the construction of the National Agricultural Framework, DANE carried out a pilot project to complement the information about land cover using Big Data specifically remote sensing data.

Big Data is defined as "*any large and complex collection of data sets that becomes difficult to process using traditional data processing applications", and therefore includes data from Earth Observations satellites. In many cases Big Data is considered to be unstructured data or data that is used for another aim than the original creator of the data intended. In the case of Earth Observation it is actually purposefully created to be highly structured and to measure specific aspects of the earth. The complexity of EO data is to extract a meaningful form of information about a real object, value, state or condition from an electromagnetic signal measured in space"*(Task Team Satellite Imagery, Remote Sensing and Geo-spatial data, 2016).

Through the extraction of land cover data from satellite images, the goal is to impute the variable "land cover" for the analysis units of the National Agricultural Framework. This will provide detailed and high quality agricultural statistical information for policies formulation and implementation, as those currently is being implemented in Colombia, for example the Land Law and Rural Development.

2. Background

National Agricultural Census - CNA

CNA was conducted during 2013 and 2014, to collect information about agriculture, forest, aquaculture and fisheries;as well as socio-demographic information fromagricultural producers and rural inhabitants. This was a declarative census, in which information was provided by suitable respondent, who knowsabout the activities undertaken at each observation unit. The census analyticalunit is the Agricultural Production Unit (UPA for its acronym in Spanish)which is defined as the area in which a single producer[1] makes decisions and takes responsibility over the productive activity. The UPA has no size limits, and it can be formed by part of a rural property, a complete rural property, or a group of continuous rural properties.

The National Agricultural Framework is a spatial representation of the UPAs and non-agricultural units (UPNA) located in rural area; and therefore, it is the basis for sampling design in agricultural surveys and any statistical operation with rural domain.The Framework includes information about thelocation (X, Y coordinates), identification (property code and politic-administrative information), and agriculturespecificdata from each unit.Given the importance of the framework for DANE regular statistical production, the information of the 3rd National Agricultural Census is fundamental for updating this tool.

Based on the information from the 3rd CNA, ten classes for land use and land cover were stablished, which are grouped into six categories (Table 1). For each UPA was assigned a predominant land coverage defined by the coverage whose participation percentage is equal or greater than70% of the UPA total area. If the condition was not fulfilled, 'mixed' predominant coveragewas assigned.

[1]The concept of agricultural producer includes individuals (natural person), as well as companies or formal partnerships (legal person)

GENERAL CATEGORY	CLASS	DESCRIPTION
Temporary	Temporary crops	"Temporary crops are those which are both sown and harvested during the same agricultural year, sometimes more than once." (FAOSTAT, 2015)
	Fallow land	Area that had crops during the last 12 months, but had no crops the day of the interview.
	Roosting area	Area that had crops in the last 3 years, but had no crops in the 12 months prior the interview.
Permanent	Permanent crops	"Permanent crops are sown or planted once, and then occupy the land for some years and need not be replanted after each annual harvest." (FAOSTAT, 2015)
Grassland	Grassland	Land on which the vegetation is dominated by grasses, glasslike plants and herbaceous.
Non-agricultural	Non-agricultural	Land where the properties are dedicated to develop non-agricultural activities, such as industry, commerce and services.
Forest land	Forest plantation	"Forest stands established by planting or/and seeding in the process of afforestation or reforestation" (FAO, 2016).
Other land cover and uses	Other land cover	Soils covered by natural waters, *páramo* vegetation, bare soil, rocky outcrops, opencast mines, etc.
	Stubble	Land area where more than three years have passed since last crop and is covered by shrubby vegetation. Census day had no crops.
	Natural forest	Land with different classes and associations of trees, shrub, herbaceous, and other plants which are not classified as a forest plantation.

Table 1. Land use and land cover categories for the National Agricultural Framework.

Related works

Remote sensing in agriculture has been applied since the seventies, covering a wide variety of fields (Carfagna, 1999), (Hanuschak & Delincé, 2004) and (Gallego, 2006); among them, vegetation monitoring and land cover mapping is highlighted.

Other remote sensing applications are related to the survey design (sampling frame and stratification), crop identification, planted areas estimation, crop status in large areas and production estimation. Remote sensing complemented with GIS exhibits great potential for creating information layers on crops that may include location at a centimeter scale for precision agriculture (Craig & Atkinson, 2013).

Furthermore, United Nations Statistics Division has recognized the need for further investigating the benefits and challenges of using Big Data for official statistics. To address this matter, the Working Group on Satellite Images and Geospatial Data was established in 2014; in this context,several pilot projects were developed, including the application of remote sensing for agricultural statistics production, presented by the Australian Bureau of Statistics (ABS).

3. Methodology

In order to impute the information on land use and land cover to the UPA that lacked of this information,a remote sensing methodology was implemented. In this case, the steps were as follows:

Step 1. Defining the area of study. Three main considerations were taken into account:

- Municipalities that include at least three general categories of land cover defined by the CNA.
- Municipalities with slope less than 20° (to avoid topographic correction on the images)
- Municipalities that show natural and/or anthropic precedents of changes on land cover that could be of interest for a multi-temporal analysis.

Three municipalities metthese criteria:*Campo de la Cruz, Santa Lucía and Suan*, located on the Caribbean coast, northern Colombia (Figure 1).

During 2010 - 2011 an intensive rainy season generated floods and landslides in different zones of Colombia. One of the biggest effects was generated by the rupture of the *Canal del Dique*dike, which caused flooding in several towns, including the ones chosen for the study.(CEPAL, 2012).

Figure 1. Study areais 852 km^2 (828 km^2 rural area).

Step 2. Satellite data selection. The imagery acquisition was done under these criteria:

- Total coverage of the study area, to avoid the need to generate a satellite mosaic[2].
- Similar sensors for the years 2005, 2010, and 2014.
- Images taken over the same area and the epoch of census field work(2014, first trimester) for 2005, 2010, and 2014.

The Landsat images met those criteria and they were downloaded free of charge from the Earth Explorer website[3] (United States Geological Survey, USGS)see Table 2.However, Landsat 7 images captured since May/2003 have gaps generated by a failure in the SLC sensor. Therefore, a filling procedure was done by using two images from the same sensor.

[2]A mosaic is one image created by merging several individual images of adjacent areas.

Program/Sensor	Path-Row	Date
Landsat7ETM+	9-53	23January2005
Landsat7ETM+	9-53	24February 2005
Landsat5TM	9-53	29January2010
Landsat8OLI	9-53	9February2014

Table 2.Landsat imagery chosen for the project

Step 3. Satellite images pre-processing.This procedure included the following activities:

- Filling the gaps for the 2005 images.The Phase 2 Gap-Fillalgorithm proposed by the USGS and NASA was used. This algorithm fills the gaps of one primary image using another image with valid data in the gap zone.A pixel with no data from the primary image is replaced by the adjusted value of same pixel of the secundary image.The pixel is adjusted using the value of the standard deviation and mean of neighboring pixels (valid pixels in both images). Every spectral band was processed separately.

- Layerstacking. This procedureconsistsof the combination of multiple separate bands in a single image. As the number of bands of the Landsat sensors (ETM+, TM and OLI) is different, only the bands common to all images were used. In this project, this process was made with the *"Layer Stack"*Erdas's tool.

- Defining LANDSAT image subset.A portion of a larger image was generated covering the study area.

- Radiometric resolution scaling:The Landsat image for 2014 has a radiometric resolution of 10 bits, and the 2005 and 2010 images have an 8 bits value. Since it is desirable to have all the images in the same rank of digital levels, a scaling radiometric resolution procedure was applied to the 2014 image to ensure the same radiometric resolution, i. e. 8 bits.

Step 4. Satellite images classification

Digital image classification involves grouping pixels to represent land cover features. There are several image classification methods and for the purposes of this project, object-based imageanalysis was chosen.

This methodis carried outthroughtwo general procedures:

- Image segmentation: This process creates objects by grouping similar pixels. It starts with each pixel forming one image object, which is sequentially merged to formbigger ones.For this process, the TA_Baatzsegmenter algorithm, which creates objects based on colour and shape (Baatz& Schäpe, 2000), was used, along with the InterIMAGE free software.

- Classification: In this process, each image object is allocated to a particular class, according to the criteria and rules defined.

Step 5. Global accuracy assessment.

To evaluate how well the classification represents the real world, the following taskswere executed:

- Estimation of the sample size (n) by using the binomial distribution formula.(Rossiter, 2014).

$$n = \frac{Np(1-p)}{(N-1)\frac{d^2}{Z^2_{(1-\alpha/2)}} + p(1-p}$$

Where:

n s mple size.
N universe (total image objects)
D sampling error (5%)
A confidence level (95%), and
p *apriori* precision (90%)

- Distribution of the random sample with the "create random points" ArcGIS tool.
- Visual classification of the sample, using Google Earth and orthophotos, taken as close to the date of the satellite images as possible.
- Comparison between visualand automatic classifications (InterIMAGE results) for sample points.
- Estimation of the coincidence percentage between the visual and automatic classification.

Step 6. Data Imputation.

To impute land cover information to the UPAs with no data, a model was implemented using ArcGIS tools. The model takes the land cover map obtained from the image automatic classification, and split the map into UPAs. As a result, every UPA without land cover information was allocated a predominant land cover.

Step 7.Change detection

In order to quantify the changes in land cover during the period of study, a pixel by pixelcomparison was conducted between the 2005 -2010, and 2010 -2014land cover maps. As a result, a change detection matrixwas created; which is a table that allows to measure changes among different land-cover/land-use classes over a time period (Jensen, 2005).

4. Results and discussion

The classeswere defined considering the CNAgeneral categories (Table 1). Nevertheless,the categories "permanent crops" and "forest" were excluded due to their small area size and quantity. The non-agricultural land category cannot be identified by satellite images, since it is mainly related to industry and services uses.

Table 3 shows the decision rules defined to classify each objects into the land cover categories. The objects which did not meet any decision rule were assigned to the Temporary category.

General category		**Decision rule**		
		2014	**2010**	**2005**
Oher land	Water	ratio(band5)<0.21	mean(band4)≤ 50.4	mean(band4)≤ 53.5
cover and	Bare	bandMeanDiv(band5,band2)<2.3	mean(band1)> 83.5	mean(band1) ≥89
uses	soil	ratio(band5)≥ 0.21		ratio(band5)<0.228
	Stubble/ Natural Forest	ratio(band5) ≥0.32	mean(band2) ≤ 37 mean(band4)> 50.4	mean(band2)≤ 80 ratio(band2)<0.2
Grassland		ratio(band3)>0.11 ratio(band5)≥ 0.21	ratio(band5) ≥0.285	ratio(band5) ≥ 0.228

Table 3. Decision Rules used in each year.

The global accuracy of the classification for each yearis presented in Table 4. The highest accuracy was obtained for the year 2014.

Year	Samples	Coincidence percentage
2005	135	57%
2010	135	70%
2014	136	84%

Table 4. Global accuracy of the classification.

Figures 2, 3 and 4show the land cover distribution for the years 2005, 2010 and 2014.

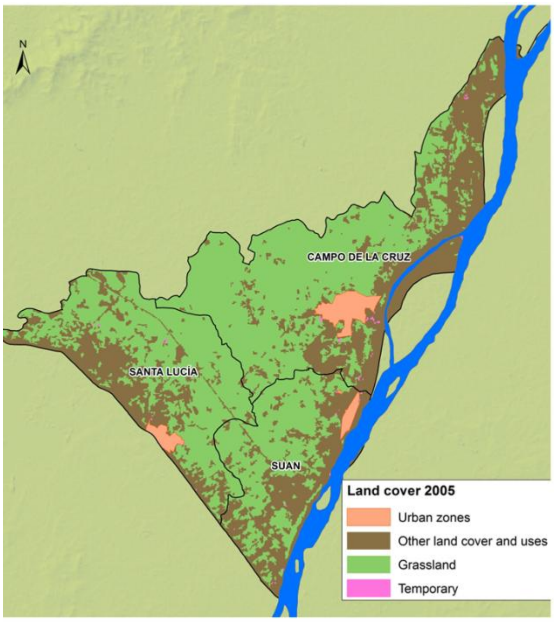

Figure 2. Land cover year 2005

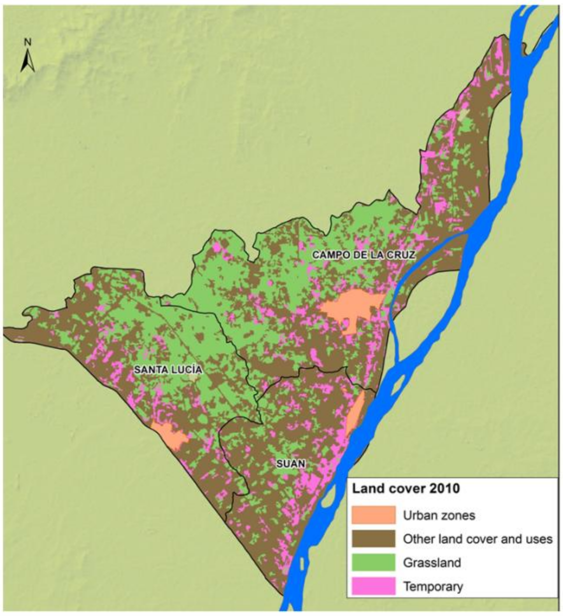

Figure 3. Land cover year 2010

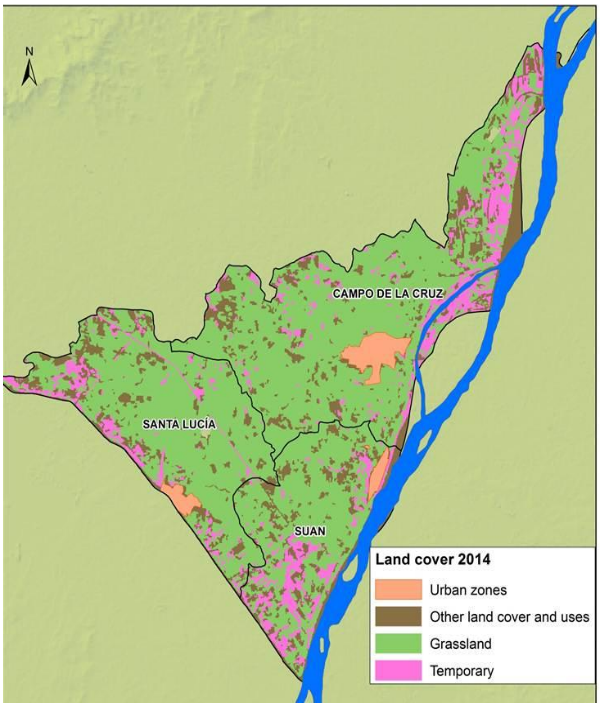

Figure 4. Land Cover 2014

With the 2014land cover map obtained from classification,it was possible to impute the predominant land cover to598 UPAs without census information (out of 2.975). Figure 5 shows the land cover map obtained from census results and imputation. Grassland areas are prevailing in the three municipalities;temporary and permanent cropsareas are located mainly in Suan and the riverbank.

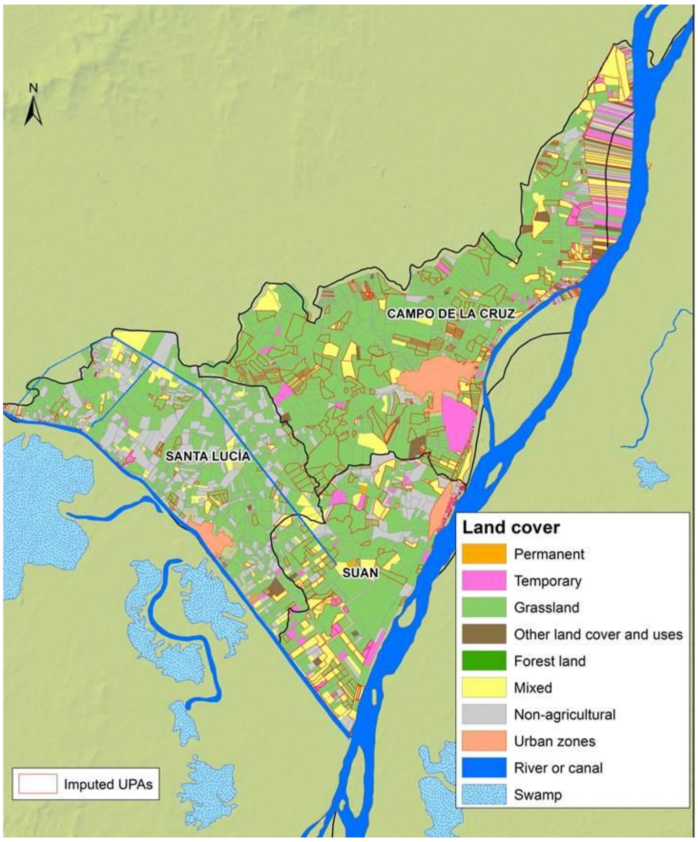

Figure 5. Predominantcoverage by UPAs. 2014

Once the post-classification and comparison methods were applied, changes were detected asreportedin Table5. From 2005 to 2010, there was an increase in land classified as 'Other land cover and uses', which includes Stubble and Natural forest. However, the most significant land cover changes are identified during the period 2010-2014, asit shows an important increase in grassland, and decrease in Oher land cover and uses.

2005-2010	Temporary	Grassland	Oher land cover and uses
Temporary	22%	17%	61%
Grassland	9%	46%	45%
Other land cover and uses	13%	11%	76%

2010-2014	Temporary	Grassland	Oher land cover and uses
Temporary	8%	79%	12%
Grassland	6%	86%	8%
Other land cover and uses	16%	58%	25%

Table 5. Change detection matrix.

A possible explanation to the 2005-2010 phenomenon is that during this time, the more common crops were scattered mango and guava trees. Due to the characteristics of these crops, they were classified as Stubble and Natural forest. It concludes that patterns of fruit trees and Other land cover and uses are similar. The increase in this category can be related to the rise of fruit trees.On the other hand, for the 2010-2014 changes, they might have been caused by the 2010 -2011 floods, as this climate phenomenon and the subsequent increase in soil moisture, may have induced a faster degradation of agricultural and productive soils.

5. Conclusions

Satellite images are a valuable source of information on land cover and they provide suitable complementary information for areas where field data are not available.More detailed results require satellite images with higher resolution (spatial and spectral) preferably collected at different months during the same year. This could be useful to make decisions based on productive cycles (temporary or permanent), crop areas, sowing and harvest periods, and to improve the results of the CNA.

The study results prove the change detection matrix to be an useful tool to measure changes in land cover; however its precision depends on the classification accuracy. In addition, it is important to highlight that an adequate use of image classification methods requires knowing the study area, in order to correctly define land cover classes and decision rules. Also, although the classification software InterIMAGE is of free access and easy to use, documentation on it use is limited.

In addition, it is important to explore remote sensing automatic techniques that allow replicate the process in other areas of the country. This could lead to face new challenges as dealing with images and algorithms for cloudy areas, development of topographic correction methods and assessment of computational efficiency for Big Data.

Finally, it was prove that Big Data from satellite imagery is considered a powerful tool to overcome lack information, and with greatpotential for the usein National Statistics Offices.

Abstract

The Farm Register is a key element for the Agricultural Statistical System. Agritourism Farms (AFs) represent a small sub-population of the units included in the Farm Register (around 20,000 out of 1.7 million in 2013), but their number is increasing along the time and acquiring importance from an economic point of view. Given the tendency of using the World Wide Web to substitute the traditional way of acquiring information, ISTAT is now experimenting the possibility to collect such information directly from the sparse and unstructured information in the Internet, belonging to the vast category of Big Data, by means of a web scraping technique. A specific scraping application is developed for one of the most important hubs (TripAdvisor) and an another one for scraping individual websites. The text collected in this way requires a specific processing step finalised to extract and structure the information of interest. At the end of the process, the obtained information is used not only to update the existing information available on the Farm Register, but also to enrich it, permitting the production and the periodical dissemination of statistics related to the activities and to the services offered by the AFs, at a minimum cost. This strategy permits also to check the information (regarding newly born farms or ceased ones) stored in the Register, pertaining to the coverage of the frame. From a statistical point of view, such derived information represent a new methodological framework, that requires the evaluation of specific quality indicators.

Keywords: Farm Register, Agritourism, Web Scraping, Internet as a Data source, Big Data

1. Introduction

Agritourism Farms (AFs) are farms where the agricultural activities are integrated with the touristic ones. They are in a growing trend in Europe at least since the 1970s, particularly in Italy. Now they are more and more popular in other parts of the world as well, especially Australia, Asia and North America. A reason of such increase could be identified by observing the decline in agricultural and other forms of rural employment in many countries, that created a need for a diversified range of rural businesses. In most cases, agritourism has become an important element of development in rural areas. The initial concentration of agritourism in Italy was in small mountains and hill farms. Today the offer is more sparse, and is characterized by structures ranging from simple family farms to luxurious estates. In 2010, with 19,973 operators and about 200,000 beds available, there were more than two million guests, out of which 50% foreigners, who spent in the farm an average of 4.5 nights (Santucci, 2013).

The Farm Register maintained by the Italian National Institute of Statistics (ISTAT) is a key element for the Agricultural Statistical System. Moreover, it represents the frame for selecting samples for any survey in this sector. Such frame is built by integrating ten different administrative and statistical sources. Agritourism farms (AFs) represent a small sub-population of the units included in the Farm Register (around 20,000 out of 1.7 million in 2013), but their number is increasing along the time and acquiring importance from an economic point of view. The main source of information for these farms is represented by the administrative data of the authorised Agritourism. A dedicated survey is carried out by ISTAT, on a yearly basis and with standard questionnaires, to collect some useful information about their characteristics. Given the tendency of using the World Wide Web to substitute the traditional way of acquiring information, ISTAT decided to experiment the possibility to collect such information through the Internet, accordingly to a strategy typical of the most recent Big Data paradigm. It has to be noted that, despite the objects of the analysis (the AFs) are limited, the quantity of information that can be derived for them from the web is huge and changes rapidly over the time. This is in line with the Gartner's definition of Big Data, that considers "*high-volume, high-velocity and/or high-variety information assets that demand cost-effective, innovative forms of information processing*"[1]. Moreover, it has to be observed that the information obtained under such paradigm is sparse and unstructured, but its proper use could permit the pursuing of the following objectives:

- improve the quality and the completeness of the administrative information already existing, that consists of *identification* (ID fiscal code of the holder, name, address, telephone, etc.), *agricultural production* (Total Area, Utilized Agricultural Area, main crops, livestock, labor force, geo-localization) and *touristic* (rooms, places, food service, other activities) data.
- collect new data in the topic as prices, wi-fi facilities, swimming-pool, organic and quality production, email address, website, horse riding, etc..
- implement a statistical system that can be updated more frequently and at a minimum cost.

The general idea of such work is to obtain structured information useful to update and enrich the Farm Register. From a statistical point of view, the use of the Big Data paradigm in this context represents a new methodological framework that should be evaluated in order to verify its efficiency and its quality. To this purpose, the administrative database (the *master dataset*) represents the benchmark according to which it will be possible to introduce specific indicators able to verify the coherence of the derived information.

Such paradigm implies the use of a new technique to collect the information: the "web scraping". But, also, it is necessary to define an integrated strategy in order to correctly link each AF referenced in the *master dat set* to the information collected on the web.

[1] http://www.gartner.com/it-glossary/big-data/

2. Web scraping and the integrated strategy

Web scraping is a computer software technique for extracting information from the web. Its objective is the collection and transformation of unstructured data (typically represented by a document written in HTML language) in more structured data. It is implemented by automatic procedures that permit to access the whole content of one or more websites, or that can select specific parts from these, by simulating a human behaviour when browsing for a specific purpose (Barcaroli *et al*, 2015a).

The use of this technique is more and more considered in the official statistics community: see Hoekstra *et al* (2012) and Ten Bosh and Windmeijer (2014).

In general, each website is characterized by a specific, and often unique, structure; an automatic approach can hardly be conceived to ensure the correct recognition of the relevant information in correspondence with all this diversity. Some facilities in this sense could derive if a special schema is applied to mark up the elements in the web pages; such approach is often used by the major search engines (that could be intended as special scrapers) to help them in identifying the target information. It has to be noted that specific standards are already defined (for instance, the definitions introduced by the Schema.org community), though not commonly used by the webmasters.

When the structure of the website is not known a priori, a phase of post-processing of the scraped texts is required, in order to gather the desired information, possibly by making use of text mining and machine learning techniques (Barcaroli *et al*, 2015b). But there are also situations (usually limited to a small number of websites) in which the structure is well defined and the information can be easily extracted with personalised applications; in such cases the results are usually more reliable (Polidoro *et al*, 2015).

In this study the two approaches have been integrated, by considering, from one side, all websites pertaining to AFs in the *master dataset* (each other different in structure and content) and, from the other side, a specific "hub" website (TripAdvisor), i.e. an aggregator of information for travellers that have large collections of pages generated dynamically from an underlying structure, like a database. This last reference gave us the possibility to retrieve data encoded into pages characterized by a common structure from which the content can be translated into the original relational form.

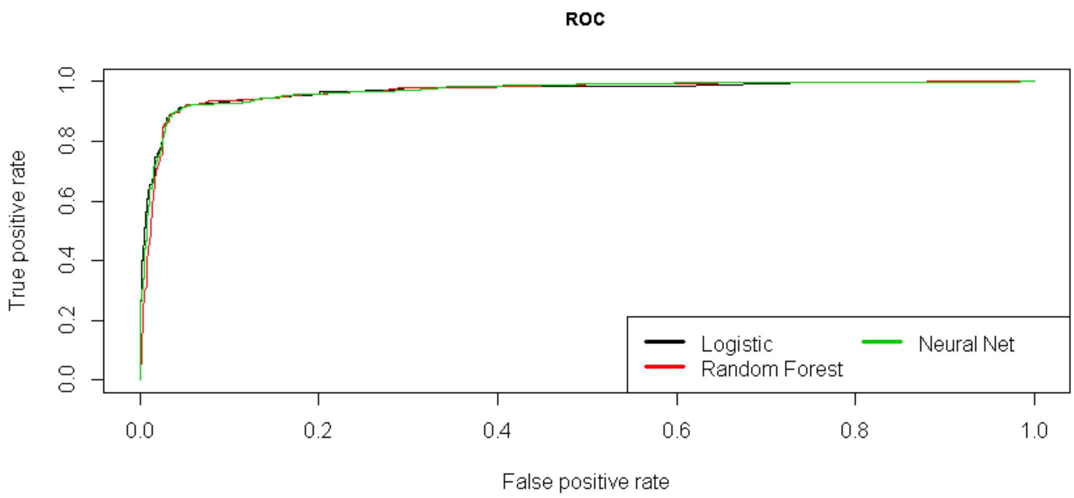
The main issue in this study refers to the proper identification of the links between the AFs as in the master frame (i.e. the database of all Agritourism Farms, originated by the legal obligation to register this activity) and their web sites or their reference in the hub website. To this purpose, the only information that can be used is the denomination and the address; unfortunately, these are often not correctly or uniquely indicated. For instance, the owner's personal information could be used in one source and the denomination of the farm in another source; the address could be different or differently written (by means of abbreviations). Moreover, there could be an implicit difference in the two sources, because in the master frame the information depends on the peculiar administrative purposes, while in the other the aim is purely informative and promotional.

To solve such issue, we used a "natural linker", able to treat also incomplete information. The perfect candidate for this scope was a "web search engine", to which specific queries (each one having in input the denomination and the address of a given AF) were submitted. The result of each query consists of different URLs, from which we should identify those referred to the specific website or those pointing to the hub. This second situation was easier to be solved, due to the fact that the presence of the text "tripadvisor.com" in one of the URLs represents the pointer to the information of the AF collected in the hub itself.

In order to identify the correct website for each AF (if existing and included in those rsulting from the query), a specific procedure was developed in which both the URL text and its content are examined: for the first the similarity between the URL and the denomination of the AF is evaluated,

while as for the content, the presence of the phone number and of the address in one of the page of the related website is verified.
This led us to obtain a vector of variables containing different values resulting from the above comparisons for each one of the 10 URLs obtained by the search engine for a given AF.. A set of models (logistic, random forests, neural networks) have been fitted in order to determine for each AF the most probable corresponding URL among those found by the search engine. The training set is the one of those AFs for which the URL is known as it is indicated in the *master dataset*. The three models perform nearly the same (as illustrated in Figure 1), and the logistic was chosen because the computed score obtained by applying this model can be interpreted as a probability.

Figure 1 – *Performance of the models in determining the true URL for each AF*



Once obtained in this way the list of the URLs pertaining to the AFs contained in the *master dataset*, the contained texts were collected and analysed. In particular, we looked for specific terms in the pages of the website (single or combinations) to verify if the AF has a "restaurant", a "swimming pool", a "wifi" and if it sells products derived from the proper activities.
Obviously, the correct determination of the presence of one of the above characteristics is not precise because it could be affected by the use of different terms, by terms written in different languages or with different lemmas, etc. More precise could be, instead, the results deriving from the characteristics extracted from the hub; in this case, in fact, the structure of the page permits to better recognize the different terms that are located in some "standard position".
Referring to the hub website (TripAdvisor), we were able to look for more additional information, like the possibility to host pets, to play specific sports (golf, tennis), to have a baby sitter service, to be near the sea, etc. Moreover from this hub it is possible to obtain information on the number of rooms and of the prices of each AF.
To implement this strategy we used the software ADaMSoft[2], an Open Source general-purpose software written in Java for data management, data analysis, ETL, etc., that integrates, between others, methods and libraries to parse HTML pages or to interpret the results of queries submitted to a web search engine. The results of these scraping procedures consist of a dataset in which the elements of the web pages are stored in its rows, while their different characteristics in proper columns. Such representation permits to preserve the logical structure of the page and to identify the hierarchy of the elements (i.e. the Document Object Model). As an example, it is possible to consider that a column in the output data set contains the reference URL of the page; then, for each

[2] http://adamsoft.sourceforge.net/

element of the page a record is created, characterized by a column that specifies its type (for instance BODY, INPUT, DIV, TEXT, IMG, etc.), a column with the associated text. It has to be noted that the procedures are executed in a multithread approach: this means that more than one website can be scraped in parallel. The number of threads depends on the amount of available memory: obviously, this has an impact on the time needed to scrape all the websites, while the final performance depends on their complexity (i.e. the number of pages and their response time). The limit to the full scrape of a website derives from the possibility to be blocked by the server due to a "high traffic" concentrated in a small amount of time. In some cases (for instance when referring to TripAdvisor) we divided the queries in blocks of one hundred and we set the maximum waiting time to 30 minutes.

The administrative database of the authorized AFs (the *master dataset*) includes 18,818 farms. As explained above, the first step of our selected strategy was the execution of a query in specific web search engine (Microsoft Bing). Through the query, 17,081 AFs (92%) have been identified in the web (namely with at least one URL found). The reason of the 1,737 AFs not found are various: different reference time, different farm denomination in the two sources, not existence of the AF in the web, errors in the denominations and addresses, etc

For those for which the query was successful, by applying the logistic model we were able to determine 3,289 websites (20%) specific of the AF; 5,525 (32%), instead, were those AFs for which a link in the TripAdvisor hub. The number of AFs for which were found both an entry in TripAdvisor and a specific website were 1,935.

Table 1 summarizes these results.

Table 1 – *main results obtained after the execution of the query related to the search of each AF*

Result of the query	**Frequency**
Not found by the search engine	1,737
Found by the search engine but the retrieved URLs are not referred neither to Tripadvisor nor as a correct link to the AF specific website	10,202
URLs recognized as correct specific websites of AFs not found in TripAdvisor	1,354
AF found in Tripadvisor, without a recognized specific website	3,590
AFs with both recognized specific websites and found in TripAdvisor	1,935
Total	**18,818**

The total number of AFs for which it is possible to gather information by the Internet is therefore 6,879 (36.6% of the total).

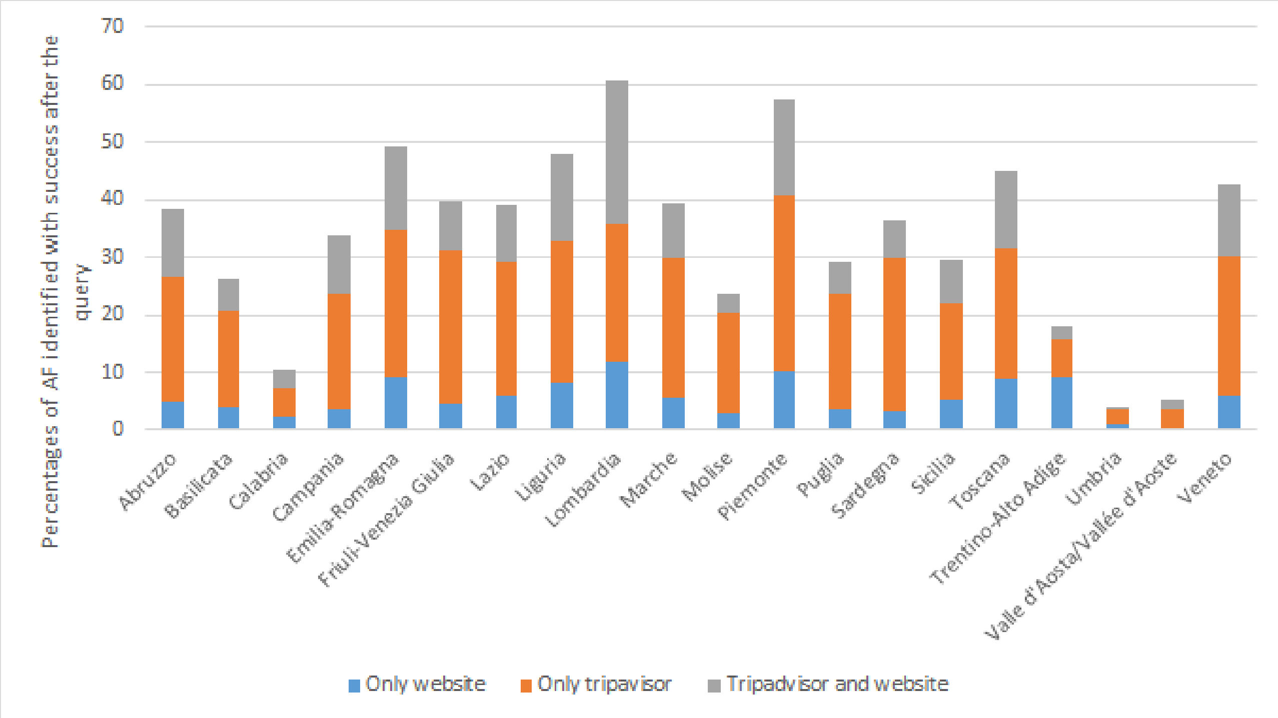
3. Analysis of the results

It is of the utmost importance to assess the representativeness of the subset of AFs whose information can be obtained after the execution of the query illustrated in the previous paragraph.

At geographical level, the coverage rates show a high variability among the Italian Nuts2 areas (Figure 2).

Figure 2 shows that the AFs identified by our strategy are not equally distributed among the Nuts2; the higher percentages (more than the 40%) are in the biggest Regions of the North and Center of Italy (Lombardia, Piemonte, Emilia Romagna, Liguria, Toscana and Veneto, while in other regions (Calabria, Umbria, Valle d'Aosta) it falls under 10%: it is therefore not possible to consider the subset of AFs found as representative by a geographical point of view.

Figure 2 - *Coverage Rate of AFs by Region*



To make proper inference we assume that the identification probabilities achieved by the retrieval procedure are uniform conditionally to the region and change among regions (that is, each AF has the same probability to be found on web given the region). If this assumption holds at least approximately we could solve the coverage issue by making use of proper weights to be assigned to each AF. Such calibration factors can be obtained by the inverse of the coverage rate in each region. This is possible because the number of AFs in the regions is known and certain.
Let us consider some important variables contained in the master DB, as the *availability of restaurant (yes/no)*. This information is contained in the *master dataset*: it is possible to verify its coherence with reference with the corresponding information found (i) only in the hub, (ii) only in specific websites, (iii) in both hub and specific websites. To this purpose let us consider the "confusion matrix" (Table 2), that cross-classifies the presence/absence of such facility with respect to the different sources. It is possible to evaluate the effectiveness of the method by considering the "accuracy rate", i.e. the ratio between the concordances (frequencies on the main diagonal) and the total number of units involved .

Table 2 – *Confusion matrix related to the availability of restaurant as in the master data set and as recognized by referring to the AFs identified only in the hub, only by considering their web sites or jointly*

Presence of restaurant as in the master dataset	**Information derived only from y the hub**		**Information derived from the specific websites**		**Information derived both from the hub and from specific websites**	
	No	**Yes**	**No**	**Yes**	**No**	**Yes**
No	1667	640	537	475	325	812
Yes	741	542	148	194	141	657
Rate of success	*61.5% (100*2209/3590)*		*50.6% (100*685/1354)*		*50.7% (100*982/1935)*	

Table 2 shows the concordances and discordances between administrative data and web data and it opens questions on the quality both the master dataset and the database obtained by the web-scraping procedure. Hereinafter, we assume the discordances between web and administrative data depend on real discrepancies between the information (and not depending on errors due to the data collection process). So how to explain these differences? In this phase of the study we give some plausible justifications that agree with the evidences given in Table 3:

i) the *master dataset* is likely to suffer of a general problem of information updating. Some structural information (as the *availability of rooms*) is correctly indicated at the moment of registration of a new AF, while some other characteristics (as the *availability of restaurant*, or the *sales of products*, or others), that may be offered at a later period, are not added in the *master dataset*, but only in the hubs and/or in the AF websites. This can explain why the differences for *availability of rooms* are small in the four columns, while are relevant for *availability of restaurant*, and highly relevant for *sales of products*;

ii) the difference among columns (2), (3) and (4) should be given by the coverage effect on the master dataset. For *availability of rooms*, the frequencies are quite stable and the performance of the weighting procedure could indicate to better investigate the procedure;

iii) the discrepancy related to the coverage is more relevant for *availability of restaurant*. The difference between 27.1% and 33.9% depends on the coverage. The remaining differences depend on the values of the variables;

iv) for *sales of products* the coverage effect is well defined by the difference between column (1) and (2) even though the frequencies of columns (3) and (4) show a relevant problem related to the quality of the variable, presumably in the master dataset.

Table 3 – *Percentages of AFs with a restaurant, that sell products and that have rooms, as in the master or as identified after the web scraping*

Variables	**Percentages of positive values (=yes)**			
	(1) Total in the master	**(2) In the common subset with value given by the master**	**(3) In the common subset with value obtained by web scraping**	**(4) In the common subset with obtained by the web scraping and after weighting**
Availability of restaurant	27.1%	33.9%	38.5%	35.9%
Sales of products	7.1%	4.4%	21.8%	18.6%
Availability of rooms	34.1%	35.1%	33.5%	32.3%

This analysis suggests the importance to collect information from the web even though it is already available in the *master dataset*. This information can be used for validating or updating it, for imputing missing values and for identifying outliers.

But one of the objectives of the strategy here proposed is also to collect additional information. Considering only the population of agritourisms identified by our strategy (6,879), *presence of swimming pools* is in 18% of cases (unweighted) and 17.1% (weighted). It is also possible to note that *wifi facilities* are in 20.6% (unweighted) and in 19.4% (weighted).

The implemented strategy would permit also to identify the prices of offered services, as related information is available in 41% of cases. Other information can be obtained with respect to the *possibility to host animals*, to offer some *sports facilities*, to *accept credit cards*, etc.

4. Conclusions and future work

This study proposes an approach based on collecting data directly from the Internet with the aim of improving the quality and the completeness of the administrative information on the Italian Agritourism Farms already available, and to produce statistics regarding structural data.

Up to 36.6% of the official AFs can be accessed in the Internet because of the availability of their websites and this number is likely to increase in the time with the spread of Internet and its potentiality in the touristic field.
Information collected from the Internet can be used in different ways, in order to:

- provide final estimations for some structural variables;
- identify outliers with respect to existing variables of the master frame;
- impute missing values in the existing variables of the master frame;
- add new variables to the master frame.

In order to assess the quality of the information obtained with this new strategy, a further step will be to provide a direct comparison of the different values obtained by the different sources, individuating also the true values: to this purpose, a sample of AFs will be selected, the corresponding websites will be manually accessed and inspected.
This manual procedure will allow to discard or confirm two strong assumptions we made when analysing the results: the adopted procedure (i) leads to identify the real value of the variable of interest on the web without error and (ii) the information on the web is updated.
Finally, new developments will regard:

- the improvement of the web scraping technique for increasing the coverage of AFs;
- the possibility to produce prices indices concerning agritourism.

THEMATIC SET

F30

USE OF REMOTE SENSING AND DRONES IN OFFICIAL AGRICULTURAL STATISTICS

Session Organizer
M. Ballin | Istat | Rome | Italy
M. Miller | USDA National Agricultural Statistics Service |Washington, DC | USA

ABSTRACT

This session will focus on technology development and utilization, as well as the survey design, of remotely sensed data for agricultural monitoring in the establishment of official agricultural statistics. This includes remotely sensed data at the macro, country level, from satellite imagery, down to micro, field level data, from drones or Unmanned Aircraft Systems (UAS). Uses of remotely sensed data include cropland stratification for sampling frame development, early warning analysis, disaster assessment, vegetation condition and soil moisture monitoring, and crop area and yield indications

USE OF REMOTE SENSING AND SATELLITE IMAGERY IN ESTIMATING CROP PRODUCTION: MALAWI'S EXPERIENCE

Emmanuel J. Mwanaleza
Ministry of Agriculture, Irrigation and Water Development, Statistics Unit, Malawi

DOI: 10.1481/icasVII.2016.f30

ABSTRACT

Malawi through the Ministry of Agriculture, Irrigation and Water Development (MoAIWD) conducted two studies on the use of remote sensing and satellite imagery to estimate crop production. The objective of the studies was to explore a statistically sound methodology for estimating crop production in order to improve the quality and reliability of agricultural statistics to ensure effective policy formulation and strengthen monitoring of Malawi's agriculture sector performance.

The Ministry piloted two methodologies simultaneously. The two studies were successfully implemented and provided useful lessons to the Ministry in terms of producing credible crop production statistics. The two methodologies had the same general technical principles but different statistical methodologies which had strong implications especially in terms of costs and statistical accuracy and validity.

Malawi currently uses a household sample survey known as Agricultural Production Estimates Survey (APES) to estimate agricultural production. APES has three modules namely crops, livestock and fisheries.

Great lessons were learnt from the pilot studies. Remote sensing and satellite imagery provide a statistically sound approach for estimating crop production. It can be used as a stand-alone methodology for estimation crop production or integrated with the household sample survey to develop a more robust methodology for estimating crop production. The use of remote sensing and satellite imagery requires less human resource and period for data collection as compared to the household sample survey. It has also uncovered an opportunity for early objective yield estimation for crops, more precise hactarege estimation, provision of tangible land use distribution criteria to use for the rural road rehabilitation programmimg and generation of crop production maps which can be used for strategic establishment of grain storage facilities in the country.

Based on the results of the pilots and an evaluation of the two pilot methodologies, Malawi has three options for incorporating the use of remote sensing and satellite imagery in its programmes for crop production estimation to improve accuracy of crop production statistics. The first option is complete adoption of the remote sensing and satellite imagery approach for substitution. This involves combining the two methodologies to make one strong methodology and replace it with crop production module of the traditional household survey. The farm household data which is generated through crops module should be collected through the livestock module. The second option is partial adoption of the use of the technology. This involves integrating some modules of the remote sensing and satellite imagery methodologies into the household survey. The last option is to completely adopt the use of remote sensing and satellite imagery for complementarily. This involves using the combined remote sensing and satellite imagery methodology on a regular period to be providing benchmark data for crop estimates.

Key words: crop production estimates, agricultural statistics

1.0 BACKGROUND

The Ministry of Agriculture, Irrigation and Water Development (MoAIWD) annually conducts the annual sample survey of agricultural popularly known as Agricultural Production Estimates Survey (APES). APES also referred to as *list frame methodology* in this paper is a household sample survey conducted to provide important information to the Government of Malawi and its stakeholders for formulating policies and planning of various activities in the agriculture sector. The survey covers three main agricultural sub-sectors, namely: crops, livestock and fisheries. Data collection for the survey is done by extension officers located in various areas across the country.

The survey is conducted in three rounds every year. The first round is conducted from September of the preceding year to January of the current year. Figures from the first round estimates are based on farmers' intentions on crops to be grown and related hectarage. The results from the first round may not conclusively inform the ultimate agricultural production as farmers' intentions can change in the course of implementing respective farm activities. Weather conditions and related parameters may also change in the course of the agricultural season. However, results of the first round provide early warning signals on national food security so that policy makers in the public, private and non state sectors can make sound strategies regarding impending food situation. The first round also involves collection of livestock and fisheries data.

The second round is conducted from February to March and focuses on verification and adjustment of area measurement of crops grown by the sampled agricultural households and results obtained are used to determine crop area for the season.

The third round of the survey which is normally considered as the final round is undertaken during harvesting period from April to May. The third round mainly involves weighing of the harvest to obtain actual yield for crops based on the sampled households. This round includes collection of livestock data as well.

Despite successful implementation of the methodology, it has been observed that there is need to improve certain critical weak areas of the methodology or review the whole methodology to response to the current situation; and adopt and employ innovative and emerging technologies in the production of agricultural statistics. The list frame methodology was designed over twenty years ago. Since then a lot of things have changed. For instance, the number of farm households has more than doubled which requires an adjustment of the sample size. The area under cultivation has also tremendously increased. On the other hand, the number of extension officers responsible for field data collection has greatly decreased due to high labour turn-over.

In a bid to improve crop production statistics, Malawi initiated the use of remote sensing and satellite imagery in the estimation of crop production in 2010. The initial step of the initiative was to conduct a nationwide survey on land cover and use. In 2012 the country piloted a project on crop area in few districts by using point frame approach. The key outcomes of the pilot were that the point frame based methodology proved to be technically feasible for the country and statistically very valuable given the precision of the crop area estimates attained. In 2013 another methodology which used area frame based approach was identified and piloted in few selected areas of the country.

In 2014/15 agricultural season the country simultaneously piloted the two methodologies national wide. The two methodologies had the same general technical principles but different statistical methodologies which had strong implications especially in terms of costs, statistical accuracy and validity. Results of the two pilot methodologies were compared with results from the list frame methodology.

The point frame methodology was developed by a consortium of ITA and EFTAS from Italy and Germany respectively while area frame methodology by Airbus from France. Both methodologies were implemented in collaboration with the Ministry of Agriculture, Irrigation and Water Development

2.0 OBJECTIVES OF THE PILOT PROJECTS

The objective of the studies was to explore a statistically sound methodology for estimating crop production in order to improve the quality and reliability of agricultural statistics to ensure effective policy formulation and strengthen monitoring of Malawi's agriculture sector performance.

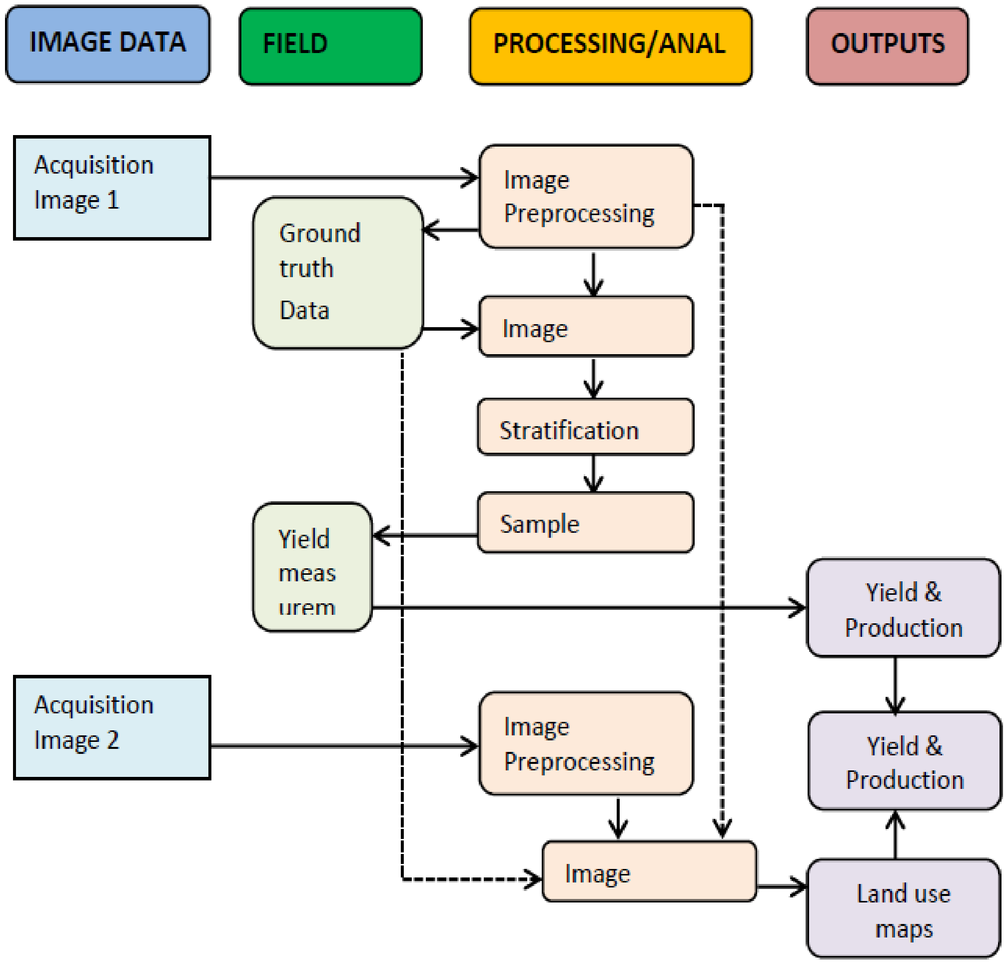
3.0 BRIEF DESCRIPTION OF THE METHODOLOGIES

3.1 Area Frame Methodology

The project used an area frame design. An area frame provides a very efficient tool to survey a territory for various purposes (precise acreage estimation of small crops, yield surveys, production practices, etc.). In the case of Malawi project it was used to estimate maize yields by use of crop cutting. Hectarage estimation was done by the use remote sensing.

Prior to the field data collection, land-use mapping was done using a classification of pairs of satellite images. The classification technique was implemented in three major steps: acquisition of the images, ground truth data collection and classification at the pixel level (Figure 1). To produce the land-use mapping, at least two SPOT 6/7 images at 6m resolution were acquired by district at different times. The first images were acquired from February 19 to April 30, 2015 and the second images were acquired from April 11 and June 9, 2015.

Figure 1: Flow Diagram of the Process



The timeframes for image acquisition were defined with regards to the known local crop calendars. Field surveys were carried out during the first mission in the 15 districts to collect ground truth information required for the calibration of the image classification process and then commonly available Geographical Information System (GIS) and Remote Sensing software (IDRISI, Quantum GIS/GRASS and ArcGIS) were used to perform all data preparation, image integration and classifications. A total of 1551 out of the targeted 1,705 cells were surveyed in all the targeted 27 districts. In each cell two fields were sampled for crop cutting. Data on yield estimate and related information were collected and sent by email to the supervisor on daily basis who after data quality control transmitted the final data to the Ministry headquarters.

Figure 2: GIS Survey Interface Showing Sampled Cells

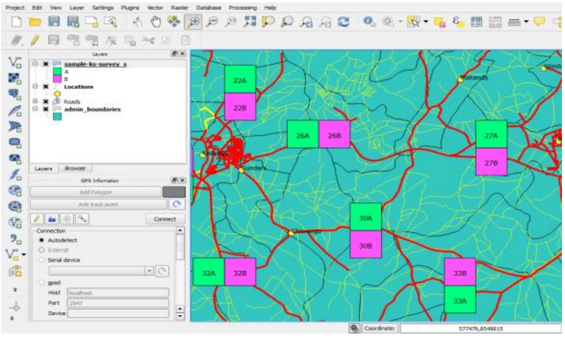


Figure 3: Sample Field with Positions for Crop Cutting

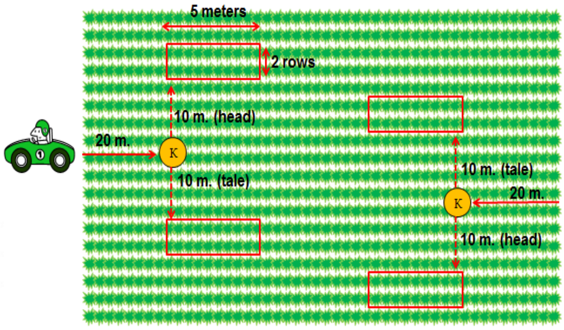

3.2 Point Frame Methodology

The methodology is point frame based whereby the surveyors were required to visit the sampled points, observe within a 3m radius the crop grown at that particular point and record the data. A total of 24000 points were sampled for the survey. Sampled points were classified into clusters of 16 points each with a distance of 250m from one point to the other. For yield estimation, farmer interviews and crop cutting were conducted to assess productivity.

Figure 4: Sample of a Cluster

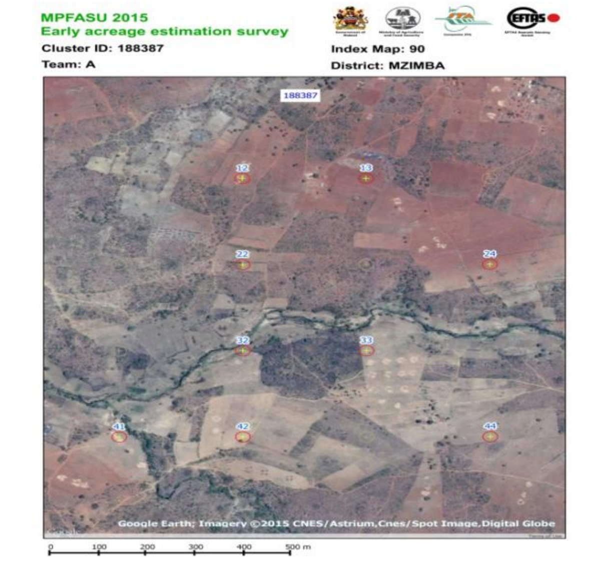

Figure 5: Sample of a Point

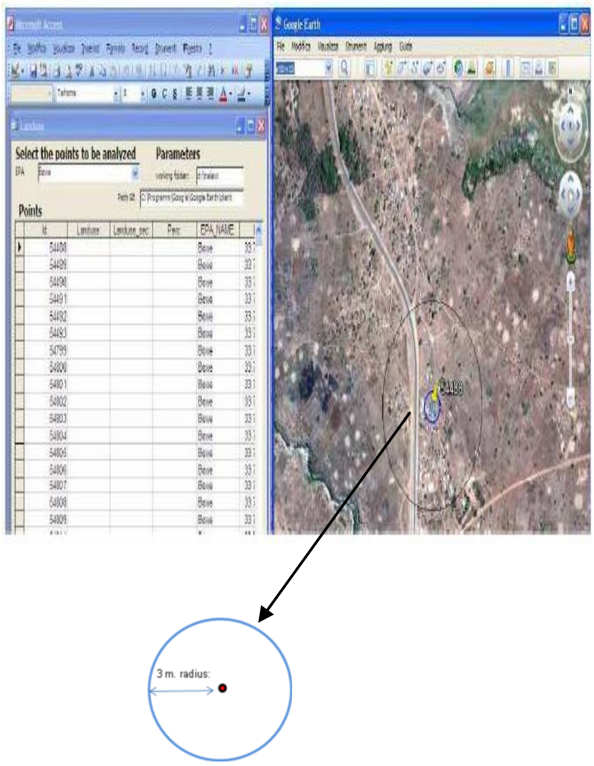


NOTE: a point is a geo-location of the area surveyed. The crop is observed within 3 meters of the point. With the guidance of the Global Positioning System (GPS), upon reaching the point the enumerator observes and records on the type of crop within the radius of the point. For mixed cropping the enumerator has to judge the percentage of each crop in the point

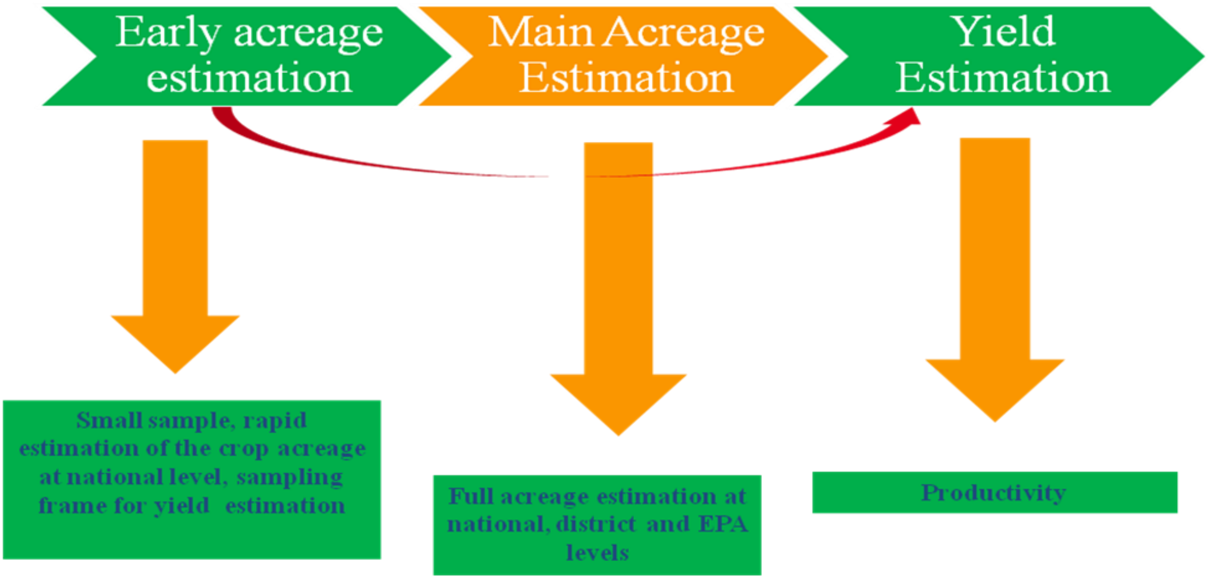
The project had three main modules:

Module1: **Early Crop Acreage Estimation:** the objective of the module was to provide a forecast of crop area at national level. The module also provided a sampling frame for selection of points for yield estimation using crop cutting method**.** The module objectives was achieved by using a sample of 300 clusters on the agricultural land with 16 sampling units (points) inside a square grid spaced 250 x 250 m.

Module 2: **Full Crop Acreage Estimation**: the second project component was designed in order to obtain crop acreage estimation across the country and for the crops of the country with a Coefficient of Variation (CV) of 4-5% for maize. The ground survey was planned to be carried out on 25,000-27,000 sampling units (points) grouped in 1500 clusters and randomly allocated separately across the country.

Module 3: **Yield Estimation**: the objective of this module was attained by interviewing 1,200 farmers located within the 300 clusters. The farm interviews collected among others data on quantity the farmer had harvest from the garden, socio-economic information and sizes of the garden. In addition crop cutting was done in selected 20 gardens within the same clusters to complement farm interviews data.

Figure 6: Main Modules of the Project



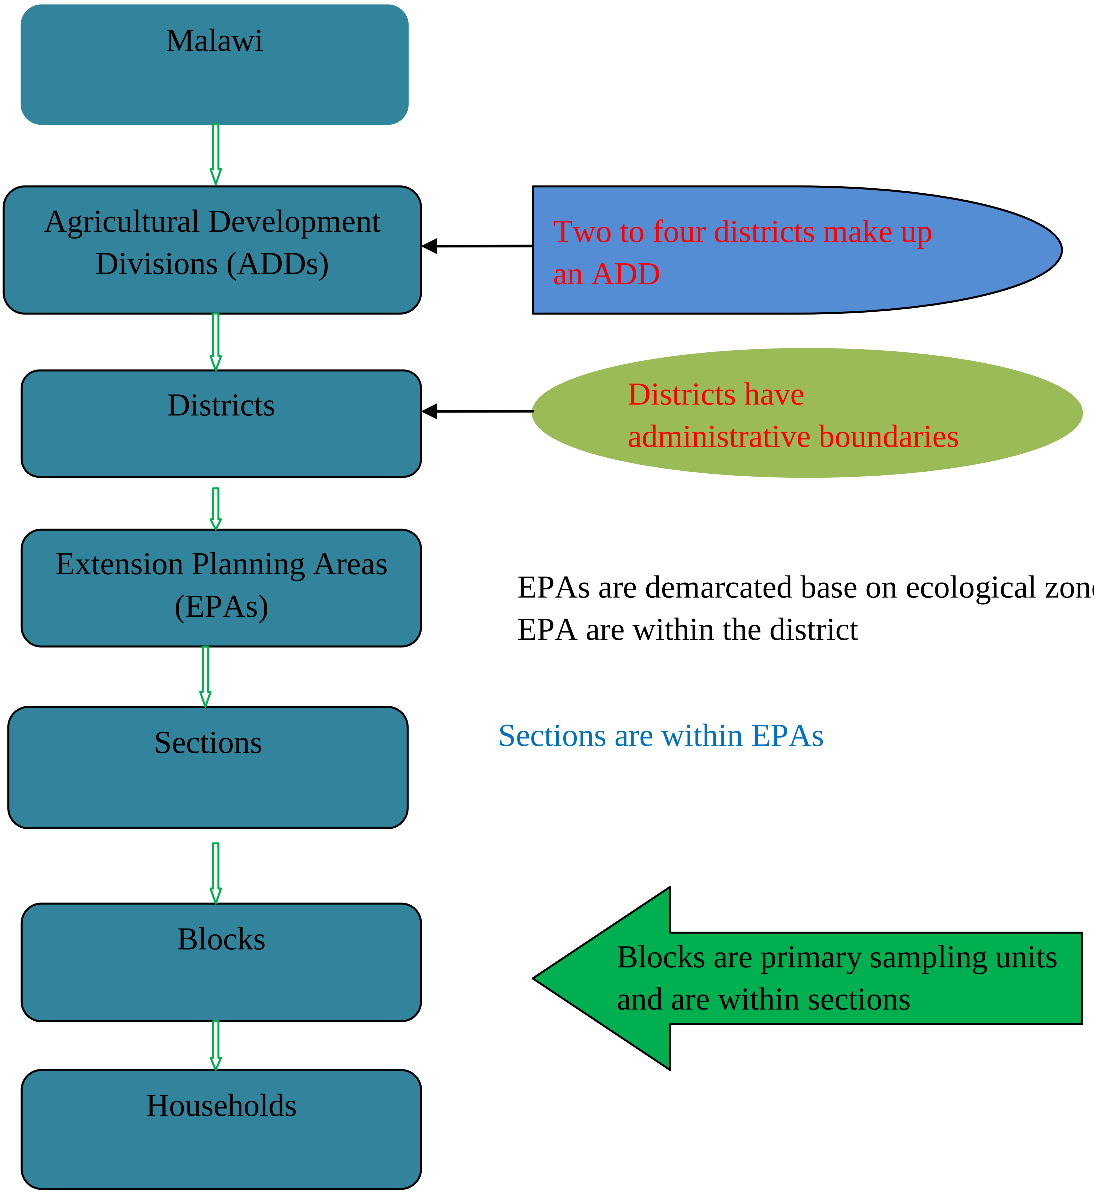
Field data collection was done by forty surveyors for a period of four weeks. Data collection and data entry was done at the same time using tablets. Data was submitted to a cloud archive server and centrally downloaded for monitoring of data flow and quality control.

3.3 List Frame Methodology

The survey begins in September every year up to April in the preceding year. The survey uses a stratified two-stage systematic sampling. Extension Planning Areas (EPAs) making up a district constitute the strata. Each EPA consists of Sections and individual Sections comprise Blocks. The Block is the Primary Sampling Unit (PSU) used in the survey (Figure 6).

The first step in sample identification involves the selection of 25 percent of the Blocks in each EPA using a systematic random method. The second step requires the identification of a Secondary Sampling Unit (SSU) of agricultural households drawn from the selected Blocks. In each selected Block, all households are listed. From the list, agricultural households are serially listed and a survey sample of 20 percent, but in any case not more than 15 households, is identified again using systematic random sampling.

Figure 7: Sampling Structure



Extension officers, who are data collectors for the survey, are required to list all households in the selected Blocks and identify agricultural households. The officer indicates if the household grows field and/or horticultural crops, keeps livestock and do any fish farming activities. For crop module, extension officers are required to conduct garden measurement exercise using the GPS in the sampled households.

For yield assessment, the estimation for the first and second rounds are subjective based on extension officer's judgment on crop development. Based on the crop stand, the extension officer is required to make a judgment whether the yield will remain the same, go up or down and by what percentage. In the third round the actual yield is estimated using crop cutting. Livestock data is collected by actual counting of the livestock from the household. Fisheries data is collected from both fish farming/aquaculture from the sampled households and capture fisheries from natural water bodies. Data processing and analysis is done at the EPA level, and then data aggregation processes are done at the district, Agricultural Development Divisions (ADDs) and national levels.

4.0 RESULTS

Results of the two projects compared with the results from the list frame approach are shown in Tables 1,2 and 3. The comparisons are made for maize only because area frame methodology focused on maize crop only. Maize is the major staple food in Malawi. The comparisons are from rainfed production only for both results as the pilot projects did not take into account winter cropping as done in the list frame methodology.

Table 1 provides results on hectarage estimation from all the three methodologies. From point frame methodology, hectarage was estimated at 1,396,477 hectares lower by 7 percent as compared to 1,499,340 hectares from the list frame. The area frame estimated hectarage at 1,812,908 hactares giving a difference of 21 percent as compared to the list fame approach. Generally, results from point frame estimation are lower across the ADDs while figures from area frame are higher as compared to the results from list frame methodology. Comparisons further show that results are close at national level with great variations at ADDs.

Table 1: Results of the hectarage estimation

		List frame Vs Point frame			List frame Vs Area frame			
ADD	List frame	Point frame	Diff	% Diff	List frame	Area frame	Diff	% Diff
Blantyre	260,999	197,610	63,389	24	260,999	266,646	-5,647	-2
Kasungu	341,783	330,423	11,360	3	341,783	402,368	-60,585	-18
Karonga	52,962	30,843	22,119	42	52,962	57,481	-4,519	-9
Lilongwe	334,212	397,450	-63,238	-19	334,212	473,174	-138,962	-42
Machinga	266,301	226,538	39,763	15	266,301	322,229	-55,928	-21
Mzuzu	144,210	145,200	-990	-1	144,210	172,340	-28,130	-20
Salima	61,588	50,486	11,102	18	61,588	59,665	1,923	3
Shire Valley	37,285	17,928	19,357	52	37,285	59,005	-21,720	-58
National	1,499,340	1,396,477	102,863	7	1,499,340	1,812,908	-313,568	-21

In terms of productivity, the point frame estimated a national maize yield of 1430 kgs lower by 129kgs representing 5 percent difference as compared to the list frame. The area frame estimated national maize yield of 1470kgs versas 1508kgs from list frame, giving a difference of 3 percent (Table 2). In both cases national maize yield from list frame is slightly higher as compared to the two pilot methodologies.

Table 2: Results of the Yield Estimation

	List frame Vs Point frame				List frame Vs Area frame			
ADD	List frame	Point frame	Diff	% Diff	List frame	Area frame	Diff	% Diff
Blantyre	1,484	612	1,163	66	1,484	1,512	263	15
Kasungu	1,790	1,543	247	14	1,790	1,825	-35	-2
Karonga	2,261	1,586	675	30	2,261	2,228	33	1
Lilongwe	1,748	1,975	-227	-13	1,748	1,259	489	28
Machinga	774	1,160	-386	-50	774	1,050	-276	-36
Mzuzu	1,452	1,014	438	30	1,452	1,676	-224	-15
Salima	1,828	1,137	691	38	1,828	1,770	58	3
Shire Valley	816	446	370	45	816	1,210	-394	-48
National	1,508	1,430	129	5	1,508	1,470	89	3

Results on national maize production are presented in Table 3. The point frame methodology estimated national maize production at 1,996,428 metric tons while the list frame estimated 2,261,581 metric tons. The area frame methodology estimated the production at 2,665,492. The results show that figures are close at national level with great variations at lower levels. Possible reasons for such differences are small sample sizes for the pilot methodologies, hence, there is need to increase the sample size to achieve good precision at lower levels. However, an investigation is required to establish factual causes for the differences. As the case with hacterage figures, generally results from point frame estimation are lower across the ADDs while figures from area frame are higher as compared to results from the list frame.

Table 3: Results of the Production Estimation

	List frame Vs Point frame				List frame Vs Area frame

5.0 LESSONS LEARNT AND RECOMMENDATIONS

A number of important lessons were learnt from the pilot studies. Remote sensing and satellite imagery provide a statistically sound approach for estimating crop production. It can be used as a stand-alone methodology for estimation crop production or integrated with the household sample survey to develop a more robust methodology for estimating crop production. The use of remote sensing and satellite imagery requires less human resources and period for data collection as compared to the household sample survey.

From the results of the pilots and lessons learnt from the pilot methodologies, Malawi had three options for incorporating the use of remote sensing and satellite imagery in its programmes for crop production estimation to improve accuracy of crop production statistics. The first option was complete adoption of the remote sensing and satellite imagery approach for substitution. This involves combining the two methodologies to make one strong methodology and replace it with crop production module of the traditional household survey. The farm household data which is generated through crops module should be collected through the livestock module. The second option was partial adoption of the use of the technology. This involves integrating some modules of the remote sensing and satellite imagery methodologies into the household survey. The last option is to completely adopt the use of remote sensing and satellite imagery for complementarily. This involves using the combined remote sensing and satellite imagery methodology on a regular period to be providing benchmark data for crop estimates.

Based on the evaluation of the two methodologies Malawi opted for partial adoption of the use of the technology by integrating some modules of the point and area frame methodologies into the list frame methodology. To maintain livestock and fisheries components of the list frame methodology, there is need to go for multi-frame approach. This means livestock and fisheries data should be collected from the list frame and crop production data from combined point frame and list frame methodologies.

The evaluation also recommended adoption of number of lessons learnt from the projects aiming at improving agricultural production statistics. The recommendations were categorized into short and long terms.

5.1 Short Term Recommendations

i) Use of Information, Communication and Technology (ICT) in Data Collection and Transmission: There is need to introduce electronic data transmission system for agricultura surveys. This is one of the important lessons learnt from both methodologies. Electronic data acquisition and transmission has proven to promote quick and error free data submission. There is need to use the existing central server located in the Ministry headquarters for data submission. Daily data transmission by data collectors should be made possible by distributing tablets (i.e., with GPS and internet access) to each of the data collector
